Neuromorphic architecture mimicking the signal transmission method of biological neurons has attracted much attention for next-generation computing with the advantages of fast response speed and high energy efficiency by parallel weight update processing. Especially, synaptic transistors have been extensively studied since they perform both calculation and memory functions and easily control channel conductance without channel damage by electrical pulses from a separated gate terminal. Among various types of transistors, electrolyte-gated transistors (EGTs) using electrolytes (e.g., solid polymers, gels, ionic liquids) as gate-insulator are a promising candidate for synaptic transistors due to the low operation voltage by electrical double layer (EDL) and high applicability to flexible electronic devices. However, conventional EGTs show volatile and irregular memory characteristics because of the rapid self-dissipation of ions in the electrolyte. Here, we have demonstrated the WiBS/polymer electrolyte-gated synaptic transistor (WEST) with ultra-violet ozone (UVO) surface treatment which highly improves the long-term memory characteristics and other synaptic functions as well. Super-concentrated WiBS electrolyte composed of excess lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) and lithium trifluoromethanesulfonate (LiOTf) in water enables the WEST to conduct synaptic functions in a voltage range of 1.23 V or higher, which is the electrochemical stability window of water. Also, the WiBS electrolyte can take advantage of the characteristics of pure water: high dielectric constant and biocompatibility. UVO treatment is one of the effective post-treatment that has been widely used to surface modification by controlling the oxygen vacancy concentration on the surface in various fields. Ultra-violet (UV) in the two different wavelengths of 185 and 254 nm decomposes metal-oxide bonds of InGaZnO (IGZO) thin film and the bonds are broken more intensively by the supplied ozone, which generates reactive oxygen radicals and they trigger the excessive ion bombardment process. We performed XPS analysis and measured hysteresis characteristics to calculate the memory window to verify the cause of the improvement in long-term memory performance of the WEST. As a result, the oxygen vacancy ratios of the UV-only and UVO-treated WEST calculated by XPS data are 0.35 and 0.44, respectively, 1.5 times and 2 times higher than the non-treated WEST, respectively. These increased oxygen vacancies act as trap sites at the interface, trapping lithium (Li) ions in the electrolyte and suppressing the self-diffusion of the Li ions. Also, the UVO-treated WEST performs long-lasting nonvolatile memory characteristics longer than 10,000 s, which is 1186 times higher than the non-treated WEST. Residual Li ions are detected only in the UVO-treated WEST and appeared as interstitial defects and Li-O bond peaks at 54.9 and 55.7 eV, respectively. After the UVO treatment, both the nonlinearity and asymmetricity of synaptic weight update characteristics are greatly improved from 5.91 to 0.32 for potentiation and from -6.11 to -0.55 for depression. By using the surface post-treatment, the WEST has shown great suitability as a neuromorphic device capable of long-lasting memory functions and elaborate weight controllability comparable to real human brains.

SESSION EL21.09: Magnetic and Spintronic Materials II

Engineering Large Spin-Orbit Torque in Silicides for Low-Power Spintronics Applications Cheng-Hsiang Hsu[1,2], Julie Karel[3], Hannah Kleidermacher[1], Niklas Roschewsky[1], Emma Blenkinsop[1], Jonathon Webster[1], Shang-Lin Hsu[1], Shehrin Sayed[1], Alpha T. N'Diaye[2], Frances Hellman[1,2] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Monash University, Australia

Magnetic memory has been a strong candidate for next-generation low power memory solution. In fact, magnetic memory has been commercialized in both standalone and embedded memory markets for the past few years. However, there are still several challenges in the current spin-transfer torque technology in magnetic memory applications. As a result, spin-orbit torque emerges as a candidate to replace spin-transfer torque due to advantages such as separate read-write current path, faster switching speed and larger material design space. To this regard, efforts in studying spin-orbit torque has been geared toward addressing several issues including material compatibility with silicon platform, trade-off between conductivity and spin-torque efficiency, and engineering field-free switching designs. Here, we propose to use silicides, a decades-old CMOS technology, for efficient spin current generation to manipulate magnetizations. In both amorphous iron silicide and cobalt silicide, we discovered a strong spin current generation efficiency that rivals the largest efficiency values discovered in topological insulators. Moreover, we discovered clear Fe (Co) concentration dependence of spin current generation efficiency in both systems that can potentially be signatures of Fermi level tuning in amorphous materials for manipulating spin current generation. At last, we show that the scaling trend between conductivity and spin current generation efficiency in both silicides are opposite to the conventional scaling trend. In the conventional scaling trend, the efficiency increases as the conductivity decreases. This is a fundamental bottleneck to adopt spin-orbit torque technology for magnetic memory applications. In silicides, the trend is opposite with an increasing efficiency as the conductivity decreases. This novel trend can lift the conventional trade-off and further enable the adoption of spin-orbit torque in magnetic memory applications. This work presents an efficient way of generating spin current in a silicon platform compatible material system – silicides – for energy efficient computing.

All-Optical Control of Magnetism—Towards Energy-Efficient (Brain-Inspired) Computing Theo Rasing; Radboud Universteit. Nijmegen, Netherlands

The ability to switch magnets between two stable bit states is the main principle of digital data storage technologies since the early days of the computer. However, the explosive growth of digital data and its related energy consumption is pushing the need to develop fundamentally new physical principles and materials for faster and more energy-efficient processing and storage of data.
Since our demonstration of magnetization reversal by a single 40 femtosecond laser pulse, the manipulation of spins by ultra-short laser pulses has developed into an alternative and energy efficient approach to magnetic recording[1]. Plasmonic antennas have allowed to push this even down to nanometer length scales[2], while photonic networks allow the development of an optically switchable MRAM[3].
However, new ICT technologies, such as Artificial Intelligence push the exponentially increasing energy requirement of data manipulation even more. Therefore, the development of radically new physical principles that combine energy-efficiency with high speeds and high densities is crucial for a sustainable future. One of those is neuromorphic computing, that is inspired by the notion that our brain uses a million times less energy than a supercomputer while, at least for some tasks, it even outperforms the latter. Ultimately, future brain-inspired technology should provide room temperature operation down to picosecond timescales, nanoscale dimensions and at an energy dissipation as low as the Landauer limit (~zJ). In this talk, I will discuss the state of the art in ultrafast manipulation of magnetic bits and present some first results[4] to implement brain-inspired computing concepts in magnetic materials that operate close to these ultimate limits.

Graphene-based Artificial Dendrites for Spatio-Temporal Processing in Spiking Neural Networks Samuel Liu[1], Dmitry Kireev[1], Maya Borowitz[1], Tianyao P. Xiao[2], Christopher Bennett[2], Deji Akinwande[1] and Jean A. Incorvia[1]; [1]The University of Texas at Austin, United States; [2]Sandia National Laboratories, United States

Neuromorphic computing has emerged as an important field to reduce the energy impact of artificial neural networks (ANNs). Among the types of neural networks, spiking neural networks (SNNs) rely on spatio-temporal spikes to transmit information, allowing even greater energy efficiency than the constant signals in ANNs. Due to increased complexity in the time domain, nonlinear dynamics in artificial neurons can significantly impact the performance of an SNN. These nonlinear dynamics can be mediated by dendrites, an SNN component that is relatively unexplored in neuromorphic computing, with few device candidates.

In this work, we propose a biocompatible graphene-based artificial dendrite that can implement tunable dendritic kernels at variable timescales, presenting a platform that can bridge between artificial and biological neural systems. We fabricated mesoscale (few mm2) and microscale (few µm2) synaptic transistor devices by interfacing graphene with a Nafion membrane. We used the dual-gate operation of the device in current mode to model alpha and Gaussian dendritic kernels, showing a transformation of input spikes to a non-spiking spatio-temporal output signal. The timing can be adjusted several orders of magnitude between microsecond to second, allowing a wide range of tunability. Device characteristics of conductance range, energy dissipation, and temperature dependence are also evaluated. A SNN constructed using the Linear Solutions of Higher Dimensional Interlayers (LSHDI) methodology is used to evaluate the performance of the artificial dendrites. We train the network offline on spoken digits from the Texas Instruments 46-word corpus using the modeled dendrites, then translate the software inputs to the dendrites into electrical signals to demonstrate functionality on a collection of hardware artificial dendrites. The results propose an artificial dendrite that is biocompatible, energy efficient, and highly tunable.

10:45 AM *EL21.10.03
Photonic Computing with Reconfigurable Integrated Circuits Wolfram Pernice; Heidelberg University, Germany

Conventional computers are organized around a centralized processing architecture, which is well suited to running sequential, procedure-based programs. Such an architecture is inefficient for computational models that are distributed, massively parallel and adaptive, most notably those used for neural networks in artificial intelligence. In these application domains demand for high throughput, low latency and low energy consumption is driving the development of not only new architectures, but also new platforms for information processing.
Photonic circuits are emerging as one promising candidate platform and allow for realizing the underlying computing architectures, which process optical signals in analogy to electronic integrated circuits. Therein electrical connections are replaced with photonic waveguides which guide light to desired locations on chip. Through heterogeneous integration, photonic circuits, which are normally passive in their response, are able to display active functionality and thus provide the means to build neuromorphic systems capable of learning and adaptation. In reconfigurable photonic architectures in-memory computing allows for overcoming separation between memory and central processing unit as a route for designing artificial neural networks, which operate entirely in the optical domain.

Resistive Memory Technologies as Dynamic Elements for Neuromorphic Computing Sabina Spiga, Mrinmoy Dutta, Manuel Escudero, Emanuele Gemo and Stefano Brivio; CNR-IMM, Italy

Hardware spiking neural networks (SNNs) and emerging unconventional computing concepts hold the great promise to build future low-power computing systems. The co-development of novel efficient neuromorphic hardware and brain-inspired learning protocols aims to deliver on this promise: it will bring a paradigm shift towards edge computing, where information processing is performed close to the data generated by portable and IoT devices, and will enable applications relying on smart analysis of sensory signals in real time.

Recently, the research in the field of neuromorphic computing has been receiving a significant boost by exploiting the physics of the broad class of memristive devices as new hardware building blocks enabling neural behavior, and then substituting or complementing CMOS circuits. These devices can support '*in memory computing*' in neural networks, thus avoiding the energy cost associated with data transfer between the memory and the processor, and then surpassing the limit of the von-Neumann computing architecture. Furthermore, as our brain uses neuronal and synaptic dynamics as working memory, it is desired that also neuromorphic chips compute with dynamics, encompassing devices and circuits with useful transients or evolution in time.

Our work focuses on resistive switching memory (RRAM), i.e. metal/insulator/metal devices that undergo reversible resistance change upon voltage application. RRAM devices, also depending on the used material stacks and programming strategies, allow the engineering of many functionalities for neuromorphic computing, such as analog dynamics response to input stimuli, and controllable stability of the device resistance states over various time scales. Therefore, RRAMs can act as volatile or non-volatile dynamic memory elements mimicking the short/long term plasticity of synapses in nervous system, or even as stochastic and non-linear elements in neuronal units. In our work, we engineered both analogue non-volatile HfO_x-RRAM as synaptic nodes in SNNs and Ag/SiO_x devices with tunable retention properties (from µs to seconds range), and exhibiting a conductance modulation as a function of input stimuli.

In an alternative approach, we developed analogue nonlinear dynamical circuits, exploiting the programmable nonlinearity of non-volatile HfO_2 RRAM devices. In particular, HfO_2-RRAMs can be programmed in different resistance states exhibiting a different nonlinearity of the current-voltage characteristic, which is used to generate complex circuit oscillations. Moreover, we have demonstrated that the circuit can be tuned from periodic (ordered) and chaotic behavior through the modulation of an input signal. In this manner, it can be used as a processing machine expanding the dimensionality of the input and enabling subsequent linear classification, in a reservoir computing scheme.
To summarize, in this talk we will show how various types of RRAMs, relying on different material stacks and mechanisms, can be used for computing by exploiting their intrinsic dynamics.

Conductive-TaOx/HfOx Based RRAM Devices with Enhanced Properties for Training Deep Neural Networks Tommaso Stecconi[1], Donato F. Falcone[1], Youri Popoff[1,2], Folkert Horst[1], Bert Offrein[1] and Valeria Bragaglia[1]; [1]IBM, Switzerland; [2]ETH Zürich, Switzerland

With the end of Moore's law approaching and the surge in compute effort required by Artificial Intelligence (AI), the quest for alternative computing schemes to the Von-Neumann architecture has intensified. In this context, in-memory computing is emerging as a promising hardware solution to improve both speed and energy efficiency [1].

By using analogue memory elements arranged in a crossbar array, we enable a fast and massively parallel computation of Vector-Matrix-Multiplications (VMM), the most called on algebraic operation in AI. Executing VMMs directly in analogue hardware enables enhanced power-efficiency compared to today's conventional computing approach based on highly advanced, digital Complementary Metal-Oxide-Semiconductor (CMOS) technologies. For the analogue alternative to be successful, it must embed memory elements with low programming and reading energy, which translates into requirements such as low-conductance, fast resistive-switching dynamics, and low operating voltages.
At the same time, many other fundamental properties such as unit cell area scalability, programming endurance and multi-state retention must be evaluated.

In this work we present RRAM devices based on an oxide bilayer structure of TaOx/HfOx, sandwiched between TiN electrodes. The bilayer structure improves the resistive switching symmetry, stochasticity and graduality. At the same time, with the TaOx resistivity being orders of magnitude lower compared to the HfOx, the forming voltage does not increase excessively compared to the baseline case of an oxide monolayer only.

By developing an ultrathin 4nm defective-rich HfOx material by ALD, we achieve forming voltages of ~4 V for $(200\ nm)^2$ devices, improving by more than 20% this specific compared to the previous generation of bilayer RRAMs (Gen_1) [2].
The reduction of the forming voltages enables a better control of the filament, leading to a ~10x lower conductance of the devices compared to Gen_1.

Our colleagues working on deep learning solutions for networks of memristors have recently developed the "Tiki-Taka" algorithm, relaxing the requirements on the conductance updates symmetry and linearity [3]. For the algorithm to accurately train a network of memristors, we update their conductive states by a train of either positive or negative voltage pulses, with fixed amplitude and duration.
We successfully demonstrate the Tiki-Taka's "symmetrization procedure" on our devices, which is an essential step for the correct execution of the algorithm. This procedure requires analogue and non-volatile bidirectional tunability of the device conductance. Both properties are excellently met by our new generation of TaOx/HfOx devices.

Origin of Discontinuous Negative Differential Resistance in Metal-Oxide-Metal Devices Robert G. Elliman[1], Sanjoy Nandi[1], Shimul K. Nath[1], Shuai Li[1], Thomas Ratcliff[1], Xinjun Liu[2], Peter Raad[3] and Assaad El Helou[3]; [1]Australian National University, Australia; [2]Tianjin University, China; [3]Southern Methodist University, United States

Metal-oxide-metal cross-bar devices that exhibit current-controlled negative differential resistance (CC-NDR) can be used to fabricate nanoscale oscillators, and are of interest as a fundamental building block for brain-inspired neuromorphic computing. For devices based on binary metal-oxides the CC-NDR response is typically manifest as S-type current-voltage characteristic that can be attributed to an increase in the oxide conductivity due to local Joule heating. However, recent studies have shown that such devices also exhibit a range of more complex behaviour that may provide additional functionality. These include an abrupt 'snap-back' response, as well as compound characteristics comprising various combinations of S-type and snap-back characteristics. Understanding such behaviour is complicated by the fact that conductivity changes can involve a combination of electronic and thermal processes, material-specific phase transitions (e.g. crystallization or metal-insulator transitions), non-linear current redistribution and measurement artifacts.

This presentation summarizes our current understanding of the mechanisms underpinning the snap-back and compound CC-NDR modes and shows how this understanding can be used to develop devices with new functionality [1, 2]. Specifically, we combine electrical, physical and thermal characterisation of NbOx-based devices, including in-situ thermoreflectance imaging of device temperature distributions, to understand the origin of the CC-NDR modes and their dependence on material and device parameters (e.g. oxide stoichiometry, electrode metal, film thickness, device area). These results are then compared with the predictions of an electro-thermal model of filamentary conduction that employs a core-shell structure to represent conduction in the filamentary path (core) and the surrounding oxide film (shell). These results show that both the snap-back and compound CC-NDR characteristics can be explained by current redistribution between the core and shell regions, with the snap-back response resulting from an abrupt current bifurcation process in which the current distribution separates into regions of low and high current density. Further analysis shows that the criterion for bifurcation is determined by the relative magnitudes of the shell-resistance and the NDR of the core region. Based on this understanding, we demonstrate how the asymmetric contact resistance of a Schottky-barrier contact can be used to construct devices with a bias-polarity dependent CC-NDR response [3].

Significantly, the results of this study demonstrate that a diverse range of CC-NDR responses can be explained by a relatively simple model that accounts for current redistribution within metal/oxide/metal device structure. Within this framework, the continuous S-type and abrupt snap-back CC-NDR responses have the same physical origin, precluding the need to invoke additional mechanisms such as an insulator-metal transition.

3:45 PM EL21.12.02
Assessing the Impact of Ti Doping and MAX-Phase Ti_2AlN Electrode in HfO_x Neuromorphic Devices Fabia Farlin Athena[1], Moses Nnaji[1], Matthew P. West[1], Samuel Graham[2] and Eric M. Vogel[1]; [1]Georgia Institute of Technology, United States; [2]University of Maryland, United States

Oxide-based non-volatile memories have great potential for neuromorphic computing applications.[1] In HfO_xfilamentary memory, when bias is applied, a conductive filament (CF) is formed, within which O ion motion in and out causes rupture and reformation of the CF, and this process primarily governs the switching. However, challenges such as high forming voltage (V_F), abrupt resistance change, and high off-state current prohibit its widespread adoption.[2]

In this study, we independently assess the impact of Ti doping and electrode material optimization on HfO_x devices with the goal of overcoming the problems in HfO_x filamentary memory. The Ti-doped HfO_x devices were fabricated, where the ~5 nm oxide was deposited via atomic layer deposition. Electrical characterization shows that the **V_F decreases** (~2.1 V) with the increase of Ti doping.[3] In addition, analog pulse measurements show that a 25% Ti doping **improves the linearity in resistance change** during the reset. However, the switching is not substantially impacted, and the **off-current is high**.[4] A few O ion motion at the CF break region governs the switching. We determined the location of the break via a direct tunneling electron transport model and a finite element analysis. Both analyses show that the break is close to the reset anode electrode; thus, the electrode has a significant impact on the switching. We hypothesize that a reduction in thermal conductivity (K) of the electrode will lower the off-current. A low electrode will cause less heat removal and more oxygen ion motion, thus will result in a thicker break in CF and less off-current. However, the challenge is that most of the electrodes have high K (e.g., K_{Au} = 310 W/m.K., K_{TiN} = 29 W/m.K). Ti_2AlN, like many other MAX phase materials, has unique metallic (high electrical conductivity) and ceramic properties (low thermal conductivity, $K_{MAX\ phase}$ ~4.63 W/m.K) as it contains alternating layers of metallic and covalent bonds.[5] Thus, HfO_x devices with Ti_2AlN MAX phase as the bottom electrode were fabricated. Alternating layers of Ti and AlN were first deposited at room temperature via magnetron sputtering and then thermally annealed to obtain Ti_2AlN. Raman spectroscopy of the electrode showed the characteristic spectra of Ti_2AlN. The HfO_x devices with MAX phase BE show a **one-order-of-magnitude improvement in the off-current** (HRS ~ 450 kΩ), a large switching window (~200), good endurance (>100) and retention (~10^4 s) of states. Furthermore, analog pulsing measurements are conducted to analyze the synaptic behavior of the devices. A COMSOL Multiphysics® model is used to develop a fundamental understanding of the observed results.
Overall, this study demonstrates that through optimization of the materials in HfO_x memory, the electrical responses can be tailored for neuromorphic application.

4:00 PM EL21.12.03
Electroforming-Free Low Switching Operation in CeO_2-based 1S1R Memristor Device for Neuromorphic Computing Applications Dwipak P. Sahu, Kitae Park, Peter H. Chung, Sola Moon and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Resistive random-access memory (RRAM) devices with crossbar array (CBA) configuration have been considered as promising next-generation non-volatile memory as well as future computing paradigms, such as in-memory computing and neuromorphic computing [1]. However, the generation of sneak path currents through unselected cells in a CBA architecture affects the efficiency and power consumption of the cells. Therefore, the sneak current issues can be resolved by vertical integration of a memristor (R) with a selector (S) in a 1S1R crossbar array [2]. However, it is also essential that the material composition and electrical properties of both the memristor and selector should be compatible for the proper functioning of 1S1R integrated device. Among various oxide switching layers, here, we have considered CeO_2-based rare-earth oxide as a dielectric switching layer for memory and selector devices due to its large bandgap, high oxygen ionic conductivity, and strong oxygen-getting ability of Ce [3]. For this, we have fabricated a memristor with $TiN/CeO_2/TiN$ structure and vertically stacked it with a selector device made of $Ag/CeO_2/SiO_2/TiN$ through a shadow mask in a capacitor structure. The selector (S) device with Ag as the top electrode (TE) acts as a volatile memory under a low current operation of 1 µA and could help in reducing the leakage current on integration with the memory (R) device. The memory device shows analog switching characteristics under a bias voltage of ±4 V with a leakage current of 430 nA at a read voltage of 1V. In memory devices with TiN electrodes, the possibility of the formation of a TiO_xN_y interface layer during the fabrication process can serve as a reservoir of oxygen vacancies which may act as a leaky dielectric layer. Upon repeating +V sweep from 0 to +4 V, the current increased by more than 10 times indicating a potential application of the memory device for synaptic weight update. However, the continuous negative voltage sweep does not return the device current to its initial stage which could be due to the formation of different interface barriers between top TiN/CeO_2 interface and bottom CeO_2/TiN interface although the device is structurally symmetric. In comparison, the 1S1R device also shows an analog switching with ±4 V and requires no electroforming process prior to the switching operation. Due to the addition of a selector device, the leakage current was suppressed by nearly four orders to 28 pA at a read voltage of 1V. Initially, both memory and selector devices are at HRS and most of the voltage drop is on the selector due to its large off-state resistance. The device shows memory switching after the selector turns on which reduces the leakage current. The present 1S1R device shows reliable data retention of 68.7% after 30 min which has the potential for studying its long-term plasticity behavior. A detailed analysis will be carried out by fabricating 1S1R in crossbar array architecture to study the synaptic behavior for the implementation of a hardware neural network.

4:15 PM EL21.12.04
Novel and Tunable Wavelength-Selective Artificial Synapses Based on Inorganic Thin Film Photovoltaic Devices Kunal Tiwari, Axel Gon Medaille, Alex Jimenez, Eloi R. Costals, Sergio Giraldo, Marcel Placidi, Edgardo Saucedo and Zacharie Jehl Li-Kao; Polytechnic University of Catalonia, Spain

Artificial synapses are an important building block for neuromorphic computing, holding the promise to reproduce fundamental brain functions and markedly improve the energy efficiency of future computers beyond the Von Neumann architecture while offering new possibilities in terms of unsupervised learning and parallel computing with a high resilience to faults. As the human brain receives nearly 80% of its inputs from visual perception, the development of efficient and tunable optoelectronic artificial synapses appears as the next frontier going forward, and several proof-of-concept devices have been reported using both organic and inorganic materials, albeit with a comparatively low degree of tunability. While carrier trapping from native and extrinsic defects is often seen as a drawback in inorganic thin film photovoltaic devices, it holds a remarkable yet currently untapped potential to simulate synaptic plasticity.
In this work, we demonstrate for the first time the properties of **long term potentiation, short term potentiation, and synaptic depression using light as a stimulus** and persistent photoconductivity as a figure of merit to characterize the plasticity in a $Cu_2ZnSnSe_4$/CdS/ZnO-based photovoltaic device artificial synapse. The dark persistent photoconductivity was found to last for **several days after a stimulation** with white light ranging from durations of a few minutes to several hours and at a power of 1000 $W.m^{-2}$. Furthermore, illumination in short bursts (few seconds and less) reveals a typical **short term plasticity behavior with a memory effect akin to that of an RC integrator**, a key element for digital computing. It is to our knowledge the first time that such behaviors are deliberately achieved and characterized for this class of materials and devices.
Even more remarkably, the fabricated devices are found to operate with some level of **wavelength selectivity**. By maintaining the incident illumination power constant and varying the illumination wavelength with 28 different LEDs over a range from 350 nm up to 1500 nm, significant changes in the synaptic response are observed which widens the number of possible programming states of the system, and relates to the different transition energies of the trapping states involved in the plasticity of the device. The response to **ultraviolet and blue illuminations below 500 nm is particularly efficient at producing both a long term and short term potentiation of the synapse**, hinting at the charging of trap states located at the vicinity of the front p-n interface. In contrast, most of the wavelengths from the visible spectrum do not lead to a measurable short term plasticity response, which could be interpreted as either the absence of transition corresponding to those wavelengths or to a screening of the photoconductivity by the photocurrent. The case of infrared illumination beyond 1200 nm is particularly peculiar as it **simultaneously can lead to a short term synaptic potentiation following illuminations of a few seconds or less, and a long term synaptic depression following an illumination of fifteen minutes** of an already potentiated synapse. Such reaction to a single stimulus has to our knowledge never be observed in either electronic or optoelectronic synapses.
Finally, it is found that the synaptic behavior of the devices can be tuned through the variation of the oxygen content in the ZnO window layer, offering further insights on the defect trapping mechanics involved in the plasticity of those artificial synapses. The complete set of results will be presented, including the current limitations of this work, and a model involving two trap levels located at the vicinity of the p-n interface will be proposed and discussed in the context of the electrical characterizations of the artificial synapses and previous knowledge acquired in CZTSe-based solar cells. This type of synapses represents an entirely novel research opportunity for ultra-low energy computing.

Interface Engineering toward Future Low-Energy and Scalable Ferroelectric Memory I-Ting Wang, Hsin-Hui Huang, Chui-Yi Chiu, Chen-Yi Cho, Tzu-Yao Lin and Tuo-Hung Hou; National Yang Ming Chiao Tung University, Taiwan

Differing from most nonvolatile memory (NVM) solutions, such as RRAM, PCRAM, STT-MRAM, SOT-MRAM, etc, the switching of a ferroelectric (FE) memory is driven by the electric field rather than the electric current. Its low operating current allows extremely low switching energy and also a compact cell size by reducing the dimension of the access transistor. The promising FE properties of thin Hafnium-Zirconium oxide (HZO) by atomic layer deposition suggest the possibility of achieving a low operating voltage, which is also critical for embedded memory in the logic process. However, some open questions remain for FE memory that might require fundamental material and physical understanding and innovative solutions. First, the thickness and area scalability of FE capacitors that satisfy the strict requirements at the advanced logic nodes remain to be explored. Second, the endurance of FE capacitors is limited by the fatigue-breakdown dilemma. Without robust endurance, the application space of FE memories with the destructive-read feature is limited. Third, the destructive-read feature is also not desirable for performing energy-efficient in-memory computing. One of the nondestructive-read FE memories is the ferroelectric tunnel junction (FTJ). However, the low on-off current ratio and the low read current of FTJ remain problematic. We analyze these challenges from both theoretical and experimental perspectives. We found that the interfaces between FE and metal electrodes play a major critical role in improving these issues. These understandings would facilitate the development of future low-energy and scalable ferroelectric memory.

GeOx-Ge Quantum Dot Assembly for Multistate Spatial Wavefunction Switched (SWS) Field Effect Transistors Raja Hari Gudlavalleti[1], Abdulmajeed Almalki[1], Pik-Yiu Chan[1], Ronald LaComb[1], John Chandy[1], Evan Heller[2] and Faquir Jain[1]; [1]University of Connecticut, United States; [2]Synopsys Inc., United States

Abstract:
This paper presents a novel twin-drain Ge quantum dot (QD) spatial wavefunction switched (SWS) field-effect transistor (FET) which demonstrates

multistate within a single device. [1-3]. An array of individually cladded quantum dots forms a quantum dot superlattice (QDSL) which exhibits discrete mini-energy bands that have very narrow density of states (DOS) separated by 0.3-0.4 eV. The QDSL serves as: (i) single/multiple transport channel, (ii) quantum dot gate on tunnel oxide, (iii) multiple drain SWS FET. The nanodevices create multiple intermediate logic states in addition to ON and OFF states [4]. The gate voltage determines the threshold for each of the intermediate states. The threshold voltage depends on size of the QD (core and cladding region thickness), gate dielectric thickness and constant. Jain et. al., experimentally demonstrated Si and Ge QD based three- and four-state state FET devices [4-6].

Prior work [1] demonstrated carrier wavefunction switching from lower quantum dot channel to upper quantum dot channel in a multistate SWSFET using SiOx-cladded Si QDs. Ge QDs exhibiting more energy mini-bands will provide additional multiple states and hence versatile multibit processing. We describe processing of a twin-drain SWSFET having four layers of GeOx-cladded Ge QDs self-assembled in the channel region. The upper two QD layers act as the transport channel from source S to drain D_1 and the lower two QD layers act as the transport channel from source, S to drain, D_2. The gate voltage, V_G, determines the spatial location of the charges in the upper or lower quantum-wells/-dots in the channel region. This property of the device allows it to encode logic levels at each threshold level of the device for the multivalued logic operation. The location of electrons in lower, upper, both and none encodes the logic states (01), (10), (11) and (00), respectively, which provides a 4-state/2-bit FET operation. In this method, a colloidal solution of cladded Ge QDs is prepared [7] and self-assembled at room temperature. The device sample with Ge dots is annealed at 350 C. The size of the Ge QDs is ~3-4nm with ~0.5 nm GeOx cladding. The experimental characteristics shows multiple state in the FET devices at room temperature.

The low temperature Ge QD preparation and demonstration of multistate within the single device at room temperature operation achieve reduced device count. Further, these novel FETs can be integrated with QD-NVRAMS with CMOS compatible processing. This integration serves as a hardware platform for distributed computing and artificial intelligence applications.

Optimization of Materials and Interfaces for Low Power Analog Conductive Metal Oxide/HfO2 ReRAM Artificial Synapses Donato F. Falcone, Youri Popoff, Tommaso Stecconi, Valeria Bragaglia, Marilyne Sousa, Folkert Horst, Antonio La Porta and Bert Offrein; IBM Research - Europe, Switzerland

The energy required for the training and inference of complex neural networks on standard CMOS technology based on von-Neumann architecture has been growing tremendously. In particular, the data exchange between memory and the processing units is power-hungry, causing inefficiency and performance mitigation. Specialized neuromorphic hardware based on analog memristors are a promising and more energy efficient alternative. When organized in crossbar arrays, memristive technologies such as ReRAM or PCMs [1] can be used to perform vector-matrix multiplications (VMMs), the most energy-expensive operation in AI’s tasks, in the analog domain, by exploiting Ohm’s and Kirchhoff’s law. Such two-terminal technologies are scalable and can be densely integrated in the Back end of the line (BEOL) of existing CMOS technology, to create a high performing synaptic analog signal processing accelerator.

Metal/Insulator/Metal Redox-based Resistive Switching Random Access Memories (Ti/HfO_2 ReRAM), exploiting filamentary conduction, are emerging as a leading option for memristors due to the compatibility with and ease of integration in CMOS technology. Nonetheless, the electro-chemical reactions at the interface between Ti and HfO_2 tend to result in an abrupt and stochastic rather than analog and symmetric switching characteristics, hindering their suitability for applications in AI analog accelerator units [1].

A promising and innovative concept of ReRAM device was proposed in [2], replacing the Ti layer by an engineered Conductive Metal Oxide (CMO), resulting in a Metal/CMO/Insulator/Metal type ReRAM device. The CMO/HfO_2 ReRAM shows superior characteristics such as gradual, linear and symmetric conductance update, large number of states, good retention and reproducibility of the switching characteristics. Nevertheless, the main limitation of CMO/HfO_2 stack with respect to Ti/HfO_2 is the increased voltage required to perform the electro-forming (V_{foming} up to 5.5V in [2]), which represents a critical challenge for combining this technology with modern CMOS technology.

In this work, we optimized the Metal/CMO/Insulator/Metal ReRAM technology. By properly engineering the stack, we reduced the forming voltage below 3.3V without compromising all the superior electrical characteristics of the CMO based ReRAM technology. The material-stack characterization by means of TEM and EDS, as well as the DC and pulsed electrical characterization of the devices will be presented. Furthermore, by controlling the forming process of CMO/HfO_2 ReRAM, two operative switching regimes are found, with kΩ and MΩ range resistive levels. Through impedance spectroscopy experiments and finite elements simulations, we established equivalent electrical circuit models and provided a physical understanding of the optimized CMO/HfO_2 ReRAM in pristine state, after forming, in the high resistive state (HRS) and in low resistive state (LRS), explaining the importance of the CMO layer in the resistive switching behavior.

The granular switching properties and CMOS compatibility of the CMO/ReRAM devices are promising for large-scale integration of this technology for future neural network training and inference.

8:50 AM EL21.13.04

Impact of Post-Annealing Time Duration on the Structural, Optical and Resistive Switching Properties of RF Sputtered β-Ga_2O_3 Thin Films Asma

O. Al Ghaithi, Inas Taha, Sumayya M. Ansari and Haila Aldosari; United Arab Emirates university, United Arab Emirates

Wide bandgap semiconductor gallium oxide (Ga_2O_3) recently began garnering increasing scientific interest owing to its large bandgap of 4.7−4.9 eV. The exceptional thermochemical stability of β-Ga_2O_3 makes it an intriguing material for several applications, including high-power electronic devices, solar-blind UV photodetectors, light-emitting diodes, photocatalysts, transparent conducting oxides, and chemical sensors. This presentation will discuss the impact of post-annealing time on the structural and optical properties of radio-frequency (RF) magnetron-sputtered amorphous Ga_2O_3thin films. 100 nm thick amorphous Ga_2O_3 thin films were deposited on p-type (100) silicon substrates and post-annealed in a tube furnace at 1000 °C under an argon (Ar) atmosphere for different time intervals: 1, 2, and 7 h. Various characterization techniques were used in this investigation, including grazing-incidence X-ray diffraction (GIXRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), energy dispersive spectrometry (EDS), and UV-visible- NIR spectrophotometry. GIXRD scans showed that the as-deposited Ga_2O_3 thin films were amorphous. In contrast, all post-annealed thin films were polycrystalline β-Ga_2O_3, exhibiting a monoclinic crystal structure with a C2/m space group and dominant (400) orientation. In addition, the degree of crystallinity and grain size increased upon increasing the annealing time. Cross-sectional TEM of 7 h annealed Ga_2O_3 thin film revealed interplanar distances of 2.93 Å and 2.88 Å, which correspond to the d-spacing of (400) and (002) planes of the β-Ga_2O_3, respectively. Moreover, no solid-state reaction occurred between the underlying Si substrate and the Ga_2O_3 layer. All the Ga_2O_3 thin films exhibit very high transmittance in the UV and visible ranges. The optical bandgap of the as-deposited Ga_2O_3 film is 4.45 eV, which increased after the post-annealing treatment. Finally, we developed a 100 nm Ag/20 nm Ga_2O_3/Si memristive system. The current–voltage (I–V) characteristics of Ag/Ga_2O_3/Si memristor under positive and negative bias voltages have provided valuable information on the ON and OFF states of the device and the corresponding resistive switching mechanism.

Spin Dynamics in Antiferromagnets and Applications Shaloo Rakheja[1], Arun Parthasarathy[2] and Ankit Shukla[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]New York University, United States

Antiferromagnetic materials have ordered spin moments that alternate between individual atomic sites, which gives them a vanishing macroscopic magnetic signature and relative immunity against perturbations from external magnetic fields. Because of their strong exchange interaction, antiferromagnets are expected to have terahertz scale magnetization dynamics, which is nearly three orders of magnitude faster compared to their ferromagnetic counterparts. Although antiferromagnets represent the overwhelming majority of magnetically ordered materials, traditionally, they have played a secondary role to ferromagnets, which are used as active elements in commercial spintronic devices like magnetic sensors and non-volatile magnetic memory. This is in part due to the difficulty associated with the electrical detection and manipulation of the order parameter in antiferromagnetic thin films. Thus, research dedicated toward understanding the antiferromagnet's material properties and electrically driven spin dynamics is necessary to harness their full potential.

We focus on the physics and modeling of spin dynamics in thin films of two unique antiferromagnets: Cr_2O_3, which is a single-phase magnetoelectric insulator and Mn_3Sn, a Weyl semi-metal. These antiferromagnetic materials and their heterostructures can overcome the central challenge of manipulating and reading the antiferromagnet's order parameter via microelectronics compatible circuitry, thus allowing us to develop antiferromagnetic spintronics along a similar route as ferromagnetic spintronics.

The principle of using Cr_2O_3 to generate a reversible exchange bias in a proximal ferromagnet for non-volatile memory operation has been experimentally demonstrated. A ferromagnet-free memory cell using Cr_2O_3 has also been experimentally reported. However, in these experiments, the actual dynamics of magnetoelectric switching in Cr_2O_3 are overlooked, even though it is important to establish whether multi-domain effects play a role. Here, we present models that describe the timescale of various domain switching mechanisms in thin films of Cr_2O_3 including nucleation, domain wall propagation, and coherent rotation. By assessing our theory against measurement data, we confirm that the switching in experimental samples is dominated by domain wall propagation, which limits the write delay of the memory cells to >10s of nanoseconds. We also show that ultrafast switching at terahertz speeds is limited by the low dielectric breakdown and high magnetic anisotropy energy, which could be mitigated via strain engineering or substitutional alloying.

Mn_3Sn is a hexagonal Weyl semi-metallic antiferromagnet in which the combination of exchange coupling and Dzyaloshinskii-Moriya interaction (DMI) stabilizes an anti-chiral 120-degrees spin structure below the Neel temperature of 420K. The combination of three sublattices having two-fold single-ion anisotropy renders the system six-fold anisotropy symmetric. Mn_3Sn displays large magneto-transport responses despite having a vanishingly small magnetic moment. In our research, we model the spin torque driven chiral spin rotation in Mn_3Sn and obtain an analytic relationship between the input spin current and the oscillation frequency of the order parameter. Using an anomalous Hall readout, we quantify the measured output voltage signal in the sample resulting from the spin rotation and correlate theory with recent experimental reports. We demonstrate the feasibility of this material platform to implement nano-oscillators whose frequency can be tuned from the megahertz to the near-terahertz regime. We also briefly discuss the use of Mn_3Sn heterostructures to emulate an artificial neuron in hardware for energy-efficient brain-inspired computing.

Our work provides valuable insight into the performance of antiferromagnetic heterostructures for applications in ultralow-power nonvolatile memory and enabling a beyond von Neumann computing paradigm.

Electro-Opto-Coupled Phenomenon in Mott-Material Towards Energy Efficient and Ultrafast Neuromorphic Processing Hyungtak Seo, Mohit Kumar, Seokwon Lim and Jisu Kim; Ajou Univ, Korea (the Republic of)

Functional quantum materials have the potential to generate new paradigms for programmable nanoelectronics, data processing, and even beyond. This can be accomplished through the downsizing of device sizes and the improvement of energy efficiency. Consequently, unlike conventional electronics, the fabrication of a novel technology that combines precisely regulated charge transfer and multilevel memory storage in a single nanoscale device requires the use of basic electronics.
In this talk, I will discuss how spatially confined (nano-to-micrometer) vanadium oxide (VO_2) nanochannels designed by local probe lithography enable a wide variety of nanoelectronics in a single device, including regulated current conductors (on/off ratio > 10^4), ultrafast (~32 ns) volatile switches, and multilevel (> 6) nonvolatile memory storage. In addition, probabilistic adaptation and classification of input patterns using multiterminal nanodevices combined on a single platform to take advantage of the in-material probabilistic computing made possible by the IMT's stochastic yet controllable nature will be shown.
Further, I will discuss the monolithic integration of the Mott material on photosensitive silicon and demonstrate the superlinear photoresponse (exponent >18) with an ultralow dark current of 4.46 pA and how it can be implemented for intensity-selective near-sensor night vision processing even with noisy inputs. The results shown in this talk reveal a conceptually new kind of programable nonvolatile nanoelectronics and will pave the way for the creation of high-performance photodetectors with potential uses, such as in night vision, pattern recognition, and neuromorphic processing.

Abstract Presented (ON-DEMAND ONLY) Exploring Bioinspired Ultra-Low Power and Opto-Induced Bio-Voltage High-Speed Memristor
Dhananjay D. Kumbhar, Navaj B. Mullani and Jun Hong Park; Gyeongsang National University, Korea (the Republic of)

The memristor is a top-notch choice for neuromorphic computing and nonvolatile memory, with potential for neuromorphic devices including high data integration density, ultrafast speed, and ultralow power consumption. Recently developed fast and energy-efficient artificial neuromorphic systems are in great need of low-power memristors, as previously described device amplitude is considerably greater than in the biological counterpart. Here we demonstrated an Opto-induced filament-based memristor using Sb_2S_3 by a novel vapor transfer deposition method for the memory applications, demonstrating excellent parameters such as a super low turn ON potential of ≈ 9 mV and a switching speed as high as 600ns, including high retention and high endurance with ON/OFF ratio of $0.3x10^3$. The ultralow-power and high-speed switching of Sb_2S_3 are associated with the lower activation energy for Ag ion migration and the presence of Sulphur vacancies. Therefore, the present optically configurable Sb_2S_3 memristors can provide a milestone to develop a single-chip-based bio-inspired computing system, converging with sensory functions.

Electrochemistry Under Confinement in Capacitive Materials for Energy Storage Applications Patrice Simon[1,2]; [1]Universite Paul Sabatier, France; [2]French Academy of Sciences, France

This presentation will give an overview of the research work achieved on capacitive 3-Dimmensional porous carbon and high-rate 2-D redox (pseudocapacitive) materials, and will show the challenges/limitations associated with the development of these materials. Starting with porous carbons [1,2], we will present the state-of-the art of the fundamental of ion adsorption mechanism in porous carbons and its practical applications. Moving from double layer to high rate redox materials, we will show how the control of the electrodes structure can help in preparing high power rate electrodes using 2-Dimensional MXene materials [3-5]. We will show how the electrolyte ion partial desolvation observed when confined in nanopores (porous carbons) or in interlayer spacing (2D materials) can result in a continuous transition from EDL formation to typical intercalation-type battery process [5]. A last part will be dedicated to the operando tracking of the ionic and electronic percolations in supercapacitor and battery electrodes using an in-plane AC impedance spectroscopy technique.

Nano-Engineering of 2D Materials for Electrochemical Energy Storage Frederic Favier[1,2]; [1]Centre National de la Recherche Scientifique, France; [2]RS2E, France

As for graphene, the main issue about 2D materials is re-stacking. This is especially true for supercapacitor electrode materials as electrode/electrolyte interface and ion transport/diffusion should be both maximized to get greater storage capabilities. Many synthetic approaches have been explored to address this issue. Starting from exfoliated materials, including graphene, MXenes, oxydes, hydroxydes… we have developed various strategies to modify the composition, structure or morphology of the layers before re-assembling them in materials with enhanced electrochemical performances.[1-4] To illustrate our progress in the field, three different approaches will be presented in this paper.

The first approach is on the synthesis of graphene-like carbide-derived carbons produced by chlorination of SiC nanosheets obtained by the magnesio-thermal reduction of a silica/graphene oxide nanocomposite. The resulting microporosity in the graphene sheets was shown to strongly improve the rate capability of the prepared electrode material.

Electrostatic stacking of layers of opposite surface charges could also be used to associate Faradaic layered double hydroxides (LDHs), for energy density, to a more stable and powerful pseudocapacitive MnO$_2$. The electrochemical performances of the resulting electrode material were assigned to synergistic effects from distinct but complementary intrinsic behaviors together with the specific morphology of the composite material.

Expanded Ti$_3$C$_2$ MXene obtained by using MgO nanoparticles as hard templates displayed an open morphology based on crumpled layers. The corresponding electrode material delivered up to 180 F.g^{-1} of capacitance at 1 A.g^{-1} over five thousand charge-discharge cycles in KOH electrolyte. On the other hand, an MXene foam prepared by decomposing an MXene-urea composite at 550°C, showed numerous macropores on the surface layer and a complex open 3D inner-architecture. Thanks to this foamy structure allowing in and through plane ion diffusion, a capacitance of 203 F.g^{-1} at 5 A.g^{-1} current density, 99 % of which was retained after five thousand cycles.

11:30 AM *EN01.01.03
Charge Storage in 3D Architected Electrodes Meets 3D Bode Analysis Debra R. Rolison[1], Jesse S. Ko[2], Megan Sassin[1], Zachary G. Neale[3,1], Ryan DeBlock[3,1] and Jeffrey Long[1]; [1]U.S. Naval Research Laboratory, United States; [2]Johns Hopkins University Applied Physics Laboratory, United States; [3]NRC-NRL Postdoctoral Associate, United States

Electrochemical energy storage relies on multiple mechanisms to store electron/ion charge in redox active materials. Using traditional voltammetric techniques to deconvolve superimposed coulombic/temporal information can be complicated when one mechanism doesn't dominate, a common outcome with high surface-area nanomaterials that amplify capacitive-flavored storage. Impedance spectroscopy can provide deeper insight into mixed charge-storage mechanisms. Mirroring the work of Bai and Conway, which tracked pseudoinductive effects as a function of both frequency and potential,[1,2] we similarly track the colors of capacitance in a protocol we designate '3D Bode Analysis.' This impedance variant can distinguish double-layer response, pseudocapacitance, and battery-like faradaic reactions at device-relevant electrodes, particularly architected electrode structures.[3–6] Using high surface-area carbon nanofoam papers (400–500 m^2 g^{-1}) painted with 10 nm–thick MnO*x*, we used 3D Bode analysis to identify the respective potential windows for pseudocapacitance and battery-like reactions for LiMnO$_4$ and the electroprecipitation/dissolution reactions that underlie energy storage in Zn-ion cells. The 3D Bode analysis can also evaluate the positive effects of carbothermal shock to improve the double-layer response of graphene oxide–carbon nanotube composites.[7] These studies highlight another electroanalytical approach to understand the complex electrochemical response of advanced electrochemical materials.

SESSION EN01.02: Theory and Characterization
Session Chairs: Veronica Augustyn and Thierry Brousse
Tuesday Afternoon, April 11, 2023
Moscone West, Level 2, Room 2001

1:30 PM *EN01.02.01
UV-vis Spectroscopy Technique for *In Situ* Monitoring Redox Processes in Electrochemical Energy Storage Danzhen Zhang[1], Ruocun (John) Wang[1], Xuehang Wang[1,2] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]Delft University of Technology, Netherlands

Understanding energy storage mechanisms in electrochemical energy storage devices lays the foundations for improving their energy and power density.

Herein, we introduce a simple and easily accessible *in situ* ultraviolet-visible (UV-Vis) spectroscopy method to distinguish battery-type, pseudocapacitive, and electrical double-layer charge storage processes, on example of Ti_3C_2Tx MXene in aqueous acidic and neutral electrolyte and lithium titanium oxide in organic electrolyte. We found a correlation between the evolution of UV-Vis spectra and the charge storage mechanism. Further, we successfully tested the methodology to distinguish non-Faradaic charge storage in Ti_3C_2Tx MXene in water-in-salt electrolyte and Faradaic charge storage in battery materials, where all of these materials had well-defined peaks in cyclic voltammograms. *In situ* UV-Vis spectroscopy is an effective method to track changes in oxidation state and determine the charge storage mechanism. It effectively supplements electrochemical characterization, providing a fast and inexpensive first-line technique for monitoring redox activity in electrochemical systems.

2:00 PM *EN01.02.02
Ti and Nb-Based Oxides as Negative Electrode Materials for High Power Batteries Olivier Crosnier[1], Etienne Le Calvez[1], Eric Gautron[1], Nicolas Dupre[1], Bruce S. Dunn[2], Laurent Pilon[2] and Thierry Brousse[1]; [1]CNRS - IMN, France; [2]University of California, Los Angeles, United States

Today, one of the main challenges of lithium-ion batteries is to have the ability to charge faster and to provide high power during longer periods, thus allowing a larger development of intermittent electric power sources [1]. The actual negative electrode materials (graphite and silicon mainly) cannot sustain such high rate capabilities. In this work, we are therefore investigated some materials of the plentiful family of niobium-based oxides. A presentation of old and interesting structures will be briefly reviewed. As an example, the case of $KTiNbO_5$ will be discussed and proposed as efficient negative electrode materials for next generation of lithium ion batteries.
The layered $KTiNbO_5$ with a two-dimensional framework represents a playground to produce a large range of closely related phases.[2] The protonated $HTiNbO_5$ analogue is obtained by ion exchange in acidic solution and it preserves a layered structure with a smaller interlayer distance. After dehydration of $HTiNbO_5$ at 400°C, the so-obtained $Ti_2Nb_2O_9$ phase displays a 2D arrangement with empty channels unlike tunnels of $H(K)TiNbO_5$.
In this work, all the synthesized phases were studied as negative electrode materials in lithium-ion batteries. Tested in 1M $LiPF_6$ in EC/DMC between 1.0V and 3.0V vs Li/Li^+, these phases have shown different electrochemical behaviors. When $HTiNbO_5$ exhibits a typical plateau during the charge/discharge experiment corresponding to a biphasic phenomenon, lithiation of $Ti_2Nb_2O_9$ is governed by a solid—solution mechanism. For a better understanding of the charge storage mechanism, we have combined electrochemical experiments with *in situ* XRD measurements. We have shown that multielectron redox and corner/edge sharing system of Ti/Nb octaedra are at the origin of an interesting capacity of more than 100 $mAh.g^{-1}$ at a rate of 0.2 $A.g^{-1}$. A good observed cyclability (< 500 cycles) is in accordance with *in situ* XRD results showing a reversible behavior of the structure during cycling. Another synthesis method, using *Chimie Douce* techniques, leads to nanoparticules for both $HTiNbO_5$ and $Ti_2Nb_2O_9$ and allows an increase of the electrochemical performance of these materials.

Unification of Bulk Storage and Supercapacitive Storage Chuanlian Xiao, Robert Usiskin and Joachim Maier; Max Planck Institute for Solid State Research, Germany

In typical insertion electrodes for batteries, the capacity is determined by bulk storage within the electroactive particles, which is comparatively well investigated and understood. In contrast, supercapacitor electrodes are dominated by interfacial storage at interfaces, which is well addressed experimentally. However the charge carrier chemistry (defect chemistry) especially in the latter case is not taken seriously. Consequently a bridge between the two important fields is absent. Following and extending our quantitative concept of job-sharing storage [1], a generalized description that includes bulk and space charge storage (electrochemical and supercapacitive storage) is possible. In other words the treatment of defect chemistry as a function of the degree of storage as well as of position is key to a unification [2].

The experimental part of our research uses TiO_2 thin films. The precise measurement of the storage capacity of titania films as a function of thickness allows us to deconvolute bulk and interfacial contributions. We discuss the results in terms of bulk and space charge capacitance. The generalized treatment that comprises both contributions shows also how the ratio of both varies with the degree of storage. We expect this work to provide a better understanding of energy and power densities of storage devices which becomes particularly important for nanoionic systems [2].

Supercapacitor Degradation: Understanding the Mechanisms of Cycling-Induced Deterioration and Failure of a Pseudocapacitor Katrina Mazloomian, Hector Lancaster, Chris Howard, Paul Shearing and Tom Miller; University College London, United Kingdom

Supercapacitors (SCs) have generated widespread interest in the field of energy storage because of their unique characteristics of high-power density, good reversibility and rapid rate of charge/discharge.[1] Their degradation, however, has traditionally been overlooked owing to their widely accepted reputation of having a long lifetime and an excellent cycle stability which has hindered the development of high-performance, next-generation systems.

SC degradation has thus far mainly been studied from an impedance perspective and mathematically modeled in numerous RC (resistor-capacitor) circuit configurations.[2–4] Studies such as this, however, do not account for variables such as dynamic voltage fluctuations and other deviations from ideality that inevitably occur in realistic use. More importantly, they do not actually explain why the supercapacitor is degrading; whether through chemical changes, mechanical stress, poor device engineering, or other mechanisms.

In this work, we utilize a multiscale characterization approach that pairs electrochemical analysis with X-ray computed tomography and complimentary spectroscopic, microscopic and diffraction analysis to reveal the modes of degradation in commercial SCs over their full charge/discharge cycle lifetime. Importantly, while the pseudocapacitor system studied was rated for long lifetimes of up to 100,000 cycles, it was found to suffer from extreme degradation linked to severe material degradation at the cathode after only 2000 cycles.

These findings therefore provide new insights into the aging processes of pseudocapacitors and highlight how essential it is to develop an in-depth knowledge of supercapacitor degradation before these devices become even more widely utilized in commercial applications.

Novel Insertion Concepts For Hybrid Electrochemical Capacitors Krzysztof Fic[1,2], Adam Mackowiak[1], Pawel Jezowski[1], Yukiko Matsui[2], Kazunari Soeda[2] and Masashi Ishikawa[2]; [1]Poznan University of Technology, Poland; [2]Kansai University, Japan

The world is looking for the perfect energy storage and conversion system. Two energy storage technologies are currently the most popular - electric double-layer capacitors (EDLCs) and lithium-ion batteries (LIBs). On the one hand, EDLCs cannot (and are not obliged to) compete with Li-based technology in terms of energy density; this feature is quite often sought as the reason for the limited commercialization of EDLCs. On the other hand, LIBs have shorter lifespan and lower power values comparing to EDLCs. Therefore, it seems reasonable to merge both technologies into one compact device, called a hybrid lithium-ion capacitor (LIC). The hybridization of energy storage mechanisms allows for acquiring higher energy density values than EDLCs while maintaining high specific power and a great number of charge/discharge cycles. The major problem occurring during LICs assembling is the pre-lithiation stage. Auxiliary metallic lithium electrode is one of the solutions – in fact, this approach was encouraging; however, after the pre-lithiation process, the metallic lithium electrode should be entirely utilized or removed and become replaced by a carbon electrode. This raises technical and safety issues because the exchange requires an inert environment. Another approach uses composite materials as positive electrodes, allowing full intercalation of lithium into graphite structure.
Nonetheless, after the pre-lithiation process, the dead mass of the composite stays in the system and deteriorates the efficiency. A different method of pre-lithiation using lithium from electrolyte was presented by Beguin et al. In this approach, the main problem identified was the consumption of lithium ions from the electrolyte and the diminished electrolytic conductivity of the solution.

In our work, we propose another concept that allows for full intercalation of the negative electrode without an auxiliary electrode or less-conductive composite on the positive side. In principle, the redox-active lithium salt dissolved in 1 mol L^{-1} $LiPF_6$ in EC:DMC electrolyte served as a charge-balancer. Thus, additional Li^+ in the redox agent structure made the Li^+ concentration in the electrolyte non-affected. Full electrochemical tests, including cyclic voltammetry, galvanostatic charge/discharge and impedance spectroscopy, constant power discharge were carried out. In further studies, optimal LIC operating conditions, i.e., voltage (2.2 – 4.2 V) and current density (0.2 A g^{-1}), were determined. The system has also been compared with commercial products.

Both, redox and non-redox processes occurring on both electrodes were identified. The capacitor's cycle life and the effect of the addition of inorganic salt on the conductivity were also investigated. Furthermore, detailed analysis has been conducted using operando mass spectrometry coupled with gas chromatography, SEM/EDS, XRD, Raman and FTIR spectroscopy.

4:00 PM *EN01.03.02
Roll-to-Roll Electrode Processing Towards the Development of a 100 F Lithium-Ion Capacitor María Arnaiz[1], Maria Canal[1], Daniel Carriazo[1,2], Aitor Villaverde[1] and Jon Ajuria[1]; [1]Centre for Cooperative Research on Alternative Energies (CIC energiGUNE), Basque Research and Technology Alliance (BRTA), Spain; [2]Ikerbasque, Basque Foundation for Science, Spain

Due to the advantage of combining both capacitive and faradaic charge storage mechanisms, lithium-ion capacitors (LICs) are regarded as a promising energy storage technology for many applications requiring high-power and high-energy. However, the lack of an internal source of lithium ions demands a pre-lithiation strategy for the viability of the technology. Many alternatives have shown their potential at the laboratory scale to achieve full pre-lithiation of the device, enhancing both energy and cycle life of the system. Dilithium squarate is one of those candidates. However, certain aspects are relevant to bring those strategies to real life. Thus, we aim to demonstrate this strategy at a pilot line level, by fabricating electrodes incorporating the sacrificial salt by roll-to-roll processing in a semi-automated electrode coater equipment. Moreover, to ensure a good response of the fabricated LICs under high current pulses, reducing the resistance of the cell is of high importance, and optimization of electrode processing becomes crucial at this point. In this work, the relevant aspects of the slurry formulation and roll-to-roll coating parameters of a hard carbon-based negative electrode and an activated carbon-dilithium squarate composite as positive electrode will be described. The different nature of the materials involved in both electrodes require to adapt the viscosity of the slurry, and the coating and drying parameters accordingly to ensure their correct mechanical properties. The quality of the slurry formulations is validated by the absence of agglomerates and appropriate viscosity, while the quality of final electrodes is validated by x-sectional SEM images and peeling tests. To conclude, 100 F multilayer LIC pouch cells have been fabricated. Their electrochemical characterization shows a device with low internal resistance, high capacitance, and good cycle life, confirming the good quality of the electrodes fabricated by means of roll-to-roll process.

4:30 PM EN01.03.03
An Oxygen-Rich Porous Carbon Cathode for Zinc-Ion Capacitors Jian Yin, Wenli Zhang and Husam N. Alshareef; King Abdullah University of Science and Technology, Saudi Arabia

Aqueous electrochemical zinc ion capacitors (ZICs) are promising next-generation energy storage devices based on their battery-capacitor intermediate energy densities, superior cycling stability, high safety, and inexpensive raw materials. Zn is an identical anode for aqueous energy storage systems for a high theoretical gravimetric capacity of 823 mAh g^{-1} and a low redox potential of −0.76 V (vs standard hydrogen electrode). Compared with the battery-type Zn anodes, the capacitive-type porous carbon cathode shows low capacitances. Developing porous carbon cathodes with high capacitances are required to achieve the high energy densities of ZICs. Herein, an oxygen-rich porous carbon cathode is proposed for ZICs with a high capacitance contributed by pseudocapacitances of hydrogen adsorption and oxygen redox reaction. The hydrogen adsorption capacity contribution is maximized by enlarging the working potential window with an optimized electrolyte. The oxygen pseudocapacitance is enhanced by a molecular-level oxygen doping strategy.

The oxygen-rich porous carbon was prepared from the direct pyrolysis of pyromellitic acid tetra-potassium salt. An optimized 3 mol L^{-1} $Zn(ClO_4)_2$ electrolyte is used to achieve a wide working potential window of 0-2.4 V. By enlarging the working window from 0.5-1.5 V to 0-1.9 V, two redox reactions show up on the porous carbon cathode, which is different from previous pure EDLC behavior. Two redox reactions are identified as reversible hydrogen adsorption during discharge and oxygen redox reactions during charge processes by studying the ex-situ characterizations. As capacitance is a synergic effect of EDLC and pseudocapacitance, we achieve an optimized porous carbon cathode by exploring the function of carbonization temperatures on the specific capacitances. The assembled ZIC delivers a high capacitance of 340.7 F g^{-1}, an energy density of 104.8 Wh kg^{-1}, and a power density of 48.8 kW kg^{-1}. For full cell assembly, we develop an interlayer coating strategy to prevent dendrite growth and achieve a stable cycling performance over 30,000 cycles. The viability of the pouch cell is verified by a high areal capacity of 4.7 mAh cm^{-2} at 6 mA cm^{-2} using a high mass loading of 0.96 g of the cathode.

4:45 PM EN01.03.04
Pseudocapacitive Energy Storage in $Ti_3C_2T_x$ MXene in a Wide Temperature Range Ruocun (John) Wang[1,2], Mark Anayee[1,2], Teng Zhang[1,2] and Yury Gogotsi[1,2]; [1]A.J. Drexel Nanomaterials Institute, United States; [2]Drexel University, United States

Pseudocapacitors have the potential to achieve high energy and high power density simultaneously, a holy grail for electrochemical energy storage. However, one obstacle facing pseudocapacitors is their shorter lifetime compared to commercial supercapacitors using the double-layer charge storage mechanism. In MXene-based pseudocapacitors, this concern is pronounced particularly at high temperatures due to the limited stability of the active material in contact with aqueous solutions, which can lead to oxidation and hydrolysis. This work shows that $Ti_3C_2T_x$ MXene thin-film electrodes in 5 M H_2SO_4 possess excellent rate capabilities from -50 °C to 70 °C but also a sufficient lifetime at 70 °C using a float test holding at -0.9 V vs. Hg/Hg_2SO_4 reference electrode. Post-mortem characterization using X-ray photoelectron spectroscopy, Raman spectroscopy, and scanning electron microscopy with energy dispersive X-ray spectroscopy showed no signs of oxidation in the bulk of the film. This work suggests sufficient electrochemical stability of $Ti_3C_2T_x$ MXene as a negative electrode in protic aqueous electrolytes across a wide temperature range, making it promising for pseudocapacitor energy storage.

Facile Synthesis Route of Various Porous Transition Metal Hydroxides for Pseudocapacitor using Poly(4-vinyl pyridine) Gyeongwon Ha and Jinkon Kim; Pohang University of Science and Technology, Korea (the Republic of)

Transition metal hydroxides are widely used in electrochemical fields because of their low cost and many advantages. In particular, porous transition metal hydroxides are attracting attention because their large surface area compensates for the disadvantage of poor electrical conductivity. Herein, we suggest facile synthesis of porous transition metal hydroxide using poly(4-vinyl pyridine) (P4VP) homopolymer by polymer-precursor method. To synthesis the metal hydroxide, we used a cyanide metal precursor present in the form of a metal hydroxide anion in an aqueous solution and coordinated it with P4VP. However, the cyanide precursor prevents the protonation of P4VP because it makes the aqueous solution basic. Therefore, in order to maintain the pH so that P4VP can be sufficiently protonated, a buffer solution that pH is not easily changed by the external environment was used. At the same time, porous transition metal hydroxide can be obtained when P4VP film was immersed in a precursor-buffer solution by inducing a nanoscale phase separation and by selective removing of P4VP through O_2 RIE. Using this prepared porous transition metal hydroxides, we compared pseudocapacitive properties of the fabricated structures depending on pH of solution. As a result, the porous metal hydroxide structure with the best efficiency among them showed satisfactory specific capacitance without optimization.

Ionic-liquid Gated Electrochemical Carbon Nanotube Transistor with High On-Off Ratio for Gas Sensing Peisheng He[1,2], Alexander Abelson[2], Jenny Zhou[2], Steven F. Buchsbaum[2], Liwei Lin[1] and Eric R. Meshot[2]; [1]University of California, Berkeley, United States; [2]Lawrence Livermore National Laboratory, United States

Carbon nanotubes (CNTs) hold great promise as gas sensing platform due to their large surface area-to-volume ratio for applications ranging from environmental to disease diagnostics. Notably, extremely low detection limit (ppb range) and room temperature operation has been realized for various gas molecules with semiconducting single-walled CNTs (SWCNTs)-based field-effect transistors. However, intrinsic CNT suffers from poor selectivity and thus functionalization with chemical selectors is required. To this end, we proposed a SWCNT-based field-effect transistor with ionic liquids (ILs) as both gating electrolyte and chemical functionalization layer for selective gas sensing. Replacing gate dielectrics in conventional transistors, ILs enable efficient gating of channel by forming an ultra-thin electric double layer (EDL) around the SWCNTs at low voltage, without restricting access to the CNT surface for analyte detection. Meanwhile, ILs are highly attractive chemical selectors for gas sensing since their chemical functions, such as gas solubility/selectivity and affinity for water, are variable depending on the combination of the cations and anions. In addition, ILs exhibit good environmental durability due to non-volatile behavior, wide electrochemical potential, and temperature stability. We have fabricated electrolyte-gated CNT transistors coated with different ILs. High on/off ratio (10^6~10^7) has been achieved with low operation voltage (gate voltage ~1V). Transfer characteristics were studied under various gases (N_2, O_2, NH_3, etc.) exhibiting different response, which could open up new avenues toward miniaturized electronic noses with high sensitivity and selectivity, while the material selection of CNTs and ILs is compatible with future flexible device integration.

5:00 PM EN01.04.04
Synthesis and Characteristics of CNT Grown Activated Carbon Using Ni Catalyst and Melamine to Prepare High Performance Flow-Electrode Dong Gyeong Kim, Donghyun Kim, Haeun Seo, Hyeryang Choi, Haeun Kim and SeungCheol Yang; Changwon National University, Korea (the Republic of)

Flow-electrode capacitive mixing (F-CapMix) is novel renewable energy technology generating electricity by using salinity difference between salt water and fresh water and ion adsorption/desorption on active materials in flow-electrode. To enhance performance of F-CapMix, charge percolation and electron transfer between active materials in the flow-electrode should be improved. In present work, we synthesized carbon nanotube (CNT) grown activated carbon (AC) for achieving efficient charge percolation and electron transport between AC particles in the flow-electrode. For this work, AC particles were impregnated with the solution including Ni catalyst. After filtering of AC suspension, wet AC particles was heat-treated under an inert condition at 300 celsius to form Ni seed on the surface of AC particles. After that, melamine was mixed with the AC particles, and heat treatment of the mixture was carried out under reduction condition at 700 celsius. Through SEM analysis, it was confirmed that CNTs on the surface of AC particles were successfully grown. The synthesized CNT grown AC was additionally analyzed with various tools, such as XPS, Raman, etc. We will evaluate F-CapMix performance with the flow-electrode made by using the CNT grown AC.

5:00 PM EN01.04.05
Thermal Modeling of a Supercapacitor Based on Calorimetric Measurement Chee-Burm Shin and Dongcheul Lee; Ajou University, Korea (the Republic of)

Supercapacitors have the potential to meet the high pulse power capability of the energy-storage systems for automotive applications. In the high pulse power operations for automotive applications, a large amount of heat is produced inside a supercapacitor cell. Because the lifetime and performance of a supercapacitor depend strongly on temperature, it is important to accurately predict the thermal behaviors of a supercapacitor for its efficient and reliable system integration from an application perspective. Modeling of the thermal behaviors of a supercapacitor can serve a valuable role when optimizing the design of future cells and the thermal management system for automotive applications.
In this work, the rate of heat generation of the supercapacitor cell during charge and discharge is measured with a large, custom-made calorimeter, because most commercial calorimeters are manufactured for testing small cells. Then, based on this measurement data, a three-dimensional modeling is carried-out to investigate the effects of the operating and ambient conditions on the thermal behavior of a 2.7 V/3500 F supercapacitor cell for a 42-V automotive electrical system. The results show that the temperature of the supercapacitor cell increases during the first 50 cycles after which it reaches a periodic steady-state value that increases with increasing ambient temperature.

5:00 PM EN01.04.06
Electrical Performance of MnO_2-Biochar Composite Electrodes as a Function of Initial Biochar Concentration Thomas Sadowski[1,2], Max Martone[1,2], Vanessa Adamski[1,2], Kaleb Roman[1,2], Jules Scanley[1,2], Rahul Singhal[3,2] and Christine Broadbridge[1,2]; [1]Southern Connecticut State University, United States; [2]Connecticut State Colleges and Universities Center for Nanotechnology, United States; [3]Central Connecticut State University, United States

The demand to diversify the global energy portfolio to include more renewable sources has illustrated an acute and critical need for advancements in energy storage technology to mediate their inherent intermittent nature. Hybrid supercapacitors offer such a solution for a wide range of commercial and infrastructural energy applications, with great potential for fabrication utilizing cost-effective and environmentally benign materials. Previous studies have identified electrodes composed of biochar alongside MnO_2 (for non-Faradaic and Faradaic charge storage, respectively) as great potential candidates that fit this sustainability-driven profile. In this study, the performance of pine-based biochar-MnO_2 hybrid electrodes, synthesized via a one-pot method of varying initial biochar concentrations, was investigated. The electrode surface area was quantified by BET surface analysis and the structure and composition using x-ray diffraction. The supercapacitive performances were investigated using cyclic voltammetry ranging from 3-200 mVs^{-1} as well as galvanostatic charge-discharge tests at 0.5, 1.0, and 2.0 A/g. This data along with scanning and transmission electron microscopy data provide preliminary insights on the structure-property-performance relationship for this composite materials system.

5:00 PM EN01.04.07
Hybrid Microsupercapacitor based on $Ti_3C_2T_x$ Mxene and Covalent Organic Frameworks Yusuf Khan, Jehad K. El-Demellawi, Yongjiu Lei, Vinayak S. Kale, Osama Shekhah, Mohamed Eddaoudi and Husam N. Alshareef; King Abdullah University of Science and Technology, Saudi Arabia

The construction of flexible, portable, and in-plane hybrid micro-supercapacitors has high demand in emerging electronic applications like energy storage, sensors, and portable devices. Here we report an in-plane hybrid supercapacitor based on a covalent organic framework as a positive electrode and $Ti_3C_2T_x$ Mxene as a negative electrode. Both these two different electrode materials are deposited on three-dimensional laser-scribed graphene current collectors fabricated by a laser-based process. The designed hybrid supercapacitor achieved promising initial electrochemical performance because of the two-dimensional Mxene and periodic porous COF, whose structures provide better active sites for charge storage and favorable ions movement. The prepared hybrid supercapacitor shows a high areal capacitance of 110 mF/cm^2, a wide potential window of 1.5 V with an energy density of 34.4 mWh/cm^2. Further optimization of the materials and devices is ongoing. The results so far seem encouraging for utilizing such devices in miniaturized energy storage devices and sensors.

5:00 PM EN01.04.08
Titanium Oxynitride Thin Films and Nanowires for Ultra-High Capacitance Supercapacitor Applications Panupong Jaipan[1], Schuyler Shi[2], Ram K. Gupta[3], David A. Muller[2] and Dhananjay Kumar[1]; [1]North Carolina Agricultural and Technical State University, United States; [2]Cornell University, United States; [3]Pittsburg State University, United States

The present research is aimed at the development of titanium-based transition metal oxynitrides, TiN_xO_y (TiNO), for electrochemical supercapacitor and solar water-splitting applications. The advantages of TiNO over other transition metal oxides are associated with the less electronegative and more polarizable characteristics of nitrogen relative to that of oxygen. The synthesis of high-quality multifunctional 2-dimensional (2D) TiNO thin films and 1-dimensional (1D) TiNO nanowires has been accomplished using a non-clean room-specific pulsed laser deposition method. The electrochemical supercapacitor measurements on the TiNO system using cyclic voltammetry have shown that the specific capacitance values for the TiNO nanowire samples (2,725 $mF.cm^{-2}$) are nearly six times more than that of the TiNO thin film samples (400 $mF.cm^{-2}$). The supercapacitor values are amongst the highest values reported for the recently top-tier nanoscale electrode materials. Furthermore, due to the pseudocapacitive-type behavior, the charge-ion transfer in the TiNO nanowire system is more rapid than in electrical double-layer capacitor-behavior materials. Therefore, TiNO nanowires have a high potential for usage as electrode material in lithium-ion batteries, enhancing the anode's conductivity in diverse phases of the charge-discharge cycle and the capacity of a battery with a larger specific capacitance.

5:00 PM EN01.04.09
Long-Lifespan Anode-Free Lithium Metal Batteries by Ag/Conjugated Polymer Wetting Agent Inducing Interfacial Fluorination Seonmi Pyo, Jinil Cho, Heejun Yun, Heebae Kim and Youn Sang Kim; Seoul National Unive, Korea (the Republic of)

Li metal batteries (LMBs) have emerged as a promising energy storage technology for high-energy-density rechargeable batteries. Since the Li metal anode (LMA) has an ultrahigh theoretical specific capacity (3862 mAh g^{-1}) and the lowest negative electrochemical potential (-3.040 V vs. SHE), its employment ensures higher energy density beyond commercial Li-ion batteries (LIBs) with the limited energy density of less than 250 Wh kg^{-1} at the cell level. In this

respect, anode-free LMBs (AFLMBs) with no Li excess is considered the ultimate system to achieve a dramatic increase in energy density (>500 Wh kg^{-1}), in which all the active Li sources are stored in a fully lithiated cathode. In addition, the anode-free design significantly reduces cost and simplifies the manufacturing process compared with traditional LMBs. However, LMA suffers from low coulombic efficiency (CE), rapid capacity fading, and safety hazards, which come from the Li dendrite growth and continuous formation and breakage of solid electrolyte interphase (SEI) during Li plating/stripping processes. Therefore, such uncontrollable interfacial reactions should be seriously addressed, especially in AFLMBs without excess Li inventory to compensate for the loss of active Li sources. Recently, many strategies have been reported to control the interfacial chemistry between Li and electrolyte as well as between Li and current collector (i.e. modification of current collector, electrolyte design, optimization of cycling protocols). Among them, studies about employing lithiopilic wetting agents on the current collector confirm an effective way to stabilize Li plating behavior, which can achieve a favorable life span. In particular, wetting agents show outstanding effects on guiding homogeneous Li deposition and thus suppressing dendritic Li growth by lowering the Li nucleation barrier. However, the critical problem of sequentially irreversible capacity loss before a stable SEI formation still remains, which is a fatal obstacle in no excess Li cells.
Herein, we introduced Ag nanoparticles incorporated p-doped conjugated polymer (Ag-PCP) wetting agent simultaneously to regulate the Li nucleation and promote a rapid stabilization of SEI at the early stage, and further prolong the life span of AFLMBs. Furthermore, we investigate interfacial fluorinated mechanism of the Ag-PCP chains to efficiently control SEI chemistry related to the LiF formation. The Ag-PCP wetting agent is fabricated by a simple one-step synthesis because of the electrostatic interaction between oppositely charged Ag cation and dopant. Critically, the PCP chain with the delocalized π-electron system induces an interfacial fluorinated reaction with F anions derived from TFSI$^-$ decomposition, and thus the F-doped PCP promotes the formation of LiF-rich SEI. Also, the presence of lithiophilic Ag nanoparticles on the PCP wetting agent act as both Li nucleation seeds and polymer chain modifiers about the structural rearrangement and closer packing of the Ag-PCP chains, thus providing both uniform Li nucleation and continuous conductive channel, resulting in an increase of LiF ratio in the SEI. The LiF-rich SEI facilitates Li ion diffusion, which effectively suppresses the Li dendrite growth and the depletion of the Li reservoir. Benefiting from the synergistic effect Ag-Li alloying process and interfacial fluorination, the Ag-PCP wetting agent optimizes Li deposition behavior and a favorable SEI chemistry, leading to superior cycling performances. Consequently, the Ag-PCP/Cu half-cell shows quite stable voltage profiles with low polarization (≈17 mV) over 300 cycles, even at a high current density/areal capacity of 3mA cm^{-2}/3mAh cm^{-2}. Moreover, the anode-free $LiFePO_4$ (LFP) full cell achieves superior cycling stability with a high capacity retention of 72% (Li inventory retention rate 99.8%) at 1C-rate after 200 cycles. This strategy contributes to the applicability of interfacial stabilization for long-life AFLMBs.

SESSION EN01.05: Pseudocapacitive and High Power Battery Electrodes

Identifying New Directions for Pseudocapacitive Materials Bruce S. Dunn[1], Patricia McNeil[1], Bintao Hu[1] and Qiulong Wei[2,1]; [1]University of California, Los Angeles, United States; [2]Xiamen University, China

The prospect of developing energy storage materials with the energy density of batteries and the power density and cycle life of electrical double-layer capacitors is an exciting direction which is of great interest for mobile power applications. To achieve these properties, our research has focused on pseudocapacitive materials in which ion insertion induces reversible redox reactions at or near the surface of an electrode material. For the most part, studies on pseudocapacitive materials have focused on crystalline solids where crystallographic pathways, such as open channels or sparsely occupied planes, lead to high ion mobility. Although amorphous materials may not have long-range crystallographic considerations, they do offer other interesting features such as a more open framework which can enable percolation pathways and facilitate ion transport. Our studies on sodium-ion insertion into amorphous VO_2 (a-VO_2) showed that the charge storage properties of the amorphous material were significantly better than the crystalline counterpart. The present paper reviews our recent work on amorphous systems and underscores their promise as energy storage materials. Our studies on lithium-ion insertion into reduced amorphous transition metal oxides, a-WO_2 and a-MoO_2, show that these materials exhibit box-like cyclic voltammograms and linear galvanostatic profiles. This voltage profile is reminiscent of an electrical double layer capacitor, except that with a-WO_2 and a-MoO_2, there are redox reactions which increase the specific capacity significantly. Our initial studies indicate that a-WO_2 exhibits 120 mAh/g (1-electron redox) while a-MoO_2 supports 1.3 electron redox, leading to over 280 mAh/g. A related direction has involved the effect of nanostructuring. In this study, the sodiation of nanoparticles of anatase TiO_2 produces amorphous layers of 3 to 5 nm thick. As a result, 10 nm particles of TiO_2 become completely amorphous and exhibit pseudocapacitive signatures as redox reactions occur throughout the particle. These materials exhibit specific capacities for sodium which are on the order of 200 mAh/g at high rates. Taken together, these studies suggest that short-range order should be considered a key factor in achieving charge storage.

9:00 AM *EN01.05.02
Boosting the Pseudocapacitive Behavior of MnO_2 with a Pinch on PGM Oxides Wataru Sugimoto[1], Yuta Takemura[1], Ryota Saito[1], Annga Hermawan[1], Keisuke Muramatsu[1], Daisuke Takimoto[2] and Sho Hideshima[3]; [1]Shinshu University, Japan; [2]University of the Ryukus, Japan; [3]Tokyo City University, Japan

Various polymorphs and morphologies of manganese dioxide and related materials have been studied as pseudocapacitive materials for aqueous supercapacitors. While the surface and near surface-confied redox processes affords high specific activity, a fairly large amount of conducting additive, typically 30 to 50 wt% acetylene black, needs to be added in order to achieve high rate charge storage. Since the conducting additive is characterized by low surface area and electrochemical inertness, the carbon additive generally does not contribute much to the specific capacitance, leading to decrease in total energy density of the cell in terms of both mass and volume. Polymeric binders such as PTFE and PVdF are also necessary to fabricate rigid electrodes with good contact.
As an alternative to these typical conductive binders and polymer binders, we have studied the possibility of using RuO_2 nanosheets as a novel inorganic binder with both high electronic conductivity and polymeric properties and excellent pseudocapacitive properties. RuO_2 nanosheets are highly conductive (comparable to activated carbon), possess characteristics as macroanion, are extremely stable within the water electrolysis potential, and shows high redox activity.
As an example, the effect of adding a small amount of RuO_2 nanosheets to MnO_2 particles (primary particle size ~200 nm) was studied.[1] A large synergetic effect was observed where the specific capacitance per MnO_2 mass exhibited a maximum value at low content; i.e. x=10-20, or 10-20 mol% of RuO_2. The increase in the specific capacitance is suggested to be associated with the decrease in charge transfer resistance of MnO_2 as a result of the RuO_2 nanosheets sufficiently working as a conductive additive to MnO_2. The amount of RuO_2 in terms of mass is 13 wt% for x=20, which is much lower than the amount generally used for conductive carbon additives despite the much higher formula weight of RuO_2 (133.07 g mol^{-1}) compared to carbon (12.01 g mol^{-1}). As

another example, the case of an all nanosheet (ns) composite, MnO_2(ns)-RuO_2(ns), with different electrode mass loading was studied. At low mass loading the conducitivy is sufficient enough so only a small synergetic effect is observed. However at high mass loadings, RuO_2(ns) acts as an active binder similar to the case of MnO_2 particles. The difference in nanoparticles versus nanosheets will also be discussed in detail in the presentation.
In another case, the effect of doping birnessite MnO2 with Ir was studied by synthesizing a new solid solution $K_{0.2}(Mn,Ir)O_2.xH_2O$.[2] Two important effects of Ir doping was found. First, the overall capacitance increased from 37 F g^{-1} for pristine birnessite to 64 F g^{-1} for 10% Ir doped birnessite, which is due to the increase in the Mn^{4+}/Mn^{3+} redox-related charge. Second, a decrease in peak-to-peak difference was observed, which indicates an improvement in the charge-transfer kinetics with Ir substitution. This uncommon behavior is attributed to a strong electronic interaction between the host Mn ion and the dopant Ir ion.

9:30 AM EN01.05.03
The Role of Defects Created by Implanted Ions on the Electrochemical Behavior of Pseudocapacitive Thin Film Electrodes Etienne Le Calvez[1], Allan Lebreton[1], Bukola Jolayemi[2], Jérémy Barbé[1], Camille Douard[1], Olivier Crosnier[1], Dmitri Yarekha[2], Kevin Robert[2], Gaetan Buvat[2], Pascal Roussel[3], Christophe Lethien[2] and Thierry Brousse[1]; [1]Nantes Université/CNRS, France; [2]IEMN, France; [3]UCCS, France

The pseudocapacitive behavior of RuO_2 electrode was initially described as a peculiar behavior in $HClO_4$ aqueous electrolyte. Since then, pseudocapacitive materials have been the topic of extensive investigations. Their rectangular shape cyclic voltammograms (CVs) are the signature of capacitive-like electrochemical behavior due to specific fast and reversible Faradaic surface and sub-surface reactions as it has also been demonstrated for MnO_2, $MnFe_2O_4$, $FeWO_4$ or VN electrodes among others. Experimental evidences plead for charge transfer at the surface of the active material particles involving transition metal redox couples. Many parameters seem to influence the extend of charge storage in pseudocapacitive electrodes: the amount of electroactive cations in the pristine material, the structural defects such as vacancies, the specific surface area, the particle size and shape, and many more, which makes it difficult to determine their individual influence. One way to overcome the presence of intrinsic defects in pseudocapacitive materials is to intentionally introduce them. This can be done by several means, including the use of ion implantation. The amount and nature od introduced defects can be tuned by playing on the dose of implanted ions and the implantation energy. Although such technique is common in microelectronic, it has rarely been applied to electrode materials for supercapacitors.
In this communication, different pseudocapacitive materials were deposited as thin films and further implanted with different cations using different energies. Some clues about the influence of the defects introduced upon ions implantation will be given with regards to microstructural/structural/electrochemical changes. Such investigation technique opens the way for unveiling the role of defects on the charge storage mechanism of pseudocapacitive materials.

9:45 AM EN01.05.04
Pseudocapacitive Responses for Systems with Two Transition Metals—$M_3Nb_2O_{14}$ (M = Mo, W) Bronze Phase Materials Yunkai Luo[1], Etienne Le Calvez[2], Yucheng Zhou[1], Eric Gautron[2], Eric Quarez[2], Molleigh Preefer[3], Olivier Crosnier[2], Johanna N. Weker[3], Laurent Pilon[1], Thierry Brousse[2] and Bruce S. Dunn[1]; [1]University of California, Los Angeles, United States; [2]Nantes Université, France; [3]SLAC National Accelerator Laboratory, United States

Recently, bronze phase materials have gained attention as high-rate lithium-ion battery anode materials. Their large tunnels and open framework are attractive for lithium-ion diffusion and high-rate performance, while the presence of two transition metals, such as W and Nb, provide a means to achieve high energy density from multi-electron redox. In this paper we report on the structure and electrochemical properties of two different bronze phase compositions having the same stoichiometry: $W_3Nb_2O_{14}$ and $Mo_3Nb_2O_{14}$. It is significant to note that both bronze phase materials exhibit pseudocapacitive characteristics. This includes a box-like characteristic in cyclic voltammetry (CV) experiments and nearly linear voltage-capacity curves from galvanostatic (GV) experiments. The CV results for $W_3Nb_2O_{14}$ were used to determine the b-value from the relationship between current (I) and sweep rate (v):= ab^v The peak located around 2.1V versus Li/Li+ shows a value of 0.85 and the peak around 1.7V vs Li/Li+ shows value of 0.95, which suggests a surface-controlled redox reaction. XPS measurements indicate that both transition metals are undergoing redox reactions. The lithium capacity for the $W_3Nb_2O_{14}$ bronze phase at C/5 is the theoretical value of 139 mAh/g corresponding to a 5 electrons redox process. In contrast to the stable behavior of $W_3Nb_2O_{14}$ bronze, the $Mo_3Nb_2O_{14}$ bronze phase undergoes an irreversible structural rearrangement upon cycling. Although the CV is initially box-like, the CV permanently becomes a broad peak shape when the scan rate is above 0.5mV/s. $Mo_3Nb_2O_{14}$ exhibits 220 mAh/g at C/5 and thus achieves multi-electron redox (1 Li per transition metal = 192mAh/g), but the capacity retention is worse than that of $W_3Nb_2O_{14}$. The change in CV shape is attributed to an irreversible structural rearrangement. XPS measurements indicate that although the Nb returns to the 5+ state on oxidation, the Mo oxidation state does not return to 6+, suggesting that lithium is trapped in the structure and leads to increased overpotential during cycling. Our results indicate that pseudocapacitive behavior is not limited to systems with a single transition metal ion. The results for both $W_3Nb_2O_{14}$ and $Mo_3Nb_2O_{14}$ bronzes show that pseudocapacitive responses can be achieved in systems where two transition metal ions undergo redox reactions.

Fast and High Capacitive Electrode Materials for Asymmetric Supercapacitors Masashi Ishikawa; Kansai University, Japan

Lithium ion capacitors (LICs) are unique energy storage devices that combine the high power technology of conventional EDLCs with the high energy density characteristics of lithium ion batteries. An important technology in LICs is lithium pre-dope to a carbon negative electrode (NE), but how the depth of charge by pre-dope affects the charging and discharging performance of LICs is not well understood so far. In this study, pitch-coated graphite (PCG), which suppresses self-discharge, was used as NE. Noting that PCG has several stage structures, the objective of this study is to investigate the effects of NE utilization conditions (utilization stages and cycle utilization capacity) on the cycling behavior of LICs. In other words, we will report the effect of different utilizing stages with controlled depth of charge by pre-doping on the cycle behavior.
A four-terminal aluminum laminate cell was used with activated carbon as the positive electrode material, PCG as NE, Li metal foil as the counter electrode and reference electrode for pre-doping, and 1.2 M $LiPF_6$ /EC : PC : DEC (3 : 1 : 4 v/v/v) as the electrolyte. Pre-doping and cycling tests were performed according to planned negative electrode utilization conditions. Pre-doping was performed up to a certain utilizing stage in a high-temperature environment, and the cycle test was conducted at room temperature for 500 cycles under constant current conditions at 5C.
First, we found that the smaller the cycle capacity, the more stable the cycle behavior is, and that there is obvious Li loss in the early cycles, which does not affect the cycle stability regardless of the NE utilization conditions. We observed the change in electrode potential (potential swing) for three cycle test conditions with a cycle capacity range of 150 mAh g^{-1} at different utilizing stages. When the cycling is centered on “dilute stage II”, the utilization stage shifts to a shallower direction with cycling, and the NE potential increases and degrades. It is considered that Li is continuously lost from the NE during cycling. When we utilize “stage II” as the utilizing stage, compared to the previous result, the NE potential does not change with cycling and shows stable cycling behavior. When we utilize “stage I”, although there is a concern about an increase in the resistance of the NE because the electrode potential falls

below 0 V vs. Li / Li$^+$ during charging, the cycle behavior looks stable. From these results, we considere that the utilizing stage has a significant impact on the cycle characteristics. Based on the above, we will extensively discuss the influence of the utilizing stage on the cycle behavior.

Metal-Phosphates-Based Materials for Hybrid Supercapacitors Qiang Fu and Sonia Dsoke; Karlsruhe Institute of Technology, Germany

Battery materials provide higher capacity than double-layer ones. However, most part of high-capacity materials suffers from intrinsic kinetics problems, due to phase transitions, slow solid diffusion and low electronic conductivity, which makes them often unsuitable for high-power devices [1]. Some of the strategies to improve the kinetics are to coat the particles with a thin carbon layer (to enhance the electronic conductivity), to reduce the particles (to shorten the solid ionic diffusion) or to tune the structure by metal doping with the aim of suppressing phase transitions [2, 3].
Metal phosphates, with the advantages of abundance, environmental friendliness and low cost are emerging as promising faradaic electrode materials. Herein we will present strategies to convert the battery-like features of materials such as $M_3V_2(PO_4)_3$ (M=Li, Na, K) to pseudocapacitive-like ones by suppressing their phase transitions [4].

Towards Flexible and Ultra-Stable Pseudo-Supercapacitors based on Nanocomposite "Silicon Nanowires/Nanometric Alumina/Conducting Polymer" Marc Dietrich[1], Pascal Gentile[1], Mathieu Deschanel[2], Cristina Iojoiu[3], Fannie Alloin[3] and Said Sadki[2]; [1]CEA Grenoble, France; [2]UGA, France; [3]CNRS, France

With the increase in the use of embedded wearable technologies: the pseudo-capacitive storage, or asymmetric systems, flexible all-solid state supercapacitors raised considerable attention in recent years with their many advantages and ease of use, including the ability to have systems that are small in size, light in weight, easy to handle and usable over wide temperature ranges.
In this context, we realized high-performance electrochemical energy storage microdevices based on nanocomposites electrodes (silicon nanowires / nanometric dielectric / conductive polymer or transition metal oxide) within aqueous electrolyte and all-solid electrolyte. This processed nanocomposite electrode is a major improvement in energy density and durability of devices: that becomes possible thanks to the Atomic Layer Deposition (ALD) technique and the homogeneous growth of Alumina layers [1, 2]. The nanocomposite is realised in three successive steps:
i) Doped Silicon nanowires (SiNWs) growth by Chemical Vapor Deposition (CVD) through a Vapor-Liquid-Solid (VLS) process [3-4].
ii) Deposition of a 3nm nanometric alumina layer deposited by ALD to chemically protect[5].
iii) Conductive Polymers coating to add a new faradic energy storage mechanism to our capacitive system, deposited (PEDOT-PSS) by drop-casting on the SiNWs, or by electropolymerization of EDOT directly on the nanostructures [6,7].
With SiNWs and nanometric (3-5 nm) layers of alumina, we obtained cyclability greater than 2 million cycles and retentions of capacities close to 100%. With the nanocomposite electrodes (SiNWs / Al_2O_3 / Conductive Polymers), the gravimetric performances proved to be excellent with a loan capacity retention of 95% over 500 000 cycles for an initial gravimetric capacity 8.5 F.g^{-1} and 11 mF.cm^{-2} and specific energies and powers of 8.2 mJ.cm^{-2} and of 4.1 mW.cm^{-2}. Such cycling stability for a polymer-based nanocomposite in aqueous media combined with first-order electrochemical storage performance is unprecedented in the literature [6]. We used also second way to deposit conductive polymer on our nanostructures, by electropolymerization in aqueous media of EDOT monomers, using micellar media and forming small aggregates targeted on our SiNWs, exhibiting a capacitance of 4.75 mF.cm^{-2}. For these flexible applications, we changed our standard substrates (silicon <111>) for growing SiNWs on carbon fiber cloth or carbon felts. For our all-solid component, we use a polymer electrolyte. Our solid-state electrolyte was obtained by bi-functionalization on polysiloxane with trimethylammonium and a crosslinkable function, i.e. methyldiallylammonium groups. The crosslinking is done in-situ by heating the sandwich device at 80° C for 48 hours. The good interface property between the polymer electrolyte and the protected SiNWs allows a very long cycling stability for a cell potential of 3 V, that was observed with galvanostatic cycling of the device.

1:30 PM PANEL DISCUSSION

2:00 PM *EN01.06.02

On the Use of Protic Ionic Liquids as Electrolytes for RuO_2 Microsupercapacitors Dominic Rochefort[1], Jensheer Shamsudeen Seenath[1,2] and David Pech[2]; [1]University of Montreal, Canada; [2]Centre National de la Recherche Scientifique, France

Ionic liquids are very appealing electrolytes for electrochemical capacitors. Being organic molecules in nature (at least for the vast majority), they offer immense possibilities for structural modifications to adjust their properties (viscosity, electrochemical stability window, melting point, etc.) or to add a functionality to do chemical reactions. With a careful design, such modifications can be made while keeping the original properties of the ionic liquid which make them attractive as functional electrolytes to improve energy storage devices.

Protic ionic liquids (PIL) are obtained by the proton transfer reaction between Bronsted acids and bases to generate the cations and anions of the ionic liquid. In contrast, aprotic ionic liquids like those based on imidazolium, pyrrolidinium and ammonium cations are formed by the quaternization of a nitrogen by alkylation. As a result, PIL are often less viscous since, for an equivalent structure, the N-H leads to fewer interactions than a N-alkyl. This, combined to straightforward synthesis, explain the interest in PIL. PIL can also be seen as functional ILs when considering their ability to exchange protons with an electrode material, allowing to carry out proton-coupled reactions that are usually restricted to aqueous electrolytes. Relevant to this presentation is their ability to transfer protons with metal oxide electrodes for pseusocapacitive energy storage. The focus of this contribution will be on the use of the protic ionic liquid triethylammonium bis(trifluoromethanesulfonyl)imide (TEAH-TFSI) to improve the energy density of RuO_2 microsupercapacitors. These electrochemical capacitors are fabricated by photolithography and are expected to find application in microelectronic devices to power sensors and data transmission for the Internet-of-Things. This first demonstration of the use of PILs for metal oxides microsupercapacitors showed an extended cell voltage up to 2 V with an energy density 4 times higher than what was obtained in a conventional H_2SO_4 electrolyte. The presentation will include results with several other PIL and propose approaches to improve cycling stability using PIL-based ionogels.

Lignin Activated Carbon and Green Electrolyte as Sustainable Components for EDLCs Devices Elisabetta Petri, Monica Giovannucci, Federico Poli, Alessandro Brilloni and Francesca Soavi; Alma Mater Studiorum University of Bologna, Italy

Activated carbon-based Electrical double-layer capacitors (EDLCs) are the preferential choice given their unique combination of chemical inertia, electrochemical stability, conductivity, and specific surface area, together with the possibility to highly tune the textural properties of these materials in terms of surface moieties and pores size distributions [1]. To improve sustainability and reduce CO_2 footprint of the production of activated carbons, the pyrolysis of real bio-waste derived from local resources enables their valorization as well as the disengaging from fossil-derived resources.
For practical purposes, to enable an effective scale-up, biomass sources must be abundant and cheap [2]. Lignin stands out because it is the third most abundant natural polymer and one of the major wastes of anaerobic digestion processes and pulp and paper making industries [3]. The exponentially growing market of Electrical double-layer capacitors (EDLCs) requires the substitution of flammable, volatile, and toxic electrolytes with less dangerous and sustainable ones. The main limitation which is hindering the promises held by aqueous electrolytes is the low maximum cell voltage if compared to the organic ones. Therefore, the investigation of novel green electrolytes, such as DES and WiSE [4, 5], featuring an improved stability window compared to conventional aqueous electrolytes is critical to increasing the energy density of aqueous-based EDLCs.

Here we report a systematic study to scale up the production of Lignin Activated Carbon (LAC) generated by a one-step carbonization route starting from a real lignin waste, using $KHCO_3$ as a mild activating agent [3]. Different process pathways have been explored and the effect of the process parameter on the textural and chemical-physical and electrochemical properties of the activated carbon are analyzed and discussed.
Moreover, the optimized upscaled LAC produced and novel green electrolyte, have been exploited to produce an electrochemical characterize lab-scale EDLCs prototypes featuring 1.7 V of maximum cell voltage.

Acetate-based Water-in-Salt Electrolytes for Electrochemical Energy Storage Mona Amiri and Daniel Belanger; Univ of Montreal-Quebec, Canada

Aqueous electrolytes are widely used in electrochemical technologies. Recently, superconcentrated aqueous electrolytes, also called water-in-salt electrolytes, have attracted much attention for electrochemical energy storage systems. These superconcentrated electrolytes can have salt/water weight ratio higher than 1. They are also characterized by a much wider electrochemical stability window, in comparison to low concentration electrolytes. In this talk, the physicochemical properties of highly concentrated aqueous electrolytes based on acetate salts will be presented. For example, the nature of ions-water and ions-ions interactions of the electrolytes will be discussed. The electrochemical behavior of these electrolytes in electrochemical energy storage will be presented and their advantages as well as limitations will be discussed.

Electrochemically Modulated Interaction of MXenes with Microwaves Danzhen Zhang[1], Meikang Han[1,2], Christopher E. Shuck[1], Bernard McBride[1], Teng Zhang[1], Ruocun (John) Wang[1], Kateryna Shevchuk[1] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]Fudan University, China

Controlling the reflection and absorption of incident electromagnetic waves at gigahertz frequencies in thin films remains a fundamental challenge. The ability to dynamically depress electromagnetic wave jamming is significant for protecting electronic devices but lacking in conventional electromagnetic interference (EMI) shielding materials. MXenes, as a large family of two-dimensional transition metal carbides and nitrides, have shown a broad range of EMI shielding performance as well as different energy storage mechanisms from electric-double-layer capacitance to pseudocapacitive behavior. Herein, we report a method for active control of electromagnetic wave interactions with various MXene films, including $Ti_3C_2T_x$, Ti_2CT_x, V_2CT_x, $V_4C_3T_x$ and

$Nb_4C_3T_x$, leading to EMI shields with unprecedented bidirectional modulation of shielding capability. The reversible tunability of EMI shielding effectiveness was achieved by electrochemically driven ion insertion/desertion and charge transfer in MXene layers with different electrolytes, accompanied by expansion and shrinkage of layer spacing. An EMI shielding 'switch' was demonstrated through electrochemical oxidation of MXene films. Our results offer opportunities to develop smart EMI protection with active modulation, which is different from conventional 'static' shielding and can adapt to demanding environments.

3:45 PM EN01.06.06
Surface Electrochemistry of Capacitive Deionization and Development of Highly Stable Cabon Electrodes Jin Soo Kang; Seoul National University, Korea (the Republic of)

Capacitive deionization (CDI), whose operation principle mimics that of the supercapacitor, has received a broad attention as a promising method for desalination. In CDI, removal of salt takes place by adsorption of Na^+ and Cl^- on charged electrode surfaces. In order to maximize the desalination capacity, activated carbon electrodes with large surface area have been widely used as electrode materials. Meanwhile, during the operation, carbon undergoes significant oxidative degradation and the CDI performance decreases to a significant extent, even leading to an inverted operation with a very low capacity. In this study, surface electrochemistry of activated carbon electrodes, which include the interactions with water and dissolved oxygen, are thoroughly investigated to understand the environment where the activated carbon electrodes are placed in CDI operation. Then based on the findings, design strategy of electrode materials and the newly developed heteroatom-doped activated carbon electrodes will be presented. Moreover, utilizing the inversion behavior of activated carbon electrodes in electrochemical desalination will be suggested as an intrinsic solution to addresses the stability issues of activated carbons.

4:00 PM DISCUSSION TIME

4:15 PM EN01.06.08
High-Performance Novel Multifunctional Structural Supercapacitors for Electrical Energy Storage Applications Atif Javaid[1,2,1], Ahmet Emre[1,1] and Nicholas A. Kotov[1,1,1]; [1]University of Michigan, United States; [2]University of Engineering and Technology, Pakistan

Carbon fiber (CF) reinforced epoxy composites are playing a significant role in a wide variety of civil and military applications because of their outstanding properties, ease of fabrication, low shrinkage after curing, and good thermal resistance. Currently, the focus is on the development of smaller, smarter, and more efficient materials that can perform multiple functions simultaneously1, including a function of structural material as well as exhibit at least one additional performance-linked function. Our goal is to create a structural material that simultaneously stores electrical energy within itself, by acting as a supercapacitor. Any load-bearing device, requiring electrical energy, can be fabricated using the structural supercapacitor concept [1-3]. This can be imagined by considering a mobile phone, without a heavy energy storage device installed, extracting the required energy from the outer casing, or cutting the weight of the heavy energy storage devices that a soldier must carry for powering up various electronic gadgets, as the lightweight structural supercapacitor can easily fit under the soldier uniform. Herein, we demonstrate a way to improve the electrochemical performances of the structural supercapacitors by impregnating modified diglycidylether of bisphenol-A epoxy polymer electrolyte into two iron selenide hedgehog particles [4] deposited carbon fabric (CF) electrodes, separated by a novel aramid nanofiber membrane separator [5,6], using vacuum bagging technique. The deposition of high surface area iron selenide hedgehog particles4 on CF mats is an effective process to improve the charge storage capacity of the electrodes and can be used in structural supercapacitors which can offer a different direction to the electric vehicle industries. Electrochemical and mechanical properties of the structural supercapacitors are investigated by chronoamperometry, cyclic voltammetry, impedance spectroscopy, chronocoulometry, dynamic mechanical thermal analysis, and in-plane shear testing, respectively. The fabricated structural supercapacitors, produced in this way, exhibit excellent multifunctional performance in capacitance and energy/power densities and exhibit a long cycle life with improved mechanical properties. Thus, this study has demonstrated that the deposition of iron selenide hedgehog particles on the surface of carbon fabrics as well as using aramid nanofiber membrane as a separator, are novel and easy approaches to improving the multifunctionality of structural supercapacitors that could be exploited in various applications including portable electronics, electric cars, and unmanned aerial vehicles (UAVs). This development of the novel concept potentially could have significant mass and/or volume efficiencies for applications that utilize both structural components and energy storage devices.

Energy Storing Structural Body Panels for EVs Jayan Thomas[1], Deepak Pandey[1], Kowsik Sambath Kumar[1], Leaford Henderson[1] and Luke Roberson[2]; [1]University of Central Florida, United States; [2]Kennedy Space Center, United States

As the global appetite for clean energy is growing like never before, energy storage devices like hybrid supercapacitors are attracting considerable attention. As electric vehicles (EVs) are becoming more and more popular, they face many challenges, including limited charge capacity and long charging times. This presentation discusses how we addressed some of these challenges by developing an electrified carbon fiber reinforced polymer (e-CFRP) composite that stores electrical energy and function as a load-bearing structural component to make EV's body panel. The carbon fiber mat electrode is developed by vertically attaching graphene sheets on carbon fibers. A high-strength multilayer e-CFRP composite is fabricated using an alternate layer patterning configuration of epoxy and gel electrolyte. The e-CFRP so developed delivered an areal energy density of > 0.31 mWh cm^{-2} at 0.3mm thickness and a high tensile strength of 518 MPa and a bending strength of 477 MPa. The e-CFRP panel is used to run a toy car to demonstrate its potential application in EVs. The energy harvested by an integrated solar cell is stored in the e-CFRP and used to power an IoT device to demonstrate its application in communication satellites.

Carbon Capture with High Mass Loading Supercapacitor Electrodes from Biomass Waste. Muhammad Bilal, Jiajie Li and Kai M. Landskron; Lehigh Univ, United States

Supercapacitive Swing Adsorption (SSA) is a carbon capture technique that achieves selective, and reversible CO_2 adsorption through capacitive charge and discharge of activated carbon electrodes in aqueous electrolytes. We report SSA with garlic roots-derived activated carbon achieving a record adsorption capacity of 312 mmol/kg at a low energy consumption of 72 kJ/mol and high mass loadings (>30 mg/cm^2) at 1 V. The activated carbons are inexpensively prepared in a one-step process using potassium carbonate, and air as activators. The adsorption capacity further increases with increasing voltage. Up to a voltage of 1.4 V there is only minor increase in energy consumption, and a sorption capacity of 524 mmol/kg at an energy consumption of 130 kJ/mol can be achieved. The volumetric sorption capacity is also enhanced, and reaches values of 85.7 mol.m^{-3} at 1.0 V, and 126 mol.m^{-3} at 1.4 V. Cycle stability for at least 130 h is demonstrated.

9:30 AM EN01.07.03
Supercapacitors for Improved RFBs Performance in Hybrid Systems Monica Giovannucci, Elisabetta Petri, Federico Poli, Alessandro Brilloni and Francesca Soavi; Alma Mater Studiorum University of Bologna, Italy

Modern energy grids must rely on renewable energy sources, such as solar and wind, which are characterized by high fluctuations in power. In view of the increased exploitation of intermittent renewable energy sources, modern grids need to adapt and necessitate more dynamic energy storage systems.

Nowadays, vanadium redox flow batteries (VRFB) are the most diffuse and established technology for stationary storage thanks to the ability of to decouple energy and power design [1]. However, this type of battery still suffers of low power peak and are not able to fulfill the demand for intermittent renewable energy source connected to the grid. Supercapacitors are electrochemical storage devices that can deliver and absorb high power peaks.

Hybrid energy storage systems (HESS) in which high-power redox flow batteries and supercapacitors work together are promising solution for applications having frequent high peak-to-average power demand. Hybridization of Energy Storage Systems (ESS) will also lead to more efficient storage systems, with longer lifetimes and with the ability to operate on all time-scale applications, from seconds to days [2].

Here we report on the hybridization of a HP-VRFB with commercial Supercapacitors (SC) by a direct parallel connection of the two devices that aims at improving the overall energy efficiency at high power rates. At first, the power and energy response of the HP-VRFB cell and SC single cell has been tested under the same discharge protocols and has been, then, compared to the hybrid assembled system.
Overall, our study highlights that the direct connection of the HP-VRFB cell with the SC makes it possible to extend the range of currents by a factor of 5. The direct connection showed also beneficial effects in terms of delivered energy under a power pulse that increased by 46%. In addition, the discharge curve of the SC was modified by the presence of the HP-VRFB, a phenomenon that we defined as an apparent capacitance increase [3]. This study is the base of future research in which green materials for high power supercapacitors and high power semi-solid electrodes for VRFB will be embedded in the hybrid system.

Green Hybrid Supercapacitive Systems Francesca Soavi, Elisabetta Petri, Monica Giovannucci, Federico Poli and Alessandro Brilloni; University of Bologna, Italy

Electrical double layer capacitors (EDLCs) are key energy storage systems for applications having frequent high peak-to-average power demand, from portable to stationary applications and e-mobility. They are also considered systems of choice to design different hybrid energy technologies, where they are connected to batteries, fuel cells or ambient energy harvesters to improve the overall power performance and reliability.
A unique feature of EDLCs is that, unlike batteries, they store energy electrostatically within a wide operational voltage range, limited only by the electrochemical stability window of the electrolyte. This dynamic response makes EDLCs easily connectable, at single cell level, with a wide range of energy harvesters/storage units including those operating at low and variable voltage, like solar cells, piezoelectric generators, and microbial fuel cells.

Depending on the defined end-use, the hybrid energy storage/conversion systems should be properly sized and designed with attention to the sustainability of materials and manufacturing processes. Specifically, the storage unit has to be tailored, both to meet the device design requirements (flexibility, thickness, size) and the electric behavior of the harvester. In addition, today, EDLCs cannot be considered as totally green. Greener component options are biochar electrodes obtained by the pyrolysis of bio-derived-waste that will enable the exploitation of ubiquitous and scalable raw materials within a circular economy approach. Electrode and membrane manufacturing by water-processable polymers is also a valuable approach, as well as novel electrolyte formulations, including ionic-liquids and water in salt electrolytes (WiSE) could solve most of the criticality of today EDLC organic solvent-based electrolytes.

Here, we report about different activities that target the design of hybrid systems, where EDLCs are designed taking into account the electric characteristics of the energy harvesters parallel connected and and manufactured by exploiting sustainable components. The main achievements obtained within the HyFLOW UE project, that targets the development of an environmentally friendly hybrid storage unit based on vanadium redox fow batteries and supercapacitors will be reported. We will discuss about the different approaches that should be followed for hybrid systems, based on different harvesters like solar cells, piezoelectric generators, or microbial fuel cells, where EDLCs play a key role in improving the output power quality and efficiency. We will also propose a semi-empirical method for proper supercapacitor sizing and component selection.

The Effect of Particle Motion on Charging Behavior Observed in a Microfluidic Flow Capacitor Brandon Stacks, Deyu Li, Kelsey B. Hatzell and Haoxiang Luo; Vanderbilt University, United States

Electrochemical flow capacitors (EFCs) are promising energy storage devices because of their large storage capacity, low fatigue rates, and fast charge/discharge rates. These devices employ the electric double layer of high-surface-area porous carbon particles in a flowable slurry, i.e., a 'flowable electrode', to store ionic charges from an electrolyte solution. In the charging process, continuous electrical paths between carbon particles and the stationary electrode have to be established in the flowing slurry. The slurry can then be pumped into storage reservoirs. To extract the stored electricity, the flow is reversed, and the stored charges can be released to the electrodes again relying on particle-electrode and particle-particle interactions. Therefore, the flow characteristics of the carbon slurry and the particle interactions could play an important role in the charging and discharging performance of the device. Despite this, there are very few studies that directly observe the particle motion inside the charging channels. Most studies consider the EFC from an electrochemical perspective, so slurry components, such as electrolyte selection, carbon particle porosity, and carbon loading percentages, are tested to achieve the best possible charging performance. This approach however does not allow the researcher to probe the effect of slurry flow characteristics on charging performance. To address this issue, we have developed a microfluidic electrochemical flow capacitor (MEFC) that is compatible with optical imaging. The device is fabricated using transparent indium tin oxide (ITO) electrodes, a transparent polycarbonate track etch (PCTE) separator membrane, and polydimethylsiloxane (PDMS) channels for the slurry to flow through. This platform allows us to investigate the influence of various slurry flow behaviors on the charging performance of the flowable electrode during the operation of the device using an inverted microscope with a high-speed camera. We have used this setup to directly observe the effect of slurry flow rate on the particle-electrode and particle-particle interactions and consequently the charging/discharging performance. We will report on the fabrication of the MEFC, the experimental setup, and the charging/discharging results under different slurry flow rates.

Ni/Co Bimetallic Flower-Like Metal-Organic Frameworks with Enhanced Performance for High-Power Energy Storage Applications Ilias Ntoukas[1], Alexander Roberts[1], Rong Lan[1], Chiara Milanese[2] and Evangelos Gkanas[1]; [1]Coventry University, United Kingdom; [2]University of Pavia, Italy

Metal-Organic Frameworks (MOFs) are compounds consisting of metal ions coordinated to organic ligands to form crystalline porous structures by self-assembly. They have emerged as a class of crystalline materials with high surface area and porosity, tuneable pore size and functionalized surface. Due to the metal nodes in the framework, they provide redox centres facilitating faradaic reactions, and due to their crystalline porous structure they provide easier access for electrolyte diffusion. Thus, they own great electrochemical properties, making them ideal for electrode materials for supercapacitors.
However, most reported MOFs own an insulating nature which is a major drawback for their electrochemical applications. A common method to solve this restriction is to incorporate another metallic element to enhance the properties of the electrode material.
Nickel materials demonstrate high specific capacitance and exhibit promising electrochemical properties as electrode materials for supercapacitors, but they own low rate capability and cycle life, which is attributed to their poor structural stability during the fast charge-discharge process. With the addition of another metal ion such as Co^{2+} into the structure, more active sites and improved conductivity can be obtained, while stabilizing the Ni species. The partial substitution of the second metal ions in the inorganic nodes will provide synergistic effects for the bimetallic framework. The ratio between the metals can also be adjusted to tune the physiochemical properties of MOFs.
For all these reasons, bimetallic Ni/Co MOFs are promising materials for electrodes in energy storage applications. Currently, Activated Carbon (AC) is used as electrode material for supercapacitors due to its high conductivity, large number of micropores and high surface area. However, the micropore structure of activated carbon limits pore accessibility and ion diffusion, thus reducing the capacitance and energy density. Transition metal oxides are also used as electrode materials for supercapacitors due to their metal centres, which provide faradaic redox reactions, and their low cost. Though, their poor conductivity leads to a low specific capacitance and causes structural destruction of the materials, thus decreasing the stability of the system.
In this study, using terephthalic and trimesic acid as the linkers, binary Ni/Co MOFs (Ni:Co = 4:1, 3:1, 2:1, 1:1) have been synthesized utilizing a solvothermal method. Various parameters that affect the structure and properties of MOFs such as time, temperature, ligands, Ni/Co ratio, and additives have been investigated. The main focus is on the effect of Co ions that substitute the Ni ones in the framework, how they affect the structure's stability and the electrochemical properties of the bimetallic Ni/Co MOFs.
These materials have been structurally characterised by SEM, EDX, XRD, XPS, FTIR, TGA, BET and TEM. The morphology consists of 2D interlayered nanosheets with smooth surface that assemble to form 3D microflower-like crystalline structures. The addition of Co^{2+} leads to a more dense, hierarchical and spherical morphology. The phase of these materials is also identified by Rietveld analysis and is: $Ni_2(OH)_2(C_8H_4O_4)$ *(CCDC no. 985792).* The addition of Co^{2+} does not alter the framework but only provides stability.
Moreover, these materials have been electrochemically tested by CV, GCD, EIS and cycling measurements. A large specific capacitance of 1503 F/g at 1A/g has been achieved with 70% retention after 3000 cycles. Finally, asymmetric coin cells using these materials and Activated Carbon (AC) have been developed and tested for their capacitance and cycle life.
In conclusion, Ni/Co MOFs have been synthesized and the effect of Co^{2+} in the framework has been investigated. The incorporation of Co^{2+} provides stability and advanced electrochemical properties, making these materials promising candidates as electrode materials for supercapacitors.

11:30 AM DISCUSSION TIME

11:45 AM EN01.07.09
High-Voltage Hybrid Electrolytes for Fast Charging Devices Jeng-Yu Lin; Tunghai University, Taiwan

Developing high-voltage electrolytes to extend the cell voltage has been regarded as an efficient strategy to increase the energy density of supercapacitors (SCs) since energy density is proportional to the square of the cell voltage. Recently, deep eutectic solvent (DES), as an ionic liquid analog, has been regarded as a green liquid media and novel alternative for non-aqueous type electrolytes for SCs due to its unique features of non-flammability, low cost, wide ESW, low vapor pressure, biodegradability, renewability, and compositional tunability. Unfortunately, due to the strong molecular interaction of DES, it shows high viscosity and low ionic conductivity behavior, resulting in a diminished capacitive performance at high current densities.
To overcome these issues, a novel hybrid DES electrolyte was developed by simply introducing the appropriate amount of water and acetonitrile co-solvents. The as-fabricated symmetric SC device using the optimized DES hybrid electrolyte showed an impressive cell voltage of 2.2 V and delivered a high energy density of 21.4 Wh kg^{-1} at the power density of 1100 W kg^{-1}, and also achieved excellent capacity retention of 86.8% after 120-h floating test. As a consequence, this work should definitely enlarge the application of the DES electrolyte systems consisting of water/acetonitrile towards high-

performance energy storage devices.

Latest Advances in Sputtered Nitride Films as High Performance Pseudocapacitive Electrodes for Solid-State Micro-Supercapacitors Christophe Lethien[1,2], Thierry Brousse[3], Bruce S. Dunn[4] and Pascal Roussel[5]; [1]IEMN - RS2E, France; [2]Institut Universitaire de France, France; [3]Institut des Matériaux Jean Rouxel, France; [4]University California Los Angeles, United States; [5]Unité de Catalyse et de Chimie du Solide, France

Micro-supercapacitors[1–3] (MSC) are a new class of miniaturized electrochemical capacitors which could be used to power the next generation of Internet of Things (IoT) devices. Despite the fact that the 1st RuO_2 // LIPON // RuO_2 MSC was proposed[4] twenty years ago by Yoon *et al*, there is still no commercially available MSC. Nevertheless, this promising technology with high power capabilities is fully complementary to solid-state lithium-based micro-batteries[5,6] (storing and delivering high energy densities) and could be combined in a single unit to power autonomous IoT devices. In that context, the development of advanced MSC at the production level is mandatory for the future. The lack of Off-The-Shelf MSC is due to two technological bottlenecks. The first limitation is that of achieving the deposition of thin or thick films electrodes at the wafer level by methods which are compatible with clean room environment: carbon-based electrodes[7,8] or pseudocapacitive oxide/nitride films[9–13] deposited by magnetron sputtering methods seem to be attractive solutions to achieve high performance electrodes using mass production compatible techniques. The second limitation deals with the development of solid electrolytes whose high ionic conductivities occur within the small footprint restricted to the area of the MSC (~ mm^2). Ionogel technology[14,15] combined with photopatternable[16,17] capabilities is the best candidate to fulfil this requirement.
This presentation will focus on the recent advances that we made to remove these two technological barriers in order to upscale the MSC technology from lab to market. The latest results that were obtained on vanadium nitride and ruthenium nitride films will be detailed.

Synthesis of 2D/2D $MoS_2/Ti_3C_2T_x$ MXene Heterostructure for High Performance Supercapacitor Thi Kim Anh Nguyen and Ruey-An Doong; National Tsing Hua University, Taiwan

Although a number of strategies have been boosted on 2D-$Ti_3C_2T_x$ Mxene as electrode material for supercapacitors, the re-stacking nanomellar and instability in structure have always inhibited its practical application. The development of 2D/2D heterostructures of Mxene with another 2D material has been proposed to combine the collective advantages of each 2D constructive and expose enhanced electrochemical performance. In this research, a rationally designed electrode 2D/2D heterostructure of 2D-MoS_2 decorated 2D-$Ti_3C_2T_x$ ($MoS_2/Ti_3C_2T_x$) was constructed by a benign hydrothermal etching method. The physicochemical characteristics of as-prepared $MoS_2/Ti_3C_2T_x$ were thoroughly in-depth investigated and the electrochemical storage mechanisms were clearly interpreted. The superior electrochemical performance and excellent long-term durability of the as-obtained $MoS_2/Ti_3C_2T_x$ are observed, which is attributed to not only the extensive ion storage site from a synergistically nanomellar effect in 3D interconnected networks but also the ultrafast electron transport channel resulting from the immobilization/bonding between 2D-MoS_2 and $Ti_3C_2T_x$ MXene. This study gives a new archetype to realize the real applications of 2D/2D heterostructures for electrochemical energy storage devices with high energy and power densities.

The Impact of Synthesis Conditions and Heterostructuring on the Capacitive Performance of MXenes Majid Beidaghi; Auburn University, United States

2D MXenes have shown promise for various applications due to their unique physical and chemical properties. The high electrical conductivity, 2D and layered structure, and rich surface chemistry of MXenes have sparked great interest in their properties as electrode materials for energy storage devices. MXenes are particularly of high interest because they can store charge in the bulk of the electrode through ultrafast intercalation of ions and fast and reversible redox reactions. The main focus of this talk is our recent studies on tuning the synthesis conditions to improve the capacitive performance of MXene electrodes. Particularly, the role of defects introduced during the MXene synthesis on the electrochemical properties will be discussed. Also, our recent work on the assembly of MXene heterostructures with improved capacitive performance will be presented, and the chemical and electrochemical stability of defected and heterostructured MXenes will be discussed. Finally, the current gaps in the knowledge about the electrochemical properties of

MXenes and some of the future research directions in this area will be summarized

4:00 PM EN01.08.04
Three-dimensional $Ti_3C_2T_x$ MXene-Prussian Blue Hybrid Microsupercapacitors by Water Lift-Off Lithography Yongjiu Lei, Wenli Zhao and Husam N. Alshareef; King Abdullah University of Science and Technology, Saudi Arabia

The accelerating development of miniaturized portable and wearable electronic devices is a significant emerging application for compatible microscale power systems. On-chip microsupercapacitors (MSCs) are promising micropower candidates, which typically exhibit high-power delivery, fast rate capability, and extended lifetime. Herein, we demonstrate an in-plane hybrid microsupercapacitor with a high areal energy density by employing battery-type CuFe-Prussian blue analogue (CuFe-PBA) as the positive electrode, and pseudocapacitive titanium carbide MXene ($Ti_3C_2T_x$) as the negative electrode. A three-dimensional (3D) lignin laser-induced graphene electrode was prepared as the substrate by a simple water-based lift-off lithography method. Thanks to the excellent match of the two types of high-rate performance materials in proton-based electrolytes and the numerous electrochemically active sites, the designed device achieved excellent electrochemical performance, even when using a gel electrolyte. In particular, the device delivers a high areal capacitance of 198 mF cm^{-2}, a wide potential window (1.6 V), an ultrahigh rate performance (75.8 mF cm^{-2} retained even at a practical/high current density of 100 mA cm^{-2}), and a competitive energy density of 70.5 and 27.6 μWh cm^{-2} at the power densities 0.74 and 52 mW cm^{-2}, respectively. The hybrid microsupercapacitor is fabricated using scalable thin-film microfabrication methods, which opens a new avenue for miniaturized and highly integrated micropower sources in future portable and wireless devices.

4:15 PM EN01.08.05
Fully-Printed, High-Temperature Microsupercapacitor Arrays Enabled by Hexagonal Boron Nitride Ionogel Electrolytes Lindsay Chaney[1], Woo Jin Hyun[1,2], Maryam Khalaj[1], Janan Hui[1] and Mark C. Hersam[1,1]; [1]Northwestern University, United States; [2]Guangdong Technion–Israel Institute of Technology, China

Abstract: Rising demand for portable electronics and sensors for the Internet of Things continues to drive innovations in the energy storage sector. In order for these devices to run remotely, they must be able to self-sufficiently store their own energy and thus require compact, integrated power sources. Microsupercapacitors are an excellent option due to their exceptionally long cycle lives and their rapid energy delivery and uptake. Additionally, their planar device architecture is easily integrated with all components of a wireless device, allowing for streamlined manufacturing directly on a single substrate. In this work, we demonstrate fully screen-printed, flexible microsupercapacitor arrays via rapid deposition of a high-temperature hexagonal boron nitride (hBN) ionogel electrolyte. The hBN ionogel can be printed onto large-area (~100 cm^2) graphene-based microsupercapacitor arrays within seconds, enabling mass-manufacturing. The devices have an areal capacitance of 0.92 mF cm^{-2}, which rivals the best graphene-based devices to date. In addition, unlike incumbent polymer-based electrolytes, hBN ionogel electrolytes exhibit stable cycling at high temperatures up to 180°C. Elevated operating temperatures result in an increase in power density and enable self-powered, remote devices to be deployed in harsh, high-temperature environments such as underground exploration, aviation, and electric vehicles. This combination of high-performance functionality in harsh conditions and a scalable fabrication strategy significantly expands the application space for microsupercapacitors.

4:30 PM EN01.08.06
Giant Energy Storage Microsupercapacitors via Electrostatic Negative Capacitance Suraj Cheema[1], Nirmaan Shanker[1], Shang-Lin Hsu[1], Mohamed Mohamed[2] and Sayeef Salahuddin[1,3]; [1]University of California, Berkeley, United States; [2]Massachusetts Institute of Technology, United States; [3]Lawrence Berkeley National Laboratory, United States

Dielectric electrostatic capacitors, although they lag behind their electrochemical counterparts in energy storage, are better suited for integrated on-chip energy storage. Here we report record-high electrostatic energy storage density (ESD) and power density (PD) in back-end-of-the-line (BEOL)-compatible HfO_2-ZrO_2 (HZO)-based thin films on silicon [1]. Until now, the promise of ultrathin (anti)ferroelectricity in HZO on silicon has mostly motivated low-power computing applications [2]. However, the same features which make HZO so promising for computing – (anti)ferroelectric order down to the ultrathin regime [3,4], high permittivity via negative capacitance (NC) [2], inherently large breakdown field, conformal growth by ALD [1-4] – are also appealing for energy storage. First, to increase its intrinsic energy storage, atomic-layer-deposited antiferroelectric HZO films were engineered near its field-driven ferroelectric phase transition to exhibit amplified charge storage via the NC effect [5], which enhanced its volumetric ESD beyond the best known BEOL-compatible dielectrics (120 J/cm^3). Second, to increase the overall stored energy, amorphous-templated HZO-Al_2O_3 superlattices overcame the conventional thickness limitations of HZO-based (anti)ferroelectricity to scale-up its high storage antiferroelectric NC behavior (100-nm regime). Third, to increase storage-per-footprint, the superlattices were conformally integrated into three-dimensional (3D) capacitors to boost its areal ESD (PD) to 9-times (180-times) the best-known 3D electrostatic capacitors: 80 mJ/cm^2 (300 kW/cm^2). Notably, this ESD value exceeds that of most state-of-the-art electrochemical microsupercapacitors and is only ~ 1 order of magnitude away from commercial Li-ion microbatteries, despite boasting over 8 orders of magnitude larger PD. Therefore, this work leverages NC ferroic engineering, superlattice thickness scaling, and 3D integration to overcome the traditional capacity-speed (ESD-PD) trade-off spanning the electrostatic-to-electrochemical energy storage hierarchy. Furthermore, this work demonstrates that HfO_2-ZrO_2 can serve as the functional material system across all technologies required for energy-efficient autonomous electronics, including on-chip microsupercapacitors [1] as well as computing units [2]. Therefore, these results establish a pathway for co-designed microelectronics in which computing and energy technologies are monolithically-integrated and synergistically-operated towards enhanced energy-efficiency and sustainability.

Liquid Metal-Based Stretchable All-Solid-State Supercapacitor Adit Gupta, Jian Lv and Pooi See Lee; Nanyang Technological University, Singapore

The components of wearable electronics should be flexible and stretchable in order for the electronics to demonstrate mechanical stability against deformation caused by human motions without experiencing performance degradation. For achieving a fully autonomous system, energy storage devices used to power the active devices on wearable electronics should be able to endure deformation along with other components. Stretchable supercapacitors (SSCs) are viewed as viable power sources for wearable electronics because of their advantages of high-power density, high cyclic stability, and superior safety. At present, SSCs are typically prepared by loading or coating the active materials on the stretchable substrate composed of the conductive filler and the polymer elastic matrix (acting as a current collector). Unfortunately, they suffer from delamination between the stretchable electrode and active material while causing exposure of noncontributing volume/mass of elastic substrate during mechanical deformation. Here, we develop an intrinsically stretchable electrode by sedimenting the conductive and electrochemical active liquid metal microparticles (Eutectic Gallium Indium alloy, EGaIn) in the stretchable conductive matrix. A similar polymer matrix is used to prepare ionogel to improve the electrolyte and electrode compatibility. An all-solid-state energy storage device is constructed by UV curing the ionogel in between the two liquid metal-based electrode. This strategy of utilizing liquid metal microparticles as the active material provides an added advantage of retaining mechanical conductivity and conserving the amount of active material present on the surface of the electrode during stretching. The liquid metal-based electrode has high conductivity, attaining a high stretchability with ~900% strain, and provides a continuous conductive network due to the flow of liquid metal during mechanical strain. Through this strategy, we are not only able to improve the mechanical and electrochemical performance during mechanical deformation but also prevent the leaching of liquid metal to produce a stable system. Our work on liquid metal-based electrodes with ionogel electrolyte is a viable path for creating next-generation high-performance, stretchable energy storage devices.

9:00 PM EN01.09.02
Template-Free Ethylene Glycol-Assisted Etching Method to Increase the Porosity of Metal-Organic Framework Derived Carbons for Supercapacitors Ruijing Xin[1], Yusuke Yamauchi[1,2] and Yusuf V. Kaneti[1]; [1]University of Queensland, Australia; [2]National Institute for Materials Science, Japan

Metal-organic frameworks (MOFs) have drawn great interests as both carbon sources and self-templates for creating carbon materials with intrinsic porosity, tuneable chemical and physical properties and high surface area. Hard or soft template methods have been primarily used in the fabrication of hierarchical porous carbons. The template-based approaches, however, require uniform combination of the carbon sources with templates and post-synthetic template removal, making the fabrication procedures costly and complex. Herein, we demonstrate a facile template-free etching strategy for enlarging the micropores in bimetallic zeolitic imidazolate framework (ZIF) particles into mesopores at room temperature. Hierarchical porous bimetallic ZIF particles (etched $Zn_{33}Co_{67}$-ZIF) exhibiting both micropores and mesopores have been successfully prepared while maintaining the framework integrity using the ethylene glycol-assisted aqueous etching method. After pyrolysis, the etched $Zn_{33}Co_{67}$-ZIF particles are transformed into cobalt- and nitrogen-doped hierarchical porous carbon (i.e., etched $Zn_{33}Co_{67}$-C) particles with increased mesoporosity. The etched bimetallic carbon (etched $Zn_{33}Co_{67}$-C) displays 1.6- and 14.8- times higher specific capacitance at a high scan rate of 100 mV s^{-1} than unetched bimetallic carbon ($Zn_{33}Co_{67}$-C) and Zn-only carbon (Zn-C), respectively as electrochemical double layer supercapacitor electrode materials. Additionally, the etched $Zn_{33}Co_{67}$-C exhibits good electrochemical stability after 5,000 cycles. The presented ethylene glycol-assisted aqueous etching process provides an useful method for enlarging the porosity of MOFs, and their corresponding porous carbon materials and improve their supercapacitor performance.

Improving Electrochemical Performance of Polyaniline-Derived Activated Carbon in Different Electrolytes for Energy Storage Devices K.A.U. Madhushani, A.A.P.R. Perera, Wang Lin and Ram K. Gupta; Pittsburg State University, United States

The development of efficient energy storage devices can be introduced as a sustainable route for storing energy for long-term purposes. Among those, supercapacitors have attracted remarkable attention in recent research and commercial activities. Herein, several techniques have been used to improve the performance of the polyaniline-derived carbon material. Through the combined process of carbonization and activation process, the surface area and porosity of the electrode material are increased, leading to better electrochemical performance of the energy storage devices. Also, this can be significantly improved by selecting the best active electrolytes. Therefore, it is essential to find the best combination of electrodes and suitable electrolytes for the fabrication of supercapacitors to achieve higher chemical performances. The electrochemical performance of activated polyaniline using various ratios of KOH as an activating agent (1:0.5, 1:1, and 1:2 wt./wt.) was studied. The electrode derived using a 1:1 ratio showed better capacitive performances in an aqueous electrolyte. A symmetrical coin-cell supercapacitor based on 1:1 activated polyaniline was further tested in an aqueous electrolyte (6M KOH) and two organic electrolytes ($TEATFB_4$ in acetonitrile and PMPyrr-TFSI). The supercapacitor based on aqueous electrolyte exhibited a high specific capacitance of 137 F/g at 1 A/g, which is much higher than that of 88 F/g and 86 F/g from $TEATFB_4$ and PMPyrr-TFSI, respectively. However, the energy and power density of these two organic electrolyte systems illustrated superior values compared to those of the aqueous electrolyte system. The highest energy and power density were owned by PMPyrr-TFSI, which was 182 Wh/kg and 1953 W/kg at 1 A/g, respectively. Our research focuses on developing an energy storage device based on the superior electrode that can be used for the fabrication of commercial supercapacitors.

Defects in Arsenic doped CdSeTe Absorbers and their Impact to Current Collection Efficiency Mariana I. Bertoni; Arizona State University, United States

Copper and arsenic have been used as primary dopants in CdSeTe photovoltaic absorbers. However, both atomic species suffer from very low dopant activation. Arsenic concentration in these devices are on the order of 10^{16} cm^{-3}, which makes it notoriously difficult to correlate nanoscale distributions to the local charge transport properties. To measure and correlate these properties, measurement techniques require high sensitivity to elemental concentration, large penetration depth, and operando compatibility. In this work, we use nanoscale X-ray microscopy to correlate chemical distribution – structure – electrical properties through X-ray Fluorescence, X-ray Absorption Near edge spectroscopy, and X-ray Beam Induced Current at a pixel-to-pixel level (50-120nm).
Our cross-section studies unveil the segregation of As and the transition of the maximum charge-collection efficiency from the back interface to the front interface as a function of processing conditions, which is correlated to the balance of acceptors and donors, and thus the activation of the dopants. We will show linear combination fitting of XANES and the presence of active species as well as inactive species through the absorber.

11:00 AM EN02.01.02
Cd(Se,Te) Densification to Moderate As Diffusion in Thin-Film PV Devices Brian Good[1,2], Eric Colegrove[2] and Matthew Reese[2]; [1]University of Illinois at Chicago, United States; [2]National Renewable Energy Laboratory, United States

Arsenic doping is a significant topic of interest in CdTe solar cells. Carrier concentrations have far surpassed those achieved with copper, and stability has also improved. However, challenges remain in reducing the V_{oc} deficit in devices. Arsenic is known to self-compensate in CdTe, which can lead to low dopant activation levels and associated voltage fluctuations that contribute to losses. Additionally, SIMS has shown significant As accumulation near the front interface, likely leading to reduced activation levels in the Se-rich region. Our modeling has demonstrated that deep levels near the interface can drastically reduce device performance. Furthermore it suggested that reduced doping near the interface can improve V_{oc} and thus a quasi- p-i-n structure was proposed where the intrinsic layer would be only a few hundred nm thick in the Se-rich region. In practice, an intrinsic layer is difficult to achieve when dopant diffusion is performed afterwards. However, reduction of the As accumulation would be ideal. In this work, we explore methods of accomplishing this through anneals on evaporated Cd(Se,Te) prior to vapor transport deposited (VTD) CdTe:As.
Our absorber preparation involves the evaporation of an undoped Cd(Se,Te) layer, followed by a thicker VTD layer of CdTe:As. Arsenic is introduced *in situ* and diffuses throughout the absorber. Since As readily diffuses along grain boundaries, we believe the small Cd(Se,Te) grains allow significant As accumulation in the evaporated layer. While $CdCl_2$ is known to increase grain size, its formation of a eutectic phase also can massively increase As diffusion rates. We have demonstrated that anneals over CdTe powder help remove voids and create more compact VTD films. We hypothesized that performing similar anneals on the undoped layer may reduce two potential pathways for As diffusion. First, it can reduce the prevalence of grain boundaries and inhibit excessive As diffusion near the interface. Second, Se vacancies, which can contribute to diffusion and recombination, may be filled in. If these are able to sufficiently reduce As pileup, it should yield a higher V_{oc} due to less near-interface compensation.
Anneals were performed with various temperatures and ambients, as well as with both CdTe and Cd(Se,Te) powder, the latter as an effort to inhibit possible Se loss in the film. The effects of hydrogen and oxygen incorporation were explored, with hydrogen expected to reduce undesired oxidation. Following these anneals, films were $CdCl_2$ annealed to obtain measurable lifetime via time resolved photoluminescence (TRPL). The highest lifetime was observed with CdTe powder in a nitrogen-only ambient at 575°C. Microscopy on annealed films showed substantive grain growth prior to $CdCl_2$ treatments, with higher temperatures yielding larger grains.
In addition to material studies of the undoped evaporated material, equivalent films were processed into devices, including VTD CdTe:As and subsequent densification and $CdCl_2$ anneals. J-V measurements showed slightly increased V_{oc} for devices with annealed Cd(Se,Te) layers compared to those without the anneal. SIMS measurements showed that As content decreased approximately one order of magnitude within ~200 nm of the front interface, a 2-3 order of magnitude decrease compared to films without the pre-VTD anneal.
Combining material characterization with device performance, we see improved V_{oc} correlated with lower near-interface As concentration and larger Cd(Se,Te) grains. The pre-VTD anneals therefore had the desired result. Ongoing work involves strategies to remove unintentional oxidation during this anneal, as well as further reducing the As content near the interface to increase the observed effect on V_{oc}. Hydrogen anneals and thicker undoped layers, respectively, are being explored for these purposes. Through this work, we hope to provide a method to reduce near-interface compensation in As-doped CdTe devices.

The Implications of Metal Saturated Growth for As Doped CdTe and CdSeTe Solar Cells Stuart J. Irvine[1], Ochai Oklobia[1], Dan Lamb[1], Stephen Jones[1], Dingyuan Lu[2] and Gang Xiong[2]; [1]Swansea University, United Kingdom; [2]First Solar Inc., United States

The drive for 25% CdSeTe solar cells depends on effective acceptor doping above 1x10^{16} cm^{-3} which can be achieved using group V doping. However, the incorporation of a Group V dopant onto the Group VI site is highly compensated with associated deep level defects. Until recently this has resulted in no discernable improvement in V_{oc} compared with much lower acceptor concentrations achieved with Cu doping. The increase in acceptor concentration leads to a reduction of the depletion width from over 1 μm to 0.2 μm. Recombination within the depletion region leads to a reduction in V_{oc}. It has become clear that high acceptor concentration CdTe and CdSeTe solar cells are less tolerant towards defects close to the front emitter. In this talk the Group V doping of CdTe will be reviewed and recent results presented on the influence of metal saturated conditions on doping with As. Using metal organic chemical vapour deposition (MOCVD) it has been possible to create a wide range of different thermodynamic conditions. In this study we have explored metal saturated growth that has led to an improvement in V_{oc} close to 900 mV. The role of the front interface will be considered as this becomes more influential in achieving high V_{oc} for high acceptor concentrations. We have used a combinatorial approach to track V_{oc} with the Group II and Group VI precursor ratio and acceptor concentration. Approaches to unlock the true potential of Group V doped CdSeTe solar cells using doped emitters with V_{oc}>1 V will be discussed.

11:45 AM EN02.01.04
Deep Level Transient Spectroscopy of Inorganic Thin Film Solar Cells Jon Major; University of Liverpool, United Kingdom

Deep level transient spectroscopy (DLTS) is capable of resolving electrically active defect levels within semiconductors. The technique works by temperature dependant analyis of capacitance transients which occur as trap states within the band gap are depopulated. DLTS allows the energetic poisition of defect levels within the bandgap to be determine, alongside estimates for the capture cross section and density of such defect level. It evolved from analysis single crystal materials such as silicon and gallium arseninde but is also able to resolve defect levels present within polycrystalline thin films. For thin film solar cells this can provide useful information on native and extrinsic defect and/or doping levels aiding the development of new processes. This presentation will demonstrate the capability of the techqiue to determine the defect content inorganic thin film materials such as in emerging antimony chalcogenide materials Sb_2Se_3 and Sb_2S_3, as well as the impact of alloying and group V doping in CdTe via analysis of $CdSe_{1-x}Te_x$ and CdTe:As solar cells. We will also demonstrate the links between device performance and deep level defect content and show how this measurment approach can be used to inform device process development.

Modeling and AI-Guided Understanding of CdTe-Based Photovoltaics Maria K. Chan; Argonne National Laboratory, United States

CdTe-based PV devices are currently the only commercially viable alternative to Si. Significant mysteries remain as to the effects of grain boundaries on device performance, and the local environment of dopants and how it relates to activation. In this talk, we will discuss characterization-informed first principles and atomistic modeling of grain boundaries and impurities in CdTe and related systems. The use of x-ray absorption near edge spectra (XANES) and scanning transmission electron microscopy (STEM), in particular, gives unprecedented atomic-level information and the interpretation of XANES and STEM data benefits from AI/ML and modeling.

First-Principles Understanding of NiO and TeO_2-Based Back Passivation Layers in CdTe PV Anthony P. Nicholson[1,2], Stephan Lany[2] and Walajabad Sampath[1]; [1]Colorado State University, United States; [2]National Renewable Energy Laboratory, United States

There is progressive interest toward fundamentally understanding the roles attributed to passivated back contact layers in thin-film semiconductor PV. Within the cadmium telluride PV community, special emphasis is given to a back passivation layer capable of reducing back interface recombination losses while ensuring carrier selectivity and the possibility for bifaciality. Transparent thin-film oxide layers such as NiO_x or TeO_x may offer a viable solution for back passivation layers in CdTe PV. However, atomic scale effects for NiO_x and TeO_x in relation to possible defect interactions during copper and/or chloride-based treatments as well as energy band alignment of the absorber/passivating oxide interfaces are not well understood. The current work uses a first-principles computational approach based on density functional theory to investigate the electronic structures of NiO and TeO_2 bulk layers in the presence of relevant defects along with the formation of pristine interfacial morphologies when either oxide layer is in contact with the absorber layer in CdTe PV. For the bulk defect studies, defect pair interactions are evaluated to determine avenues of dopability and/or compensation that may affect bulk carrier transport within the oxide thin-film layers. Additionally, an atomic-scale perspective of the pristine absorber/oxide interface structures is given with respect to plane orientation, termination layer, and associated surface reconstruction to give insight on how NiO and TeO_2 differ in band alignment features influencing charge transport at the back interface. Details from the first-principles-based computational study provide further insight on the mechanisms inherent to passivating oxide layers that could potentially lead to benefits in CdTe thin-film PV device performance.

Impact of Defects on Solar Cell Performance in Low-Dimensional Selenium Seán R. Kavanagh[1,2], Alp Samli[1], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

Low-dimensional trigonal selenium (Se) was the first material to exhibit the photovoltaic effect and has recently experienced a renaissance in research interest as a candidate solar cell absorber, due to its desirable properties (suitable band gap, high earth abundance, low temperature processing), potential implementation in silicon tandem cells and *'simple' elemental chemistry*. Though cell efficiencies have improved much since its initial application in 1883, Se still lags behind leading technologies such as silicon and lead-halide perovskites, with the fundamental limitations (doping density, defect-mediated recombination, intrinsic Urbach tailing…) remaining unclear.

In this work, we use hybrid density functional theory to investigate the electronic properties, band alignment and defect chemistry of Se, in order to shed light on the key limiting factors for solar cells. We find the crystal dimensionality to dictate the energies of intrinsic defects (vacancies and interstitials) in this system and their impact on electronic properties. In doing so, we identify key deleterious impurities for performance and important considerations for the experimental fabrication of high-efficiency selenium solar cells, as well as establishing an outlook for the attainable performance of Se solar cells based off the fundamental intrinsic limitations.

2:30 PM EN02.02.04
Designing Nanostructured Ferroelectric Films: Geometry, Polarization and Electronic Properties of the $BaTiO_3$/Hematite Interface from First Principles Jorge Ontaneda[1], Ricardo Grau-Crespo[2], Keith T. Butler[1] and Joe Briscoe[1]; [1]Queen Mary University of London, United Kingdom; [2]University of Reading, United Kingdom

By coupling together a junction-based photovoltaic system and a bulk photovoltaic effect-based material in a nanocomposite thin film device, the well-known limitations[1–3] of both technologies could be overcome. This idea relies on the proven ability of ferroelectrics to influence coupled materials, such as photocatalysts and organic photovoltaics. By using the recently-developed Electronic Lattice Strain procedure,[4] we identified the $BaTiO_3$/hematite interface as a promising candidate for the proposed device. Screening was performed in terms of epitaxially-compatible interfaces (to minimize defects) and appropriate band alignment (to minimize charge transfer). To gain insights into the geometry, polarization and electronic properties of the aforementioned system, Density Functional Theory (DFT) modelling is employed. To this purpose, we assume the $BaTiO_3$ (110) surface as substrate on which the hematite (100) surface grows epitaxially strained to it. Within the supercell approach, we are required to employ 5×5 surface unit cells of $BaTiO_3$ (110) and 4×2 units of hematite (100) to reproduce the minimally strained interface (~2.6%).

Our preliminary tests show that GGA-PBE functional with a Hubbard-type correction to the Ti 3*d* orbitals, where $U_{\mathrm{eff}} = 2.6$ eV, can reproduce the spontaneous polarization in $BaTiO_3$. However, the bandgap is still poorly described: ~30% off with respect to experimental value. In the case of hematite, where $U_{\mathrm{eff}} = 3.5$ eV is applied to the Fe 3*d* orbitals, the bandgap is in excellent agreement with experimental reports. Even though bandgaps can be accurately described by DFT via hybrid functionals, such as HSE06, their application for the above heterojunction is impractical due to the size of the interface model which consists of 855 atoms.

In order to estimate a proper offset from the $BaTiO_3$/hematite heterojunction, we will employ bulk HSE06 values to correct the band alignments of this interface, which is computed with the PBE+*U* method. Our scheme is tested with heterojunctions that can be tackled with the HSE06 hybrid functional, ranging from covalent to ionic solids. This scheme might allow us to model not only this complex epitaxially-compatibles interface, but also other heterojunction for novel devices.

Bulk Photovoltaic Effect in Ferroelectric Vertically Aligned Nanocomposites Emanuele Palladino[1], Subhajit Pal[1], Muireann A. de Hora[2], Judith MacManus-Driscoll[2] and Joe Briscoe[1]; [1]Queen Mary University of London, United Kingdom; [2]University of Cambridge, United Kingdom

Exploiting physical and electrical properties of polar materials is currently an area of substantial research interest, with the scope to create multifunctional materials that aim to solve the challenges of the next decades in the fields of renewable energy, transportation, and quantum computing to name a few. Among these, ferroelectric materials whose spontaneous polarisation can be switched by an applied electric field, are known to generate currents without the need of a heterojunction as required for traditional semiconductors. The phenomenon is known as the bulk photovoltaic effect (BPVE), and it results in large photovoltages well above the bandgap which have the potential to surpass the Shockley-Quessier (S-Q) limit for single junction devices[1,2]. However, the high photovoltage is limited by the conductivity which combined with the intrinsic wide band gap results in unremarkable efficiencies below 1%[3,4]. Different approaches have been adopted to overcome this limitation like ionic doping, heterostructures or localized surface plasmons resonances (LSPR)[5]. Here we report the use of a two-phase nanocomposite approach coupling a ferroelectric with a narrow band gap material that allows us to exploit the built-in voltage of the former with the high absorption and conductivity of the latter. Epitaxial nanocomposites thin films of $BaTiO_3$:Sm_2O_3 and $BaTiO_3$:MgO were fabricated via pulsed laser deposition (PLD) and the secondary phase was etched away and replaced with α-Fe_2O_3 phase. The combination of atomic force microscopy allowed us to assess the electrical properties of the films, the presence of BPVE and how these are affected by strain in vertically aligned nanocomposites (VANs).

Flexible Kesterite Solar Cells—Optoelectronic Characteristics Implied by Mechanical Deformation William Jo; Ewha Womans University, Korea (the Republic of)

We will present recent progress of photovoltaic devices using chalcogen-based compounds: kesterites and chalcopyrites. Kesterite $Cu_2ZnSn(S,Se)_4$ (CZTSSe), promising earth-abundant materials for thin film solar cells, has been widely studied and active research efforts raise the efficiency of flexible kesterite solar cells close to 12%. To fabricate the robust and highly efficient flexible thin film solar cells, understanding the changes in device properties under mechanical stress is crucial. In this study, transport of photogenerated carriers with mechanical stress was characterized. CZTSSe samples with and without Na deposited on flexible Mo foil were prepared and solar cell parameters after the mechanical bending were measured. Degradation of open-circuit voltage (V_{OC}) was varied by the direction of mechanical bending and the existence of Na elements. Photo-assisted Kelvin probe force microscopy was utilized to characterize the transport of photogenerated carriers, and it was found that the magnitude of surface photovoltage changed under mechanical bending state. It refers the degradation of local V_{OC} and transport of the photogenerated carriers was limited with mechanical stress resulting in decrease of V_{OC} of devices. In addition, CZTSSe sample with Na doping showed the larger SPV under bending than sample without Na which suggest the passivation of defects and prevention of damage from bending. To quantify the disorder in energy band structure under mechanical bending, Urbach energy was obtained from absorption coefficient function. Attribution of Na in transport of photogenerated carriers will be investigated to clarify the robust carrier transport under mechanical stress compared to the CZTSSe without Na.

4:00 PM EN02.03.02
Characterization of Ag Alloyed CuInSe Solar Cells Using Bias-Dependent Admittance Spectroscopy Jessica de Wild, Jonathan Parion, Romain Scaffidi, Guy Brammertz and Bart Vermang; imec, Belgium

The well-known Shockley-Queisser limit for single junction solar cells can be overcome using multiple solar cells with different band gaps on top of each other. In the case of a tandem solar cell, the ideal band gap of the bottom cell is about 1 eV, of the top cell about 1.7 eV and efficiencies of 42% can be achieved theoretically.[1] As bottom cell often Si is used, which has a band gap of 1.12 eV. For a full thin film tandem structure, which could be suitable for flexible or light weight applications, $Cu(In,Ga)Se_2$ (CIGS) can also be used. The band gap of CIGS varies between 1.0 and 1.6 eV depending on the Ga/In ratio. Optimal performance of CIGS solar cells is achieved with about 30% Ga and using Ga gradients at the front and the back. The band gap is then around 1.2 eV, thus above the ideal value for a bottom cell. Without Ga in the absorber layer the band gap will be reduced to 1 eV, but also the quality of the absorber layer and its interfaces are less optimal without the Ga gradients. When low band gap CIGS (low or without Ga) will be used as bottom cell, other methods to increase the absorber quality and its interface with the buffer layer need to be investigated. For this purpose, we explore incorporation of small amount of Ag in the absorber layer (ACIS) to improve the bulk properties, and stoichiometric growth in combination with InSe on the surface to improve the buffer/absorber interface.
CIS layers were grown by a 3-stage process on Mo with or without a 10 nm Ag layer. When Ag is added in the CIS absorber, the efficiency of the ACIS solar cell increases about 2% absolute, mainly due to an increased fill factor. Depositing InSe on top of a stoichiometric CIS layer, increases the Voc by 50-60 mV. The efficiency increases about 1% absolute compared to the copper poor CIS. When depositing InSe on a stoichiometric ACIS absorber layer, the solar cell performance deteriorates. The cell is completely shunted, and Voc, FF and Jsc are reduced.
The various solar cells are then further analysed using bias-dependent admittance spectroscopy. The data of these measurements is presented in a so-called CVf-map, and with SCAPS modelling the CVf-maps may be analysed.[2, 3] At first the difference between ACIS and CIS is analysed. Minor differences in the CVf-maps are observed between ACIS and CIS. The CVF-map of ACIS looks slightly cleaner in a larger bias and frequency range, but in general they are very similar, indicating that there are no large differences in the absorber or at the interfaces. The 'cleaner' CVf-map for ACIS, corroborates with the higher FF measured for ACIS. When InSe is deposited on a stoichiometric CIS sample, the apparent doping is much higher, which could explain the increase in Voc measured for this kind of structure. When InSe is deposited on a stoichiometric ACIS sample, the apparent doping still increases but a defect signature is seen at 0V bias voltage which seems to be responsible for the deterioration of the performance.
Temperature dependent CVf measurements are further performed to allow for disentanglement of the various features that are seen in the CVf maps. Using SCAPS modelling, CVf maps and low-temperature data, a model is proposed on why the ACIS absorber layer has such a different response when InSe is deposited and how this can be improved.

Semi-Monolithic Integration of Chalcopyrite Solar Cells into Multijunction Devices Kai C. Outlaw-Spruell[1], Christopher P. Muzzillo[2], Kai Zhu[2] and Nicolas Gaillard[1]; [1]University of Hawaii, United States; [2]National Renewable Energy Laboratory, United States

Monolithic integration, the process by which solid-state devices are made by sequentially depositing layers of materials on top of each other, is used in all commercial thin film-based technology. This process is so foundational nowadays that it is difficult to imagine any other way to create high-efficiency solid-state devices. In the context of photovoltaics (PV), monolithically-integrated multi-junction (MJ) cells have demonstrated their capability in overcoming the thermodynamic efficiency limits of single-junction (SJ) devices, as well as being a practical solution to create devices with sufficient photovoltage for direct solar-to-hydrogen (STH) conversion.Despite its wide acceptance, however, monolithic integration presents major limitations in process compatibility, restricting materials selection and synthesis to a sub-set of compatible systems while limiting the adoption of emerging promising candidates.

The strategy we present in this communication, further referred to as *semi-monolithic* integration, relies on the exfoliation and bonding at room temperature of independently processed, substrate-grown SJ devices to create a whole thin film-based MJ device. By design, this scheme allows successive integration of thermally, chemically and/or mechanically incompatible material classes onto a single substrate without compromising state-of-the art SJ fabrication processes. First, we report on whole chalcopyrite-based semi-monolithic MJ devices comprised of 1.85 eV ordered vacancy compound (OVC) $CuGa_3Se_5$ and 1.13 eV $Cu(In,Ga)Se_2$ sub-cells. Our process takes advantage of the weak out of plane van-der Waals forces in the $MoSe_2$ layer which naturally forms at the $Cu(In,Ga)Se_2$/Mo interface. Both chalcopyrite cells were successively transferred and bonded onto a single rigid FTO host substrate at room temperature using transparent conductive composites (TCC). A champion $CuGa_3Se_5$/CIGSe MJ device showed power conversion efficiency of 5.04% with open-circuit voltage (Voc), short-circuit current density and fill factor of 1.24 V, 7.19 mA/cm^2, and 56.7%, respectively. Following this successful proof-of-concept demonstration, we constructed the world’s first whole-chalcopyrite triple junction MJ device comprising 1.13 eV and 1.44 eV $Cu(In,Ga)Se_2$ and 1.85 eV $CuGa_3Se_5$ sub-cells. The device exhibited a V_{OC} of 1.85 V and was capable to splitting water with an STH efficiency of 3% in a PV-electrolysis configuration.

Approaching 24% Flexible All-perovskite Monolithic Tandem Solar Cells Enabled by Reducing V_{OC}-deficit in Wide-bandgap Subcell Huagui Lai[1], Jincheng Luo[2], Yannick Zwirner[1], Selina Olthof[3], Alexander Wieczorek[1], Fangyuan Ye[4], Quentin Jeangros[5,6], Xinxing Yin[7], Fatima Akhundova[8], Tianshu Ma[9], Rui He[2], Radha K. Kothandaraman[1], Xinyu Chin[5,6], Evgeniia Gilshtein[1], André Müller[1], Changlei Wang[9], Jarla Thiesbrummel[10], Sebastian Siol[1], José M. Prieto[11,8], Thomas Unold[8], Martin Stolterfoht[4], Cong Chen[2], Ayodhya N. Tiwari[1], Dewei Zhao[2] and Fan Fu[1]; [1]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]Sichuan University, China; [3]University of Cologne, Germany; [4]University of Potsdam, Germany; [5]École Polytechnique Fédérale de Lausanne, Switzerland; [6]Sustainable Energy Center, Centre Suisse d’Electronique et de Microtechnique, Switzerland; [7]Jiaxing University, China; [8]Helmholtz-Zentrum Berlin, Germany; [9]Soochow University, China; [10]University of Oxford, United Kingdom; [11]Humboldt-Universität zu Berlin, Germany

Tandem solar cells (TSCs) are one approach to exceeding the efficiency limits of single-junction solar cells by making better use of the solar spectrum with multiple junctions. Among various types of perovskite-based TSCs. All-perovskite TSCs are of particularly attractive for building- and vehicle-integrated photovoltaics, or space energy areas as they can be fabricated on flexible and lightweight substrates with a very high power-to-weight ratio. However, the efficiency of flexible all-perovskite tandems is lagging far behind their rigid counterparts primarily due to the challenges in developing efficient wide-bandgap (WBG) perovskite solar cells (PSCs) on the flexible substrates as well as their low open-circuit voltage (V_{OC}). Firstly, the relatively rougher surface of the flexible substrate poses a certain difficulty in the deposition of a uniform layers through solution processing. Moreover, the WBG PSCs suffer from a larger V_{OC}-deficit (E_g-V_{OC}) when compared with narrow-bandgap (NBG) PSCs, which has been constantly reported to be >550 mV. To construct a high-performance flexible all-perovskite TSC, there is an urgent need to develop high-quality WBG PSC based on flexible substrates with a reduced V_{OC}-deficit.

Here, we first developed a modified spin-coating protocol of [2-(9H-carbazol-9-yl)ethyl] phosphonic acid (2PACz) on flexible ITO substrate. Long resting time together with multiple spin-coating ensure the deposition of a uniform 2PACz layer, which serves as a lossless hole selective contact and allows the subsequent uniform growth of a 1.77 eV WBG perovskite. This translates to ~40 mV gain in V_{OC} of the devices compared to those based on poly-triarylamine. To further reduce the V_{OC}-deficit, we employed a post-deposition treatment (PDT) on the perovskite surface with 2-thiopheneethylammonium chloride (TEACl), which suppresses both the bulk and interfacial recombination, boosting the V_{OC} of the flexible NIR-transparent WBG PSC by ~100 mV. We identified an accumulation of TEA^+ on the surface of perovskite, which widens the surface band structure and reduces the interfacial recombination by realizing a better band alignment between perovskite and electron transport layer. In addition, we found that Cl^- tends to diffuse more into the bulk perovskite, which could be helpful for reducing the non-radiative in the bulk. Based on this, we achieved a high V_{OC} of 1.29 V and 15.1%-efficient NIR-transparent WBG (1.77 eV) PSCs grown on flexible substrates. The high V_{OC} corresponds to a record low V_{OC}-deficit of 480 mV for perovskite with a bandgap around 1.80 eV. In conjunction with flexible NBG (1.24 eV) PSCs, a 23.8% monolithic flexible all-perovskite TSC (0.09 cm^2) with a superior V_{OC} of 2.1 V is achieved, which is on par with the V_{OC} reported on the 28% all-perovskite tandems grown on the rigid substrate. Moreover, a 23.6% efficiency was also realized on a larger area device (1.04 cm^2), which is close to that of the small device and shows a great upscaling potential of the flexible monolithic TSC.

In summary, our work provides a holistic and effective approach to improve the performance (V_{OC} in particular) of flexible NIR-transparent WBG PSC and all-perovskite monolithic TSC. The understanding of the passivation mechanism of TEACl PDT sheds new light on the future work in targeted choice of passivation reagent for the perovskite solar cells. Further reducing the V_{OC}-deficit within the WBG and NBG subcells will be the key for reaching a 30% efficiency in flexible monolithic all-perovskite TSCs.

Chemical and Electronic Properties of the $Mg_xZn_{1-x}O/CuGa_3Se_5$ Interface with a Cd^{2+}-Treatment Mary Blankenship[1], Brooklynne Jacobellis[1], Dirk Hauschild[1,2,2], Lothar Weinhardt[1,2,2], Imran Khan[3], Christopher P. Muzzillo[3], Andriy Zakutayev[3], Nicolas Gaillard[4] and Clemens Heske[1,2,2]; [1]University of Nevada, Las Vegas, United States; [2]Karlsruhe Institute of Technology, Germany; [3]National Renewable Energy Laboratory, United States; [4]University of Hawai‘i at Mānoa, United States

Ordered-vacancy wide band gap $CuGa_3Se_5$ is a promising candidate as absorber material for the top cell in tandem solar cells as well as in photoelectrochemical water-splitting devices. For wide band gap absorber materials, it is increasingly important to also use a wide band gap buffer layer to avoid absorption losses. Instead of the traditionally used CdS buffer layer, a conductive oxide $Mg_xZn_{1-x}O$ (MZO) was thus chosen in this study, deposited by RF sputtering on the absorber. To further improve the interface properties, a Cd^{2+} partial electrolyte treatment (CdPE) can be applied to the $CuGa_3Se_5$ surface prior to MZO layer deposition. Further optimization of the interface requires a more detailed understanding of the chemical and electronic properties at the MZO/absorber interface, such as the band edge positions, band gaps at the interface and, in particular, the band alignment.

In this contribution, we investigate the $CuGa_3Se_5$ absorber after CdPE, as well as its interface with the MZO layer using a toolchest of electron spectroscopies, including laboratory-based x-ray and UV photoelectron spectroscopy (XPS and UPS), x-ray-excited Auger electron spectroscopy (XAES), and inverse photoemission spectroscopy (IPES). With this combination of techniques, a detailed electronic and chemical picture of the interface is painted and will be discussed in view of its impact on the performance of $CuGa_3Se_5$ solar devices.

Structural Flexibility of Photovolatic Materials—The Key to High Efficient Solar Cells Susan Schorr[1,2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Freie Universität Berlin, Germany

Photovoltaics (PV) based on crystalline silicon wafers has developed into a mature technology for the conversion of sunlight into electrical energy. Thin film PV is an emerging alternative technology because of short energy payback time and minimum use of high purity materials, addressing the urgent need for cost-competitive renewable energy technologies.
Compound semiconductors with a high absorption coefficient are the most advanced and most efficient absorber materials in thin film PV technologies. Highly efficient devices are based on absorber layers out of ternary or quaternary chalcogenides or hybrid halide perovskites.
Record efficiencies are reached with solar cells based on $Cu(In,Ga)Se_2$ (CIGSe) $Cu_2ZnSn(S,Se)_4$ (CZTSSe) and $(Cs,MA,FA)Pb(I,Br)_3$ absorbers (power conversion efficiency of 23.3%, 13.0% and 25.5% respectively [1]). CIGSe crystallizes in the chalcopyrite-type structure, whereas CZTSSe adopts the kesterite-type structure. Both compounds (and silicon as well) belong to the adamantine family [2] which is characterized by a 3D network of corner sharing tetrahedra. $(Cs,MA,FA)Pb(I,Br)_3$ (MA-methyl-ammonium, FA-formamidinium) crystallizes in the perovskite-type structure, characterized by a 3D network of corner sharing octahedra. In this sense chalcogenide materials are based on common building blocks: an A_2B_2X-tetrahedron in ternary $A^IB^{III}X_2$ and an A_2BCX-tetrahedron in quaternary $A^I_2B^{II}C^{IV}X_4$ chalcogenide semiconductors. The parent structure of the adamantines is the diamond-type. In binary, ternary and quaternary adamantines the metals are ordered on defined cation sites which led to typical superstructures with lowered symmetry. The parent structure (aristotype) of ABX_3 perovskites is the cubic perovskite-type structure in which the B cations are octahedrally coordinated by the anions. Thus, the PbX_6-octahedra are the building blocks of hybrid halide perovskites. Tilting and distortions of the octahedra led to structures with lowered symmetry (Bärnighausen tree [3]), but all these crystal structures are named perovskite structure which leads to confusion sometimes [4]. IN the chalcogenide compounds it is a tilting and distortion of the tetrahedra which led to crystal structures with lower symmetry (e. g. wurtz-stannite structure).
The success of CIGSe, CZTSSe and $(Cs,MA,FA)Pb(I,Br)_3$ as PV material has to do with their overall structural flexibility. In the tetrahedrally coordinated chalcogenides this flexibility originates from the propensity of the crystal structure to stabilize intrinsic point defects as vacancies, anti-sites, and interstitials. Deviations from the stoichiometric composition led to the formation of such intrinsic point defects without dramatic structural changes, but with significant influence on the electrical and optical properties of the material [5,6]. On the other hand, hybrid halide perovskites were shown to have a high defect tolerance. Here the flexibility of the crystal structure gives remarkable positional freedom of the molecular cation and ionic movement.
The presentation will give an overview of the basic building block principle of these compound semiconductors, the flexibility of the crystal structure and the resulting effect on the optoelectronic materials properties.

Role of CdTe Deposition Temperature in the Fabrication and Optimization of Sputtered CdTe Solar Cells Mohammed Alaani[1], Prakash Koirala[1], Nikolas Podraza[1], Stephen K. O'Leary[2] and Robert W. Collins[1]; [1]The University of Toledo, United States; [2]University of British Columbia, Canada

Thin film CdTe solar cells have been fabricated through RF magnetron sputtering on soda lime glass substrates coated with transparent conducting oxide layers. The performance of such devices is expected to be sensitive to the CdTe absorber layer deposition parameters, such as the target power, which controls the flux of depositing species, gas pressure, which controls the energetic bombardment of the growing film, and deposition temperature, which controls the surface diffusion of the depositing species. Recent studies of the Urbach absorption tails of both sputtered and close space sublimated CdTe applied in solar cells have suggested that the broader band tails found in the sputtered form of CdTe provides a route for photogenerated carrier recombination [1]. Such broader band tails appear to be associated with smaller grains and residual stresses that exist even after an optimized $CdCl_2$ thermal treatment. These results motivates the study of sputtered CdTe solar cells prepared with absorbers fabricated at elevated temperatures in order to explore the role of deposition temperature in controlling the grain size, Urbach tail breadth, and band tail recombination for both as-deposited and $CdCl_2$ treated materials. The $CdCl_2$ treatment may play the dominant role, however, compared to deposition temperature, in controlling the CdTe grain size and the resulting optoelectronic properties. Although the effect of the $CdCl_2$ treatment on the quality of CdTe films and devices has been studied extensively, few studies have investigated the role of the as-deposited material properties which in the case of low temperature sputtered CdTe are more strongly modified by the treatment [1]. In this work, we have fabricated CdS/CdTe solar cell devices on 15 cm x 15 cm TEC-15/HRT glass substrates in the superstrate configuration with the CdTe deposition temperatures varied from 150 to 330 °C. The structural and the optical characteristics of the as-deposited and treated CdTe materials are investigated using X-ray diffraction, scanning electron microscopy, photothermal deflection spectroscopy, and spectroscopic ellipsometry (SE) in order to compare the impact of deposition temperature and the $CdCl_2$ treatment on the CdTe film structure and optoelectronic properties. Mapping spectroscopic ellipsometry (M-SE) in conjunction with specialized calibration procedures have been applied to optimize the window layer and back contact layer thicknesses independently for each deposition temperature [2]. In this process, it has been found that at the low sputtering pressures an appreciable thickness of the CdS window layer evaporates prior to the CdTe sputter deposition at the elevated temperature, and this possibly unrecognized effect has a significant influence on solar cell process optimization at elevated temperatures.

5:00 PM EN02.04.04
A Pathway to Enhance the Photovoltages in CdTe and Other Polycrystalline Mosaic Solar Cells Steluta A. Dinca and Eric A. Schiff; Syracuse University, United States

Polycrystalline "mosaic" semiconductors as used in current state of the art solar cells have grain boundaries that primarily extend throughout the cell's thickness. Extensive work done in the impact of grain boundaries on the photovoltaic properties of cadmium telluride (CdTe) and other mosaic cells suggests that grain boundaries dominate the recombination of photocarriers, and thus largely determine the open-circuit voltage of such cells. Further, CdTe solar cells, one of the important commercial cells, have now achieved laboratory power conversion efficiencies above 20%. A better understanding of how this was achieved may guide research to improve efficiencies in this class of polycrystalline cells.

The work reported here illustrates a potential route to enhance the open-circuit voltage of polycrystalline solar cells by eliminating a photocarrier recombination channel that has not, to our knowledge, been identified in earlier work. We used the semiconductor modeling software Sesame to do two-dimensional numerical calculations of the optoelectronic properties of an idealized n-CdS/p-CdTe solar cell assuming that the recombination of the carrier occurs primary at the grain boundary. We find that the electron carriers photogenerated closer to the CdS interface, but relatively distant from the grain boundary, follow a shortcut through the front CdS emitter to recombine with a hole in the CdTe absorber layer. The recombination event occurs at a “hot spot” near the intersection of the grain boundary with the CdS layer. This recombination channel reduces the open-circuit voltage in the models by about 0.05 V. Blocking the shortcut recombination channel could raise the efficiency of champion thin film CdTe cells from 21%, where it has been for several years, to 22%.

Atomistic Models of In and Ga Diffusion in $Cu(In,Ga)Se_2$ Aaron S. Gehrke, David Sommer and Scott Dunham; University of Washington, United States

To improve the performance of $Cu(In,Ga)Se_2$ (CIGS) thin-film photovoltaic devices, a robust understanding of the dominant diffusion pathways of the alloy species In and Ga is needed. For example, because the bandgap of CIGS varies significantly between pure $CuInSe_2$ (CIS) and pure $CuGaSe_2$ (CGS), knowledge and control of In/Ga interdiffusion in the system is necessary to optimize the spatial bandgap tuning. This in turn is necessary to produce the highest-quality devices. Here, we identify the most probable defects and mechanisms for mediating In and Ga diffusion by reviewing previous experimental and computational literature. We determine that defect complexes comprised of In_{Cu} and Ga_{Cu} antisites and V_{Cu} vacancies are the primary drivers of diffusion. With the aid of density functional theory software packages, we calculate the binding energies and migration barriers of these complexes in bulk CIS and CGS. We find that the binding between In_{Cu}, Ga_{Cu}, and V_{Cu} defects can be modeled as simple electrostatic interactions between point charges. We also find that the migration barriers for Ga_{Cu} are much higher than those for In_{Cu}, explained by a larger lattice distortion arising during Ga_{Cu} migration than during In_{Cu} migration. Using these results, we develop rate expressions for the different atomistic processes and incorporate them into analytic models and kinetic lattice Monte Carlo (KLMC) simulations, which are employed to predict the diffusivity of In and Ga in CIS under variations in composition and temperature. The activation energy of In diffusion in CIS from our KLMC simulations is 1.24 eV, and for Ga it is 1.54 eV. We show that In diffusion is dominated by correlated hops, where most In_{Cu}-V_{Cu} exchanges quickly reverse. Consequently, very few hops contribute to net long-range diffusion. In contrast, Ga diffusion is dominated by uncorrelated hops, which show little to no memory of the previous state and move in a random walk. We develop an analytic model for In and Ga diffusion, suitable for use in a continuum simulation, and show that it predicts complex formation and diffusivity as seen in our KLMC simulations with great accuracy. We find our models produce results that match well with experiment. The methods used here are highly transferable and can be applied to understand diffusion of both native and extrinsic species in many different materials.

Measuring Steady-State and Time-Resolved Photoluminescence of a Thin Film CIGS Solar Cell by a Positionable, Micrometer-Sized Observation Volume Eugeny Ermilov, Volker Buschmann, Christian Oelsner, Frank Birke, Matthias Patting and Rainer Erdmann; PicoQuant GmbH, Germany

Over the years, luminescence spectroscopy has established itself as one of the fundamental methods for analyzing the photophysical properties of a variety of samples, ranging from simple organic molecules to semiconductor light-emitting materials and photovoltaic (PV) devices. The commonly used steady-state methods (i.e. excitation and emission spectroscopy) provide valuable insights into the photophysics of samples. However, such results give only a partial view of sample`s behavior after photoexcitation.

A further piece of the puzzle is often revealed by performing time-resolved luminescence spectroscopy, as it provides deeper insights into the photophysical processes occurring in the sample under investigation. It is worth to mention, that the luminescence lifetime is an intrinsic characteristic of emitting species. It indicates how long species under consideration will remain in electronically excited states before returning to ground state. Each emitting species has a characteristic luminescence lifetime, that can be influenced by its environment.

A series of spectroscopic and microscopic methods based on luminescence lifetime have been developed and provide further information, which are not accessible by steady-state experiments. Acquiring time-resolved spectroscopic data at regions of interest (ROI) of the sample can help in inferring structural-to-photophysical relationships in different materials and can give information about important photophysical processes as well as changes in the local environment of emitting species. For example, fluorescence lifetime imaging microscopy (FLIM) is a very well established imaging method in life sciences where the lifetime information is combined with spatial localization in the sample, allowing investigating biochemical or physical processes, or probing the local environment of the fluorophore. As processes commonly investigated in materials science are mostly not classical fluorescence processes, in general the term time-resolved photoluminescence (TRPL) imaging is more adequate. In materials science, TRPL imaging can be used for the characterization of key parameters like e.g. charge carrier dynamics and mobility in semiconductors. It is worth to mention, that very often these processes occur on timescales ranging from tens of picoseconds to several hundreds of nanoseconds.

Here we will demonstrate the performance of a spectrometer-microscope assembly for characterization and analysis of different materials in terms of lifetime, spectral and spatial resolution. Using a laser driver with burst capabilities enables measurements of long luminescence decays in the range of µs to ms. The benefitsof this multi-dimensional approach will be demonstrated with a series of examples reflecting a broad range of applications in materials science research.

5:00 PM EN02.04.07

Time-Resolved Photoluminescence Mapping of CIGS Devices Using a Combination of a Superconducting Nanowire Detector and a Confocal Microscope Eugeny Ermilov[1], Volker Buschmann[1], Felix Koberling[1], Jürgen Breitlow[1], Hugo Kooiman[2], Johannes W. Los[2], Jan van Willigen[2], Martin Caldarola[2], Andreas Fognini[2], Mario U. Castaneda[2], Jessica de Wild[3,4,5], Bart Vermang[3,4,5], Guy Brammertz[3,4,5] and Rainer Erdmann[1]; [1]PicoQuant GmbH, Germany; [2]Single Quantum, Netherlands; [3]Hasselt University, Belgium; [4]imec, Belgium; [5]EnergyVille, Belgium

Over the years, luminescence spectroscopy has become one of the fundamental methods for analyzing the photophysical properties of a variety of samples, ranging from organic molecules to semiconductor materials and photovoltaic (PV) devices. It is worth emphasizing that detection sensitivity is a key parameter to meet today's demands for handling weak luminescent samples and forshort measurement times in the optical evaluation of PV devices. The introduction of single-photon counting based data acquisition has proven to yield a major sensitivity increase and very high dynamic range – it is the ideal method for measuring weak photoluminescence (PL).

The commonly used steady-state luminescence spectroscopy methods provide valuable insights into the photophysics of a sample. However, such results give only a partial view of the sample’s behavior after photoexcitation. A further piece of the puzzle is often revealed by performing time-resolved luminescence spectroscopy, as it provides deeper insights into the photophysical processes occurring in the sample under investigation. An even more comprehensive picture is gained by including spatial information. Acquiring time-resolved spectroscopic data at regions of interest (ROI) in the sample can help in inferring structural-to-photophysical relationships in PV materials. Gathering such information is an important step toward the optimization of structure as well as preparation process of such materials in order to increase the performance of PV devices.

In terms of detector performance, superconducting nanowire single-photon detectors (SNSPDs) stand out due to achievable close-to-unity detection efficiency in NIR spectral range, picosecond time resolution (down to < 20 ps (FWHM)), and low dark noise (< 100 counts/s)[1,2]. SNSPDs are a rather new technology that is being used in multiple applications in the field of quantum optics, luminescence lifetime measurements, and singlet oxygen detection. The high quantum efficiency is especially important for material science applications in the NIR-range beyond 1000 nm, where other available single photon detectors have low sensitivity, high dark noise and slow time response.

In this report we demonstrate the combination of the MicroTime 100 upright confocal fluorescence lifetime microscope with the Single Quantum EOS SNSPDs as a powerful tool for photophysical research on CIGS ($Cu(InGa)Se_2$) devices, yielding spatial and temporal information on semiconductor samples studied through PL emission.

While one of the used SNSPDs had a classical single-mode fiber coupling to guide the light onto the sensor, the other detector used an internal multi-mode fiber instead[2]. We detected a significant increase in photoluminescence sensitivity of both designs compared to a standard NIR-PMT (H10330-45, Hamamatsu) as well as a several times higher sensitivity of the multi-mode fiber coupled nanowire compared to the singe-mode fiber one, in spite of comparable photon quantum efficiencies in this wavelength range for the sensor only. The increased sensitivity combined with the lower dark count rate resulted in an increase of the signal-to-noise ratio by more than 3 orders of magnitude compared to the NIR-PMT. Moreover, the very high sensitivity of the SNSPD as well as high temporal resolution (instrument response function of the overall system was below 100 ps) reveals clearly the differences in the PL decay profiles of the defect and unquenched areas of the weakly luminescent thin-film CIGS sample[3] even at low illumination levels, which is extemely difficult to resolve when using the NIR-PMT detector.

5:00 PM EN02.04.09
Setting the Baseline for the Modelling of Kesterite Solar Cells—The Case Study of Tandem Application Axel Gon Medaille[1,2], Alex Jimenez[1,2], Alejandro Navarro[1], Sergio Giraldo[1], Kunal Tiwari[1], Marcel Placidi[1,2], Alejandro Perez-Rodriguez[2], Edgardo Saucedo[1] and Zacharie Jehl Li-Kao[1]; [1]Polytechnic University of Catalonia, Spain; [2]Institut de Recerca en Energia de Catalunya, Spain

The research on Kesterite-based solar cells is reaching a turning point. After a strong effort and record efficiencies in the early 2010s, this promising thin film photovoltaic absorber, free of toxic and critical raw materials, has seen a decade of relative stalling in terms of performance despite the continuous progress of competing technologies. Recent advances in the understanding of the bottlenecks hampering Kesterite solar cells have permitted **new efficiency records** within the past two years, finally breaking the 13% threshold. **Device modelling is bound to be instrumental** going forward and in spite of an extensive usage throughout the past decade, no realistic and quantitative representation of a Kesterite solar cell has been reported. This often leads to models relying on a partial knowledge of material and device parameters extracted from different sources, and this lack of consistency severely limits the accuracy of those models both quantitatively and qualitatively while rendering results' comparison between different laboratories almost impossible. In the meantime, low-cost tandem devices combining either inorganic thin film, perovskite and crystalline silicon cells have emerged as the next frontier for future efficient large scale photovoltaic deployment, and accurate quantitative device modelling combining electrical and optical simulation is more than ever needed to assess existing devices and predict possible improvements in future architectures.

This work reports on the modelling of Kesterite solar cells by combining SCAPS for the electrical part and the transfer matrix method for the optical part, using an in-lab developed modelling program. The objective is twofold. Firstly, **accurate and quantitative baselines based on the systematic characterization of Kesterite solar cells** fabricated at our group using a consistent experimental process are proposed. Our focus is on narrow bandgap Kesterite $Cu_2ZnSnSe_4$ (CZTSe) and wide bandgap Kesterite Cu_2ZnSnS_4 (CZTS). Specifically, we demonstrate in both cases the **simultaneous reproduction of all four photovoltaic figures of merit (voltage, current density, fill factor and efficiency) with less than 1% of relative discrepancy between the model and the experimental devices.**

Secondly, and using the aforementioned accurate modelling baselines and transfer matrix optical modelling, a case study on the potential of Kesterite solar cells in tandem devices is performed, namely for a narrow bandgap CZTSe subcell in tandem with a Perovskite top cell, and for a wide bandgap CZTS top cell in tandem with a crystalline silicon bottom cell. In each case, several material and optical improvements to the Kesterite cell are proposed and evaluated by the model with a high degree of quantitative accuracy, including bulk defect density, interface defects, bandgap engineering, doping gradient and selective contacts. It is found **that a moderate reduction in the density of Sn_{Zn} antisite defect permits to significantly enhance the efficiency of CZTSe solar cells up to 16%, which in combination with a 21% efficient Perovskite top cell allows to reach a total tandem efficiency of 30%**. In contrast, even ambitious optimizations to the wide bandgap CZTS solar cell do not permit to overcome the 26% efficiency threshold in tandem with a silicon subcell. The results from our simulation are compared with experimental values reported in the literature using Kesterite in tandem devices, allowing to assess the excellent robustness of the baseline parameters determined in this work. The complete set of material, optical and device input parameters are **openly shared**, which not only allows various research groups working on Kesterite solar cells to assess their validity, but also permits for the community to use common baselines for the numerical modelling of devices for **more consistent comparisons between research groups**.

Ultra-Thin Si Solar Cells with Hyperuniform Disordered Light Trapping Alexander Lambertz[1,2], Nasim Tavakoli[1], Stefan Tabernig[1], Richard Spalding[3], Anja Tiede[4], Anna Fontcuberta i Morral[4], Jorik Van de Groep[2], Marian Florescu[3] and Esther Alarcon-Llado[1]; [1]NWO-i AMOLF, Netherlands; [2]University of Amsterdam, Netherlands; [3]University of Surrey, United Kingdom; [4]EPFL, Switzerland

Mono- and multicrystalline silicon as absorbing materials in solar cells comprise about 95% of the global photovoltaics market and a total worldwide installed PV capacity of close to 3TW was reached in 2020. The benchmark efficiency of 19% for industrial modules reached in 2018 was enabled by the widespread adoption of Passivated Emitter and Rear Cell (PERC) device architecture. Typically, these cells feature 160μm-thick absorbing layers produced via the Czoralski method, which expunges up to 40% high-quality silicon as kerf loss. It has been inferred that the PERC baseline is not able to achieve the cumulative installed PV capacity target set by the IPCC of 7-10 TW by 2030 and further reduction of capital expenditure (capex) is needed. Reducing the thickness of Si-wafers for solar cells to 50μm could potentially reduce the manufacturing capex by 48%, module cost by 28%, and LCOE by 24% [1]. Thin c-silicon suffers from poor light absorption already at 100μm thickness necessitating light trapping to reach competitive efficiencies. High-performance light-trapping structures with sub-micron features, however, usually involve slow and complex manufacturing processes hindering their adoption by industry.

We present hyperuniform disordered (HUD) light-trapping structures applied to ultra-thin solar cells via substrate-conformal imprint lithography. This approach enables rapid patterning of large areas (m^2) at the nanoscale and can be performed on virtually any substrate and for any type of functional layer, such as the absorber, back-reflector, anti-reflection coating or carrier transporting layers. Correlated-disorder structures were shown to outperform periodic as well as random light trapping approaches [2] and the hyperuniform platform in addition offers engineered light scattering [3]. We developed a coupled-

mode theory (CMT) approach for estimating absorption with HUD patterns, which reduces the parameter space at low computational effort and is used as a starting point for numerical optimizations. Furthermore, we show experimentally measured absorption in ultra-thin, free-standing, hyperuniform-patterned silicon slabs of thicknesses ranging from 1-30µm and compare with simulations. Though silicon is our main candidate, also other PV materials can benefit from our approach and some of these examples will be presented.
Finally, we show the performance of ultra-thin Si solar cells before and after the application of HUD light trapping structures.
In conclusion, our work aims to further expand the success of earth-abundant silicon to ultra-thin, flexible and semi-transparent PV devices, which can be produced with kerfless bottom-up technologies at significantly reduced capex and accompanying CO_2 emissions while maintaining high power conversion efficiencies – A type of device that could literally pave all roads, roofs, walls, and windows by 2050!

Ultrathin Wide-Bandgap a-Si:H/oxide Transparent Photovoltaic Devices with Improved Open-Circuit Voltage via Electron Transport Layer Optimization Alex J. Lopez-Garcia[1], Gustavo Álvarez[1], Eloi R. Costals[2], Lorenzo Calvo[3], Pablo Ortega[2], Cristobal Voz[2], Joaquim Puigdollers[2], Victor Izquierdo-Roca[1] and Alejandro Perez-Rodriguez[1,3]; [1]Institut de Recerca en Energia de Catalunya, Spain; [2]Universitat Politècnica de Catalunya, Spain; [3]Universitat de Barcelona, Spain

Transparent Photovoltaic (TPV) devices open novel and unexplored pathways for the development of alternative photovoltaic technologies with a clear aim towards distributed applications, focusing on on-site generation while reducing visual impact as well as other inconveniences found in conventional PV applications. Implementation of TPV architectures can potentially allow for a wide array of applications, for example, smart windows in façades and other glazing elements such as vehicle windows, or canopies. Other examples can be the use of TPV to ubiquitously power up sensors and future IoT devices with a low-power draw. In order to deploy these applications into everyday life, it is crucial to develop the technology to be cost-effective. To do so, the pursuit of functional devices that rely on cheap, earth-abundant, stable, and non-toxic materials is of paramount importance if lab research is to be translated to industry. Additionally, the use of industrially scalable techniques is also an important requirement.
In this work, we report the development of wide-bandgap inorganic-based TPV devices that are fabricated using an ultrathin a-Si:H as a highly transparent absorber and oxide layers that are acting as carrier selective contacts and transparent electrical contacts. The basic device structure is FTO/AZO/a-Si:H/MoO_3/ITO, where FTO and ITO serve as back and front contacts while AZO is also used as electron transport layer. We will also report results on structures including V_2O_5 as hole transport material and AZO as top contact, comparing them against the reference HTL/front-contact stack, MoO_3/ITO. We will present results showing that the introduction of an intrinsic ZnO nanometric layer in-between the AZO ETL and a-Si:H leads to an overall performance increase, with the most notable improvement coming from an increased V_{oc} as compared to reference devices, as well as an increase in FF. Preliminary results show that there is an optimal thickness value for the ZnO interfacial film, and beyond this value there is a worsening of the device performance, which has been attributed to an increase in series resistance leading to poor transport in the TPV devices. This increase in PCE directly translates into an increased Light Utilization Efficiency (LUE), as the introduction of the ZnO interfacial film does not reduce Average Visible Transmittance (AVT) or Color Rendering Index (CRI) of the devices.
At the present time, spectrophotometry and J-V measurements performed in dark and under AM1.5G illumination (from the front and back sides) as well as Spectral Response measurements (under no bias as well as under light and electrical bias) have been carried out. As a preliminary result, we present devices with PCE>1% and AVT=40% (LUE>0.4%), overcoming the barrier of PCE ≤0.5% that has been observed in literature for state-of-the-art oxide-based devices. Record device efficiency achieved with these devices in our lab is PCE = 2%. We provide robust statistics showing that the process is reproducible thanks to the use of PE-CVD and ALD techniques, which allow for chemical composition tailoring and high film conformality even at the nanometric scale. These techniques are industrially scalable and could thus allow for a rapid TRL transition towards higher tiers. Ongoing characterization with XPS is also being performed. Ongoing work is exploring further optimization of the ETL via introduction of novel dipolar materials based on organic polymers: (PEI) and exploring different generations of dendrimeric molecules (PAMAM).
The work presented is of high relevance for the development of the field of inorganic thin film Transparent PV technologies, especially those working on extremely thin absorbers. It might also spark interest in thin film technologies in general that rely on advanced ETL/Active layer/HTL architectures.

This work has received funding from the European Union H2020 Framework Programme under Grant Agreement no. 826002 (Tech4Win).

Studies on Short-Circuit Currents of Subcells in a Compound Multijunction Solar Cell Hao Lo[1], Chia-Hua Huang[2], Chieh Lo[3], Chia-Chieh Hsu[4] and Wen Lour[4]; [1]University of Minnesota Twin Cities, United States; [2]National Dong-Hwa University, Taiwan; [3]National Taiwan University, Taiwan; [4]National Taiwan Ocean Univ, Taiwan

An InGaP compound semiconductor together with $In_xGa_{1-x}As$ related layers on a Ge substrate is one of the most popular active materials in the research of multijunction (MJ) solar cells formed by serially connecting multiple p-n junctions for its applications for power generation and space satellites. According to their energy band gaps, every p-n junction in the MJ solar cell forms an individual subcell being responsible for their own light spectrum independently. Then, an overall open-circuit voltage (V_{OC}) of the MJ solar cell is equal to the sum of V_{OC} of the individual subcell. However, an overall short-circuit current density (J_{SC}) of the MJ solar cell is determined by the subcell having the minimal J_{SC}. Thus, it is of particular importance to avoid any one of the subcells failing and producing a small J_{SC}. The conversion efficiency of the MJ solar cell cannot be improved without so-called current match. Here, a current mismatching ratio (CMMR) for the InGaP-InGaAs-Ge based solar cell is defined as:: CMRR=($|J_{SCT}$-$J_{SCM}|$)/(J_{SCT}+J_{SCM}), where J_{SCT} and J_{SCM} are the short-circuit current densities of the InGaP subcell and the InGaAs subcell, respectively. Besides, an average value of the J_{SCT} and the J_{SCM} represents a possibly optimized overall J_{SC} in the triple-junction (3J) solar cell.
In this work, a concept of J_{SC}-modulation effects was applied to optimize layers' parameters of every subcell in a MJ solar cell so that a fabricated MJ can be easily verified and theoretically simulated to achieve a high-efficiency MJ solar cell. An appropriate light spot with an adjustable power was used to change and to compensate the J_{SC} of one of the subcells in the MJ solar cell. For example, the appropriate light spot is with a wavelength of 405 nm. The one of the subcells is the InGaP subcell which is proposed to have the minimal J_{SC}. In the case, the measured overall J_{SC} will then be increased with increasing 405 nm light-spot power until it no more dominate the overall J_{SC}. Both J_{SCT} and J_{SCM} are then extracted. In experimental, the structure used to fabricate InGaP-InGaAs-Ge MJ solar cells consists of an InGaP subcell, an InGaAs subcell, and a Ge subcell. The 3J solar cell was fabricated to with a cell area of 0.25 cm^2 and a shielding ratio of 5%. To fabricate double junction (2J) solar cells having the same absorption spectrum, only 5% area of InGaP-

based layers was removed. Thus, 95% area of an InGaP-based layer remains upon the 2J solar cells to work as a short wavelength filter. Various compensated lights were employed to determine key CMMR of InGaP-InGaAs-Ge related 3J and 2J solar cells. Experimental results of using a 405 nm compensated light reveal that J_{SC}s of 9.37 mA/cm^2 and 10.28 mA/cm^2 were determined for the InGaP subcell and InGaAs subcell, respectively. Thus, the CMMR for the as-fabricated 3J solar cell is about 4.44%. The possibly best design for the J_{SCT} and/or J_{SCM} in the 3J solar cell is considered to be 9.814 mA/cm^2. An optimal conversion efficiency of 18.47% is expected. Thus, remind that a 4.44% CMRR will lead to 0.82% (18.47% - 17.65%) reduction in the conversion efficiency. Excellent agreement in evaluated properties was obtained when a 532 nm, a 638 nm, and 808 nm compensated lights were used. Another 3J solar cell fabricated with an anti-reflected coating was also evaluated. Measured results reveal that an overall J_{SC} of 13.5 mA/cm^2 is still limited by the InGaP subcell, resulting in a conversion efficiency of 27%. Together with determined J_{SC} of 15.5 mA/cm^2 for the InGaAs subcell, a possible optimum conversion efficiency of 29.11% is expected.
Finally, J_{SC}s for our 3J and 2J solar cells under multiple suns were also nondestructively evaluated. Important conclusions concerning CMMR variation and improvement in conversion efficiency will be reported.

Understanding the Role Thin Film Interfaces Play in Solar Cell Performance and Stability Mirra M. Rasmussen[1], Kristopher O. Davis[2], Laura S. Bruckman[1] and Ina T. Martin[1]; [1]Case Western Reserve University, United States; [2]University of Central Florida, United States

As more efficient and cost-effective photovoltaic (PV) architectures are developed, solar becomes an ever more competitive and viable replacement for fossil fuels. Full grid electrification necessitates the development of efficient, reliable, cost-effective technologies - and there is room for many different kinds of PV in this expanding market. The practical challenges and constraints of terawatt PV production have brought scalability and durability into sharp scientific focus. From a materials perspective, there are commonalities in the materials questions and challenges across different PV technologies. Whereas most PV technology is referred to by the absorber layer - e.g. silicon, or perovskite solar cells, other layers in the device are equally important to performance and durability. These layers are often composed of metal oxides, and are common across device technologies - for example, interfacial layers (such as charge transport layers, CTLs), and transparent conducting oxides (TCOs) used as electrodes.This work addresses materials oxide characterization and its relationship to materials and device performance and degradation across PV technologies.

Among the most promising PVs to date are two technologies with different levels of thin film incorporation: silicon heterojunction (SHJ) and perovskite PV. SHJ cells are part of the industrial Si PV portfolio, and perovskite cells are starting to be commercially produced after a decade of intensive research. However, there are well-known stability and cost limitations associated with each technology. Understanding the thin film materials science in these devices, and using that understanding to enhance device performance and stability is key to more reliable and cost effective electricity production.

Under practical aging conditions, careful materials-level characterization is required to understand the degradation mechanisms of these materials and the complex effects of aging on the multilayer system. This work details the effects of practical degradation challenges such as damp heat (DH) exposure and encapsulation degradation on the stability of inorganic metal oxides in both the SHJ and perovskite thin film photovoltaic architectures. For perovskite devices, $MAPbI_3$ films were deposited by spin coating onto a range of substrates and CTLs; substrates of glass and indium tin oxide (ITO) were paired with metal oxides (MOs) including MoO_X, NiO_X, and ZnO. SE and SEM were used to characterize the surface and bulk properties of the perovskite films. Results demonstrate that the underlying layers affect the rate of absorber degradation when exposed to heat and moisture.

Unencapsulated SHJ cells (a subset of which were exposed to low concentrations of acetic acid under an applied voltage) were aged under DH 85°C/85% relative humidity conditions. The contact-ITO interface was examined via optical profilometry (OP), spectroscopic ellipsometry (SE), and scanning electron microscopy (SEM). SHJ cells have interfaces unique to their architecture, namely the c-Si/a-Si:H and a-Si:H/ITO interfaces at the top of the device. Examining the degradation of unencapsulated SHJ cells and comparing those results to historical degradation profiles of encapsulated SHJ cells in addition to the simulated effects of acetic acid exposure will help to decouple the effects of encapsulation on ITO stability in this architecture. It is well known that ethylene vinyl acetate (EVA) encapsulation degrades and produces acetic acid upon exposure to heat and humidity. When under an applied voltage, even small concentrations of acetic acid can quickly corrode the contact-ITO interface, leading to decreases in efficiency and increases in series resistance of the cell. Here, XPS was used to monitor the changes in the front contact of the SHJ cells during DH and acetic acid exposure. Changes to the materials will be correlated to changes in device performance under the same aging conditions.

5:00 PM EN02.04.15
ZnS Buffer Layers: Novel Precursors for Aerosol-Assited Chemical Vapour Deposition Max Robson and Andrew Johnson; University of Bath, United Kingdom

The efficiency of thin film solar technologies continues to increase; most notably, that of copper indium gallium selenide (CIGS) which has demonstrated lab-scale conversion efficiencies comparable with crystalline silicon-based solar cells.(1) Marketing such technology also provides an alternative to cadmium telluride thin films which have unavoidably toxic properties. The same hazards can be avoided via the deployment of zinc-based buffer layer materials, in replacement of the popular cadmium sulfide. Alloys of zinc oxide and zinc sulfide, Zn(O,S), exhibit a tuneable bandgap such to facilitate alignment with respective solar absorbers. This tunability requires control of Zn/S stoichiometry whilst also exercising high uniformity during fabrication, and given the intricate nature of thin film architectures, controllable and scalable fabrication methods must be considered. In this vein, chemical vapour deposition (CVD) is a viable technique for thin film deposition as single-source precursors can afford stoichiometric control. However, given their thermal sensitivity, single-source metal chalcogenide precursors are ill-suited for conventional CVD methods requiring volatile precursors. Instead, aerosol-assisted chemical vapour deposition (AACVD) presents an attractive deposition process which circumvents this criterion by atomizing a solution of the appropriate precursor.
In this body of work, a novel single-source precursor design is explored as a basis for low-temperature deposition of metal chalcogenides via AACVD. A series of zinc thioamidate complexes is presented as potential precursors for the deposition of ZnS. Viability studies were conducted using thermogravimetric and NMR experiments. Viable precursor candidates give precedent for ZnO/ZnS co-deposition via AACVD for solar cell technology, and, more broadly, clean deposition of metal chalcogenide materials.

Improvement of Interface Quality Between Chalcogenide-Based Absorption Layer and Buffer Layer for Low-Cost Thin Film Solar Cells Yong Tae Kim, Jae Yu Cho and Jaeyeong Heo; Chonnam National University, Korea (the Republic of)

Orthorhombic tin sulfide (SnS) is a promising absorber material for thin-film solar cells (TFSCs) due to its ideal optical band gap of ~1.3 eV, non-toxic and relatively earth-abundant constituents, high absorption coefficient ($\geq 10^{-5}$), and the high theoretical limit of ~32%. To date, the cell efficiency has mostly

remained below 4% for SnS TFSCs, which is fairly low compared to its theoretical limit. The improvement in the efficiency of SnS is mostly hindered because of its low heterojunction quality with the CdS buffer layer.
This work reports the study on improving the heterojunction quality at vapor-transport-deposited (VTD) SnS absorber/CdS interface via an annealing process. The highest efficiency of ~4.3% with good long-term stability was achieved by optimizing the annealing conditions for the heterojunction interface. This improved performance was primarily attributed to the reduction in interface defects of the SnS/CdS heterojunction, which can occur either during the deposition of transparent electrodes (Al-doped ZnO) or direct annealing of SnS/CdS heterojunction at 300 °C. The enhanced heterojunction interface quality is well supported by the reduced reverse saturation current density and shunt conductance of the fabricated devices measured under dark conditions. Although the SnS/CdS device exhibits an efficiency of over 4%, significant short-circuit current loss, mainly due to recombination, was revealed by quantum efficiency and optical analysis. Admittance spectroscopy analysis shows the presence of numerous defect densities of Sn and S vacancies (〉 10^{17} cm^{-3}) in the VTD-grown SnS absorber. Here, a detailed analysis of the device's performance will be presented.

5:00 PM EN02.04.18
Surface Passivation and Detrimental Heat-Induced Diffusion Effects in RbF-Treated Cu(In,Ga)Se_2 Solar Cell Absorbers Amala Elizabeth[1,2], Sudhir K. Sahoo[3], Himanshu Phirke[4], Tim Kodalle[5], Thomas D. Kühne[3], Jean-Nicolas Audinot[6], Tom Wirtz[6], Alex Redinger[4], Christian A. Kaufmann[5], Hossein Mirhosseini[3] and Harry Mönig[1,2]; [1]University of Münster, Germany; [2]Centre for Nanotechnology (CeNTech), Germany; [3]University of Paderborn, Germany; [4]Université du Luxembourg, Luxembourg; [5]PVcomB/ Helmhotz-Zentrum Berlin, Germany; [6]Luxembourg Institute of Science and Technology, Luxembourg

The remarkable efficiency improvements of Cu(In,Ga)Se_2-based chalcopyrite thin film solar cells to more than 23 % in the past few years have been largely attributed to post deposition treatments (PDTs) of the absorbers with heavy alkali metal compounds such as KF, RbF and CsF [1]. Therefore, understanding the effect of alkali PDTs on the electronic properties and defect physics of the chalcopyrite absorber surfaces are of utmost importance in view of the p/n junction formation and device optimization of such solar cells. In the present work, we adopt a combined analytical approach using scanning tunneling spectroscopy (STS) with a lateral resolution in the nanometer-regime and X-ray photoelectron spectroscopy (XPS) to compare the defect electronic properties and chemical composition of RbF-treated and non-treated Cu(In,Ga)Se_2 absorber surfaces [2]. Our STS results show that RbF PDT is effective in passivating the electronic defect levels at the absorber surface, as indicated by the low differential conductance within the bandgap. This is achieved by preventing surface oxidation and the formation of In, Ga and Se oxides on RbF-treated samples, as opposed to bare Cu(In,Ga)Se_2 surfaces. The passivating effect of RbF PDT is confirmed by ab-initio density functional theory (DFT) calculations which show that the chalcopyrite surfaces after the PDT are significantly less prone to oxidation and the incorporation of oxygen into such surfaces is energetically less favored. Furthermore, our XPS data indicate the presence of chemisorbed Rb species on the surface with a bonding configuration similar to a $RbInSe_2$ bulk compound, which is the likely cause of the observed surface passivation. A quantitative analysis of the XPS data shows that the Rb coverage is only in the sub-monolayer regime. During device fabrication, the chalcopyrite absorber usually undergoes several heating steps. Hence, to understand the effect of heat on RbF-treated samples, they were investigated before and after annealing under ultra-high vacuum conditions up to 320 °C. Our measurements indicate that there is a homogeneous distribution of Rb on the surface both before and after annealing, albeit with an increased concentration at the surface after the heat treatment. This suggests that the heat treatment leads to elemental diffusion of Rb from the bulk to the absorber surface. Additional depth-resolved magnetic sector secondary ion mass spectroscopy (SIMS) measurements highlighted that this diffusion in the bulk occurs predominantly along the grain boundaries. Annealing the samples to temperatures higher than 100 °C is found to lead to the formation of metallic Rb species on the surface, which results in a significant increase in the electronic defect levels and/or surface dipole formation as shown by STS and XPS measurements. Thus, heat-induced diffusion of Rb towards the surface effectively degrades the surface and will likely cause the deterioration of the absorber-window interface due to increased recombination losses at the p/n-junction. Our results strongly suggest that RbF PDT is a double-edged sword, where in addition to its advantageous surface passivation effect, a potential detrimental effect needs to be considered, especially during further device fabrication steps (e.g. the sputter deposition of ZnO on RbF-treated Cu(In,Ga)Se_2 thin films) at elevated temperatures.

Quantifying V_{oc} Loss Pathways in Polycrystalline Solar Cells Marco Nardone, Eva Mulloy, Sakshi Gupta and Andrew Prostor; Bowling Green State University, United States

The power conversion efficiency of thin film photovoltaic (PV) devices has improved considerably over the past few decades, but thermodynamic limits and practical limits determined by device simulations suggest that there is yet significant room for improvement. In addition, the typically reported efficiency of champion devices represents the tail end of a wide distribution; narrowing that distribution is critical to the continued success of the thin film PV. An ongoing challenge is determining exactly where in the devices the greatest losses are occurring. Even in crystalline devices, identifying and quantifying the various loss pathways requires multiple test structures and characterization techniques. The difficulty is further exacerbated by the polycrystalline nature of thin film PV due to the presence of grain boundaries, incommensurate interfaces, a wide array of bulk deep defects, large band tails, various crystallite facets, nonuniformities, and uncertain dopant activation energies.

The goal of this work is to explore the possibility of developing a universal method for independently quantifying V_{oc} losses due to front interface, back interface, and bulk recombination mechanisms. If a universal approach is not feasible, then best practices and general guidelines will be developed. From a practical perspective, the scope of work considers determination of three key parameters: i) the effective front surface recombination velocity; ii) effective back surface recombination velocity; and iii) effective bulk lifetime. These parameters, while not exhaustive, are critical for diagnosing the regions of most significant performance losses and providing guidance for further improvement. Our approach is based on considering combinations of characterization techniques, test structures, and numerical simulations to minimize the coupling between the key parameters. Hypothesis testing of such decoupling will be done by employing numerical simulation of characterization techniques such as current-voltage as a function of temperature and intensity (JVTi), quantum efficiency (QE), capacitance-voltage (CV), time resolved photoluminescence (TRPL), and others. The role of band tails in V_{oc} loss, such as Urbach tails, will also be considered through analysis of sub-band gap features in photoluminescence (PL) data. Numerical simulations are conducted using the finite element method to solve to the semiconductor equations with time and temperature dependence and customized photogeneration scenarios. Cd(Se,Te) PV devices will be used as specific case study.

One approach considered so far employs a set of test structures, TRPL, and simulations in a sequential procedure to minimize the number of fitting parameters in each step. Three test structures are required: i) well-passivated double heterostructures (DHs) of various thicknesses (e.g. Al_2O_3/Cd(Se,Te)/Al_2O_3); ii) DHs of various thicknesses with one contact emulating the device back contact (e.g. Al_2O_3/Cd(Se,Te)/b.c); and iii) a complete device. Initial results from a thickness series of DHs quantified the front and back surface recombination velocities and the bulk lifetime. A challenge to this approach is maintaining consistent absorber properties while varying the DH thickness and between DHs and devices. Modifications to this approach and additional methods will be explored to spatially quantify recombination and identify regions of V_{oc} loss.

8:30 AM EN02.05.02

Interfacial Manipulation through Oxygen Management for 20%-Efficient Cd(Se,Te) Solar Cells Dengbing Li[1], Sabin Neupane[1], Chuanxiao Xiao[2], Manoj Jamarkattel[1], Adam Phillips[1], Michael J. Heben[1], Jonathan D. Poplawsky[3], David Cullen[3], Randy Ellingson[1] and Yanfa Yan[1]; [1]University of Toledo, United States; [2]National Renewable Energy Laboratory, United States; [3]Oak Ridge National Laboratory, United States

Bandgap gradient has been successfully applied in efficient Cu(In,Ga)Se_2 and Cu(Zn,Sn)Se_2 solar cells. However, this approach has not been realized in Cd(Se,Te) thin-film solar cells. Here, a facile strategy was proposed and demonstrated to incorporate the bandgap gradient in CdTe solar cells. The key to this achievement is proper oxygen management during the device fabrication, which is compatible to state-of-the-art CdTe production. Through oxygen management, a Cd(O,S,Se,Te) region with a gradient bandgap near the front junction can form without introducing any detrimental interface. With this bandgap gradient, the devices show significantly reduced nonradiative recombination and thereby demonstrated a record efficiency of 20.03%.

8:45 AM EN02.05.03

Minimizing Roughness Induced Optical Losses for a 4-Terminal CdTe/Si Solar Device John W. Keil[1], Bryan M. Cote[1], Vinodh Chandrasekaran[2], Andrei Los[2] and Vivian Ferry[1]; [1]University of Minnesota, United States; [2]First Solar, United States

CdTe/Si four-terminal tandem solar cells are a techno-economically advantageous option for high efficiency, low-cost photovoltaic cells. The tandem design reduces thermalization losses and can increase efficiency above commercial Si cells, and both junctions can be mass produced at relatively low cost. A four-terminal configuration provides flexibility in the electrical design of the tandem module, as the top and bottom cells avoid the current matching requirement that can limit performance. However, this configuration introduces significant optical challenges, as three high-transparency conductive layers and an insulating interlayer are required that all lead to increased parasitic absorption and reflection losses. This study uses a combination of experiments and simulations to characterize and understand CdTe roughness induced optical losses and provide strategies to increase optical coupling in the CdTe/Si four-terminal module.

The CdTe device stack is comprised of a planar front transparent conductive oxide (TCO) deposited on plate glass with a $CdSe_xTe_{1-x}$ absorber layer. A conformally grown back TCO serves as the rear electrode and adopts the roughness characteristics of the polycrystalline $CdSe_xTe_{1-x}$ absorber layer. Transmission measurements of the devices measured with UV-Vis spectrophotometry demonstrated that the sub-bandgap $CdSe_xTe_{1-x}$ module transmission was enhanced with reduced $CdSe_xTe_{1-x}$ roughness.

Surface height data from atomic force microscopy (AFM) measurements were incorporated into finite-different time-domain (FDTD) simulations of the $CdSe_xTe_{1-x}$ cell to capture the influence of roughness on the optical properties. The $CdSe_xTe_{1-x}$ transmission was modeled into air and into ethylene-vinyl acetate (EVA). The reduced index contrast by encapsulating the back TCO with EVA increases the transmission and through the $CdSe_xTe_{1-x}$ top cell by as much as 33%.

The dominant loss mechanisms preventing sub-bandgap $CdSe_xTe_{1-x}$ transmission were backscattering, reflection, front TCO absorption, and back TCO absorption. The optical losses are mitigated through decreased roughness and inclusion of the interlayer. The reflection and front TCO absorption are both controlled by the increased backscattering from the rougher back surface of the $CdSe_xTe_{1-x}$. Spatially resolved maps of the back TCO absorption show a non-uniform absorption profile with regions of light localization and absorption enhancement controlled by the surface topography. Mesoscale sized surface features create a focusing effect from constructive interference of the scattered and diffracted optical plane waves. The roughness induced regions of local absorption enhancement leads to the global enhancement of the back TCO absorption. The reduced index contrast with inclusion of the EVA does not eliminate the focusing effect but reduces the magnitude of the intensity enhancement. Simulations on an ideally flat surface indicated that planarizing eliminates the light localization and parasitic absorption enhancement.

Higher index optical coatings were also simulated to increase optical coupling in the tandem device. 1.7 and 1.9 refractive index optical coatings with finite thickness did not significantly increase the $CdSe_xTe_{1-x}$ transmission compared to just the EVA interlayer, but combining a 1.9 and 1.7 index film to create a graded index coating increased the sub-bandgap transmission by about 2% between 900 and 1000 nm.

This study describes how increased roughness and different interlayer materials influences the reflection, TCO absorption, and optical coupling in a CdTe/Si four-terminal tandem device, and demonstrates methods to mitigate losses and promote $CdSe_xTe_{1-x}$ transmission to the Si cell.

Modeling Recombination Junctions for Tandem Solar Cells Johan Lauwaert; Ghent University, Belgium

Thin film solar cells of the 2nd and 3th generation with CIGS, CdTe, CZTS and perovskite based absorber layers are very promising solar cell technologies. One of the main advantages comparing to silicon technologies are the limited materials consumption and the flexibility to deposit them on a variety of surfaces including flexible substrates. Both silicon, CIGS and perovskite solar cells have nowadays already a descent efficiency. To further improve the efficiency of solar cells scientists are often investigating their potential in tandem structures. This can be tandem structures with a thin film solar cell on top of silicon but also a combination of thin film technologies.
For monolithic solar cells not only the optical quality of the junction between both cells but also electrical losses need to be minimized. Traditionally in tandems based on III-V semiconductors this is done with tunnel junctions. However for the materials used as carrier selective contact in thin film solar cells creating heavily doped layers to enhance the tunnel probability is still questionable. Therefore recombination junctions are good candidates to fulfill the task of forming a good optical and electrical contact between the two solar cells. Nonetheless traditionally in modeling potential thin film tandem solar cells the cells are modeled individually and combined as a monolithic cell by connecting both IV curves in series and adjusting the irradiation spectrum of the bottom cell. This often results in an overestimate of the performance by not including the electrical losses in the connection in between. Many TCAD simulation packages are not including the possibility to add an interface defect that allows a direct coupling between the electron and hole currents from both sides via this recombination.

In this work we developed a theoretical model for the current voltage characteristics (IV) of a recombination junction in between solar cells. Based on this IV curve the voltage loss of a tandem solar cell with known IV curves for the individual solar cells is evaluated.
We implemented the equations for such a recombination defect in DeVSim TCAD software, which allows python scripting. These TCAD simulations allow to solve the continuity equations for holes and electrons for the whole tandem structure. This software package is used to calculate the efficiency of a 1D - Perovskite CIGS solar cell. These calculations show a good correspondence with our theoretical model. Based on these TCAD simulations the impact of the recombination junction and its properties on the performance of the a CIGS – Perovskite tandem solar cell is evaluated.

P-Type Doping and Phase Transformation of N-Substituted ZnSe1-xTex Thin Films Andriy Zakutayev and Sage Bauers; National Renewable Energy Laboratory, United States

N-doped ZnTe is a common p-type material with the valence band matched to CdTe absorber. The ZnSe1-xTex semiconductor alloys offer the potential to tune the valence band position to match other absorbers, however p-type doping if these materials is less explored. In addition p-type doping of these alloys would be beneficial for wide-gap absorber applications in photoelectrochemical CO2 reduction reactions for sustainable fuels.
This presentation will discuss N-doped ZnSe1-xTex thin films grown by RF sputtering from compound targets with N2 gas as a N source. Crystalline films form across a large range of growth conditions, with a p-type carrier density of p = 1e19 cm-3 and a carrier mobility of mu = 0.05 cm2/Vs determined by Hall effect, and verified by Seebeck coefficient measurements.
Surprisingly, some N-doped films there is a transformation from the usual zinc blende structure to wurtzite. Depending on the temperature and N2 flow rate during growth, wurtzite phase can be synthesized across most of the composition range, ranging from Te-rich (x ~ 0.7) to nearly pure ZnSe (x ~ 0.1). Density functional theory calculations suggest that dilute N concentrations help stabilize the wurtzite polymorph of ZnSe0.5Te0.5.
Ongoing progress towards controlling the p-type doping towards N:ZnSe1-xTex p-type contact applicaiton, and improving the charge trasnport properties of the ZnSe1-xTex alloys towards photoelectrochemical solar energy conversion, would be discussed in this presentation.

Nitrogen stabilizes the wurtzite polymorph in ZnSe1-xTe x thin films. Journal of Materials Chemistry C 2022. DOI: 10.1039/d2tc02716j

Examining Short-Range Order in $ZnSnN_2$-ZnO Alloys *via* STEM EELS Allison Mis[1], Celeste Melamed[1,2], Adele Tamboli[2], Raymond R. Unocic[3] and Geoffrey L. Brennecka[1]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States; [3]Oak Ridge National Laboratory, United States

Ternary pnictides offer a vast landscape of promising optoelectronic materials, many of which are composed of non-toxic, earth-abundant elements. Though many of these materials provide unique combinations of band gap and lattice constant compared to traditional semiconductors, making them of interest for multi-junction solar cells and other applications, their potential utility is magnified by the possibility of optical property tuning with cation ordering. This tunability could enable homoepitaxial stacks in which layers of the same material with differing degrees of ordering provide different optical properties without introducing performance-reducing crystalline defects.
One paradigm for examining cation ordering is “Short Range Order” (SRO), which examines the local bonding of the anion. For instance, in a system with the anion nearest-neighbor bonded to four cations, it is possible for those cations to be 2 of metal A and 2 of metal B, 3 A and 1 B, etc. Only some of these arrangements, or motifs, conserve the local octet rule, and the presence of octet-rule-violating motifs can strongly affect electronic and optical behavior of the material.
One system for which the SRO behavior has been examined is ZnSn(O,N). $ZnSnN_2$ has potential for application in photovoltaics, but nitride growth is often contaminated by oxygen, leading to a wurtzite $ZnSnN_2$-ZnO alloy. Computationally, it is predicted that $(ZnSnN_2)_{0.75}ZnO_{0.25}$ is capable of perfect SRO and that the ordered alloy would have a band gap ~0.3 eV above that of the disordered material at the same composition. [1]
This work expands upon previous study of $ZnSnN_2$-ZnO alloy thin films. These films were grown via RF co-sputtering and then in-situ annealed. Prior X-ray Absorption Near-Edge Structure (XANES) measurements of these films indicate differing degrees of SRO with differing in-situ anneal treatments. Prior optical measurements also show a shift in band gap similar to the shift predicted computationally. [2] In this work, cross sections of these films are examined using Scanning Transmission Electron Microscopy Energy-Dispersive Electron Spectroscopy (STEM EELS), specifically focusing on the near-edge fine structure of the oxygen and nitrogen peaks. Similarly to XANES, the near-edge structure of EELS is sensitive to bonding environment and can be related to the presence of various SRO motifs. In this work, peak shape and location is correlated to SRO.
STEM EELS provides several orders of magnitude improvement in spatial resolution over XANES, allowing for the study of SRO motif density across the film growth direction as well as across grain boundaries and other features. Here, variations in SRO among samples, as measured by EELS, are discussed and compared to XANES results, and spatial variation in SRO within each sample is assessed. Changes in anion bonding environment at grain boundaries are illustrated. This work also discusses the extraction of spatially-resolved bandgap from low-loss EELS and correlating bandgap and local SRO.
Microscopy research conducted as part of a user project at the Center for Nanophase Materials Sciences (CNMS), which is a US Department of Energy, Office of Science User Facility at Oak Ridge National Laboratory.

10:45 AM EN02.06.03
Quaternary Adamantine $CuAlC^{IV}X^{VI}_4$ – Crystal Growth, Structure and Properties Versus Ternary Chalcopyrite Yvonne Tomm[1], Joachim Breternitz[1] and Susan Schorr[1,2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Freie Universität Berlin, Germany

Adamantine-type compounds, including kesterites, are currently the most promising material for fully inorganic thin-film photovoltaic technology that is free of critical raw materials and thus offers sustainable solutions. To avoid indium and to find new compounds for absorber layers as well as window materials in thin film solar cells, the $A^{I}B^{III}X^{VI}_2$ chalcopyrite compound family is extended by chemical substitution to quaternary "defect adamantines" such as A^{I}-■-B^{III}-C^{IV}-X^{VI}_4 compounds. With band gap energies ranging from 1.42eV for $CuGaSnSe_4$ [1] to 2.34eV for $CuAlGeSe_4$ [1], the defect adamantines are interesting materials for photovoltaic applications.

Quaternary compounds of the Adamantine family are of type A^{I}_2-B^{II}-C^{IV}-X^{VI}_4 and A^{I}-■-B^{III}-C^{IV}-X^{VI}_4. Replacing one monovalent and one trivalent cation by one IV-valent cation in the chalcopyrite crystal structure and keeping the tetrahedral coordination, the quaternary compound A^{I}-■-B^{III}-C^{IV}-X^{VI}_4 with cation vacancies can be derived, the so called “defect adamantine”. These quaternary A^{I}-■-B^{III}-C^{IV}-X^{VI}_4 compounds crystallize in the chalcopyrite-type crystal structure (space group *I-42d*) or the cubic spinel-type structure (space group *Fd-3m*). The common feature of the cubic spinel structure and the tetragonal chalcopyrite structure is the tetrahedral coordination of the chalcogen, which is arranged in an (almost) cubic close spherical packing. In spinel, 1/8 of the tetrahedral voids are occupied by A^{I} cations and half of the octahedral voids are occupied by B^{III} and C^{IV} cations.
Starting from the ternary chalcopyrite $CuAlS_2$ and $CuAlSe_2$, we studied the group of defect adamantine with the general formula $CuAlC^{III}X^{VI}_4$ with C=Ge, Sn and X= S, Se.
Here we report on the growth of single crystals of these quaternary compounds such as $CuAlGeSe_4$, and $CuAlSnS_4$ and their structural as well as optoelectronic properties. The single crystals were grown by chemical vapor transport using iodine as a transport agent.
The evolved material and the crystals grown were characterized by X-ray diffraction (XRD) at 298K and LeBail analysis of the diffraction pattern. For $CuAlGeS_4$ and $CuAlSnS_4$, we determined the crystal structure to be the chalcopyrite-type (space group *I-42d*) and the cubic spinel structure (*Fd-3m*), respectively. The chemical composition of the crystals was determined by X-ray fluorescence.
The band gap energy was determined from the diffuse reflectance measured by UV-VIS spectroscopy.

Role of Ligand Exchange on the Optoelectronic Properties of $NaBiS_2$ Nanocrystals Yi-Teng Huang[1], Igal Levine[2], Hannes Hempel[2], Markus Schleuning[2], Marin Rusu[2], Artem Musiienko[2], Szymon Zelewski[1], Akshay Rao[1] and Robert Hoye[3]; [1]University of Cambridge, United Kingdom; [2]Helmholtz-Zentrum Berlin, Germany; [3]University of Oxford, United Kingdom

Ternary chalcogenides are gaining increasing attention for photovoltaics, and we recently showed $NaBiS_2$ to have intriguing properties, including $>10^5$ cm^{-1} absorption coefficient at its pseudo-direct bandgap of 1.4 eV[1]. As a result, the spectroscopic-limited maximum efficiency (SLME) of this material can reach 26% with an absorber thickness of only 30 nm. This demonstration was made with nanocrystals (NCs) coordinated with long-chain organic ligands, which allowed us to probe the bulk properties, but severely limited intra-NC transport. Furthermore, we found that the inhomogeneous distribution of Na^+ and Bi^{3+} cations, which both occupy the same crystallographic lattice site, results in the formation of S *p* states within the bandgap of $NaBiS_2$ and facilitates the formation of small hole polarons that intrinsically limit the bulk mobility of this material.

In this work, we examined whether the intra-NC and inter-NC charge-carrier transport could be improved through ligand engineering. We showed through FTIR measurements that the long-chain organic ligands used during synthesis were completely substituted by short LiI, NaI, KI, or TMAI (tetramethylammonium iodide) ligands dissolved in methanol. $NaBiS_2$ NC films treated by these iodides all showed surface photovoltage (SPV) under illumination, with enhanced sum mobility from OPTP (optical-pump terahertz probe) and TRMC (time-resolved microwave conductivity) measurements. Together, these measurements suggest an enhancement in intra-NC mobility following ligand exchange. However, OPTP measurements showed that the enhanced mobility in iodide-treated films still decayed by ~80% within 1 ps, suggesting that carrier localisation cannot be suppressed through ligand exchange treatment. Nevertheless, from TRMC measurements, we noticed that the residual mobility after localisation was higher than the non-treated samples, meaning that more carriers could be extracted. Solar cells based on these iodide-treated $NaBiS_2$ NC films have reached external quantum efficiencies exceeding 50%, but their power conversion efficiencies were still below 1%. We showed that, apart from the low photocurrents limited by carrier localisation, ion migration is another hidden limitation for $NaBiS_2$ devices. We finish with a discussion of possible routes forward to overcome these limiting factors.

Phosphorus-Rich Phosphides: A New Frontier for Thin-Film Photovoltaics Andrea Crovetto[1,2,3], Thomas Unold[3] and Andriy Zakutayev[2]; [1]Technical University of Denmark, Denmark; [2]National Renewable Energy Laboratory, Gabon; [3]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Certain phosphorus-containing III-V semiconductors (GaP, InP and related alloys) are among the best-performing PV absorbers. Yet, there is hardly any other phosphide material that has received extensive attention for applications in PV or optoelectronics in general. Exciting progress has been reported within the family of Zn-based phosphide compounds (Zn_3P_2, $ZnGeP_2$, $ZnSnP_2$ etc.), but high PV efficiencies are yet to be demonstrated.

In this contribution, I will discuss a radically different class of semiconductors that is quite unique to phosphides. They can be referred to as “P-rich phosphides”. In stark contrast to almost any other compound semiconductor previously investigated for PV applications, P-rich phosphides contain bonds between nonmetallic atoms (in their specific case, phosphorus-phosphorus bonds).

Due to their distinct bonding mechanisms, phosphorus-rich phosphides give us an opportunity to find new materials design routes for high-efficiency PV, potentially overcoming some of the design limitations of “standard” semiconductor featuring only metal-nonmetal bonds.
I will present the first successful thin-film synthesis [1] of any polycrystalline P-rich phosphide. The synthesized material is CuP_2, which is a 1.5 eV band gap semiconductor with strong optical absorption and native p-type doping in an attractive range for thin-film heterojunction solar cells.

Finally, I will highlight a recent computational screening study [2], in which five P-rich phosphides were identified as highly promising materials for PV. These new materials are still awaiting thin-film synthesis.

11:30 AM *EN02.06.06

Emerging Chalcogenide for Thin Films Photovoltaics Lydia H. Wong; Nanyang Technological University, Singapore

In this talk, I will present a brief review of emerging binary (i.e.Sb_2S_3, $Sb_2(S,Se)_3$ etc), ternary (i.e $CuSbS_2$, $AgBiS_2$, etc), and quaternary ($Cu_2ZnSn(S,Se)_4$ and its emerging derivatives) chalcogenides, focusing especially on the comparative analysis of their optoelectronic performance metrics, electronic band structure, and point defect characteristics with established CdTe and CIGS thin film PV [1]. We found that the performance of these emerging materials are limited by Voc deficit which arises from non-radiative recombination. The defects in emerging chalcogenide are generally attributed to the anisotropy in binary and ternary compounds or due to the structural complexity of quaternary compounds. Here, I will also share our strategy to facilitate directional growth of the higher mobility [hk1] planes of $Sb_2(S,Se)_3$ resulting in power conversion efficiency of > 9% [2]. I will also show the effect of Zn substitution in CXTS (where X is Mn,Mg,Sr,Ba,Ni,Co,Fe) on the structural, optoelectronic and photovoltaic properties [3]. We found that cation substitute must have d-orbitals to replace Zn and form a stable quaternary compound. The most promising Zn substitute is Cd as it passivates the Sn deep defects and resulted in an efficiency of ~8% for Cu_2CdSnS_4 device [4].

1:30 PM *EN02.07.01
CdTe Photovoltaics: Successes and Challenges James Sites; Colorado State University, United States

CdTe has fundamental advantages for photovoltaics that include its near-optimal band gap for the solar spectrum and the ability to keep its defect level small in thin-film applications. At the same time panels with CdTe as an absorber can be manufactured on a large scale at low cost and demonstrated long-term stability. These advantages have translated into major commercial success in the U.S. and to some extent in China as well. Recent areas of progress have been the effective use of a CdSeTe alloy layer, enhancement of the transparent front contact, higher voltage with an organic PTAA rear layer, high luminescence efficiency of the cell structure, development of semi-transparent panels, and progress towards bifacial performance. However, several significant challenges remain, and the combination of these is limiting the voltage of the cells. Most fundamental is the large valence-band energy of CdTe, which makes it difficult to contact the typical p-type material. In addition, doping to a desired hole concentration while maintaining the low defect level has been difficult, and the passivation of interfaces and grain boundaries in a completed cell has been only partially successful. Each of these issues has been showing improvement, but the overall challenge is to find the right combination of materials and processes that can be collectively optimized. Since this challenge may be too large for an individual laboratory, researchers at several locations have formed a consortium to combine facilities and experience to jointly increase the overall progress of the CdTe technology.

2:00 PM *EN02.07.03
Control of Doping for Efficient CdTe-Based Thin-Film Solar Cells Yanfa Yan; University of Toledo, United States

Cadmium telluride (CdTe) photovoltaic is the most cost-competitive thin-film photovoltaic technology due to its low manufacturing cost and high module efficiency. In the past decade, the power conversion efficiency (PCE) has been significantly improved. For most efficient CdTe solar cells and modules, doping with Cu or a group-V elements such as As is essential. Introducing the appropriate amount of dopants at the appropriate location is critical for achieving high PCEs. In this talk, we will discuss the situation of Cu and group-V doping via an ex-situ process, i.e., diffusion of dopants into $CdCl_2$-treated CdTe thin films. For Cu doping, we fabricated CdTe thin film solar cells using a metallic Cu source and ionic Cu sources (solution processed CuCl and $CuCl_2$). We found that the ionic Cu precursors offer much better control of Cu diffusion than the metallic Cu precursor. Therefore, we also used group V high ionic materials (i.e., group V chlorides, VCl_3 such as PCl_3, $AsCl_3$, $SbCl_3$, and $BiCl_3$) as dopant precursors in a solution method for ex-situ group V doping of CdTe films. Our ex-situ group V doped CdTe solar cells achieved V_{OC}s as high as that of Cu doped CdTe solar cells. We found that a low dopant density increases the carrier lifetime, while excessive dopants reduces the carrier lifetime. A higher dopant density near the back interface is beneficial for maximizing the fill factor of CdTe solar cells. For thinner CdTe absorbers, it is necessary to tune the doping process to optimize the cell performance.

2:30 PM EN02.07.04
Controlling Device Instabilities with i-ZnO Oxygen Content in Chalcogenide Solar Cells Alejandro Navarro[1], Alex Jimenez[2,1], Kunal Tiwari[2,1], Sergio Giraldo[1], Edgardo Saucedo Silva[1], Zacharie Jehl Li-Kao[1] and Marcel Placidi[1,2]; [1]Universitat Politècnica de Catalunya, Spain; [2]Institut de Recerca en Energia de Catalunya, Spain

Intrinsic zinc oxide (i-ZnO) is systematically used in combination with a buffer layer (generally cadmium sulfide) and a transparent conductive oxide (TCO) for the fabrication of the n-type side of thin film chalcogenide solar cells. However, despite this near ubiquitous empirical use, its role remains debatable. Moreover, a particularly intriguing factor regarding the performances is the role of oxygen content in the ZnO. Its concentration modifies mainly the oxide stoichiometry, conductivity and transparency. Oxygen is commonly used during the preparation of the transparent oxides, and allows improving the transmission to the detriment of the resistivity. While incorporating a little amount of oxygen during the TCO deposition is generally used for this reason , the role of oxygen in i-ZnO remains unclear but appears necessary to obtain a high resistivity layer, by preventing oxygen vacancies or zinc interstitials responsible of the n-type conductivity. Moreover, adding oxygen during the i-ZnO deposition could also affect the CdS buffer surface in a similar way as sputtered oxygenated CdS (CdS:O) commonly used in CdTe heterojunction solar cells, and could also reduce the film crystallinity, increase the optical bandgap, change the composition at the surface of the CdS and/or increase the defects density. As a result of these multiple interplays between oxygen content and film properties, the solar cells' performance are significantly impacted.
The work here presented brings insights on the role of the i-ZnO layer in the solar cell structure by investigating the effect of the oxygen incorporation during its preparation and its influence on the performance of the devices. By varying the oxygen ratio (from 0 to 15% of oxygen in the total gas mixture with Ar) during the i-ZnO deposition, several batches of solar cells (using both CZTS and CIGS absorbers) were prepared and characterized. Limited differences were observed in their optoelectronic properties, with all the oxygen ratios leading to comparable values under illumination. However, a clear difference was observed in the dark behaviour before illumination, with devices with high oxygen content requiring longer light soaking times to reduce instabilities. To highlight this instability, a series of J-V measurements in (1) dark, (2) red light, (3) white light and (4) again dark conditions was

performed in CZTSe devices. These measurements were made after keeping the samples in dark for several days to avoid any possible effects from light-sensitive defects states. A first J-V measurement in dark (dark1) was recorded followed by a red illuminated J-V curve (using a 550 nm long pass filter with a 1 sun 1.5 AM spectrum white light), then a 1 sun 1.5 AM illuminated curve and finally another dark J-V curve (dark2). All the measurements are shown in the figure 1, and put in evidence a charging mechanism with white light illumination, that is required to stabilize the devices. It will be shown during the presentation that this relates to ionized acceptor defects at both the CdS and CdS/i-ZnO interfaces, which are neutralized when photogenerated holes are created with UV absorbed photons. The potential role of oxygen vacancies in this behaviour will be discussed. These results demonstrate the importance of controlling the defects density at interfaces to reduce device instabilities. More interestingly, this photo-induced mechanism, which shows reversibility after dark discharging, could be further exploited into specific light-based memory devices, which will be the developed in another presentation of MRS Spring 2023.

3:30 PM *EN02.08.01
Fabrication of Characterization of PERC-Like CdTe Solar Cells Heayoung Yoon; University of Utah, United States

Remarkable progress has been achieved in CdTe photovoltaics (PVs) to improve cell performance while reducing manufacturing costs. At the best efficiency of 22 %, researchers have demonstrated the short-circuit current (J_{sc}) and fill factor (FF) close to the limit of their maximum values via band-gap engineering and front-contact optimization. Considerable efforts have been devoted to increasing the carrier lifetime and the doping density ($N_A > 10^{16}$ cm^{-3}) to improve the open-circuit voltage (V_{oc}) of CdTe-based solar cells. Recent studies suggested that the Voc improvement in polycrystalline CdTe PVs requires well-passivated back contact. One possible strategy is to engineer the band-gap offset (e.g., CdMgTe; $\triangle E_{CB} \approx 0.2$ eV) to reflect minority carrier electrons, thereby decreasing surface recombination. Another approach is to utilize a stable Al_2O_3 layer as an electron reflector; experimental works confirmed the improved performance with a conformal Al_2O_3 layer. In this configuration, the precise control of Al_2O_3 ($\approx$ 1 nm) over the entire CdTe layer is essential because the J_{sc} greatly depends on the tunneling current. While promising, both CdMgTe and fully covered Al_2O_3 passivation on CdTe introduce unfavorable valence band offset that blocks the hole transport.

Here, we describe the design and fabrication of PERC-like (passivated emitter and rear contact) CdTe solar cells. Conventional lithography and wet-etching processes were used to pattern variable hole arrays on 20 nm-thick Al_2O_3 coated $CdSe_{(1-x)}Te_x$ (CST) solar cells. The CST absorber materials were doped with traditional copper elements or group-V dopants (e.g., P, As, Sb; GrV). We performed quantitative and qualitative PV analysis for a series of Cu-doped and GrV doped PERC devices. In contrast to the similar behaviors of J_{sc} and FF, we show a significant difference in the V_{oc} behaviors for Cu-doped and GrV-doped CdTe PERC solar cells. The V_{oc} of GrV-doped CdTe PERC remains constant, whereas the V_{oc} of the Cu-doped PERC shows a radical decrease with an increase in the exposed CdTe area. The defect chemistry of GrV-doped CdTe can be significantly different from that of traditional Cu-doped CdTe absorber materials. We will discuss the possible mechanisms responsible for these Voc changes of the CdTe PERC devices.

4:00 PM *EN02.08.02
Zinc Phosphide: a Promising Material for the Next Generation of Solar Cell Absorbers Mirjana Dimitrievska[1,2] and Anna Fontcuberta i Morral[2]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]École Polytechnique Fédérale de Lausanne, Switzerland

The path towards the next generation of inexpensive and high efficiency solar cells is based on the utilization of earth-abundant, environmentally-friendly, and chemically stable materials. One promising candidate is zinc-phosphide (Zn_3P_2), with a direct bandgap of 1.5 eV, high absorption coefficient ($> 10^5$ cm^{-1}), and excellent air stability. This work will present an overview of recent key findings related to the engineering of Zn_3P_2 absorbers for incorporation into high-efficiency solar cell devices.

First part of the talk will focus on three different approaches for synthesizing high crystal quality Zn_3P_2 thin films. These will include monocrystalline layer growth using molecular beam epitaxy [1], selective area epitaxy [2] and Van der Waals epitaxial growth on graphene substrates [3].

The second part of the talk will showcase the tunability of zinc-phosphide functional properties achieved by variation in the compositional stoichiometry [4,5]. In this case, we will show how electron and X-ray diffraction and Raman spectroscopy, along with density functional theory calculations, point to the favorable creation of P interstitial defects over Zn vacancies in P-rich and Zn-poor compositional regions. Photoluminescence and absorption measurements show that these defects create additional energy levels at about 180 meV above the valence band. Furthermore, they lead to the narrowing of the bandgap, due to the creation of band tails in the region of around 10–20 meV above the valence and below the conduction band. These results are also corroborated with the transport measurements on Zn_3P_2 devices.

Finally, we will discuss the device architecture for a polycrystalline Zn3P2 thin film solar cell on an InP substrate with a 4.4 % conversion efficiency. We will show the dominant recombination mechanisms in the device using different techniques and identify the key factors that limit the device efficiency. Additionally, we will provide a perspective on the next-generation Zn_3P_2-based solar cells.

Crystallographic Structure and Point Defects vs. Efficiency and Stability in $Cu_2ZnSn(S,Se)_4$ Monograin Solar Cells (S/(S+Se)=0.8) Galina Gurieva[1], Kaia Ernits[2], Nikita Siminel[3], Alicia Manjon Sanz[4], Denis Sheptyakov[5], Maxim Avdeev[6], Melanie Kirkham[4], Dieter Meissner[2,7] and Susan Schorr[1,8]; [1]Helmholtz-Zentrum Berlin, Germany; [2]crystalsol OÜ, Estonia; [3]Institute of Applied Physics, Academy of Sciences of Moldova, Moldova (the Republic

of); [4]Neutron Scattering Division, Oak Ridge National Laboratory, United States; [5]Paul Scherrer Institute, Switzerland; [6]Australia's Nuclear Science and Technology Organisation, Australia; [7]Tallinn University of Technology, Estonia; [8]Freie Universität Berlin, Institute of Geological Sciences, Germany

In recent years quaternary chalcogenides have gained a lot of attention, especially the kesterite-type semiconductor compounds $Cu_2ZnSn(S,Se)_4$ (CZTSSe) which consist mostly of earth abundant and non-toxic elements. These compounds are a promising low-cost alternative absorber material for thin film solar cells due to their suitable criteria for photovoltaic applications: *p*-type semiconductor behavior, direct band-gap between 1.0-1.5 eV and absorption coefficient>10^4 cm^{-1}[1]. The record conversion efficiency of 13.5% reported for a CZTSSe based thin film solar cell was reached when the polycrystalline absorber layer exhibits an off-stoichiometric composition [2]. Deviations from stoichiometry cause intrinsic point defects (vacancies, anti-sites, interstitials), which determine the electronic properties of the semiconductor significantly [3]. It is agreed in literature that large band tailing observed in Cu-based kesterite-type semiconductors causes voltage losses limiting the efficiency of kesterite-based devices. The Cu/Zn disorder (Cu_{Zn} and Zn_{Cu} anti-sites in Cu-Zn planes at z=¼ and ¾), which is always present in these compounds [4,5], is discussed as a possible reason for band tailing. Conventional structural characterization is done with X-ray diffraction, but in the case of isoelectronic cations, like Cu^+ and Zn^{2+}, they are difficult to distinguish. Nevertheless, the neutron scattering lengths of Cu and Zn are different; by neutron diffraction we can distinguish between Cu^+ and Zn^{2+} site occupation in the crystal structure [4,5]. Kesterite-type based thin film solar cell technologies are mainly based on polycrystalline absorber layers, which makes it quite hard to correlate the crystallographic structure (determined via neutron diffraction) to the photovoltaic performance of these materials. A promising low-cost alternative technology uses CZTSSe monograins (single crystals of 50-100 µm size) which are fixed in a polymer matrix to form a flexible solar cell [6].

An in-depth analysis of neutron diffraction data provides information on the cation distribution in the crystal structure allowing the determination of the type and concentration of intrinsic point defects including a distinction between Cu and Zn [5]. On the other hand, neutron diffraction requires large sample volumes, thus kesterite monograins offer the unique possibility to correlate structural disorder in kesterite-type absorbers with device performance parameters.

We will present a detailed structural investigation of CZTSSe monograins with S/(S+Se)=0.8 based on neutron powder diffraction experiments, examining the influence of small changes in the chemical composition on the Cu/Zn disorder. We will show a correlation between all of the obtained knowledge on the chemical composition, the presence and types of secondary phases, the Cu/Zn disorder, the intrinsic point defects, the optical bandgap obtained from diffuse reflectance with the stability and efficiency of the respective devices. We will compare the “optimal” composition area of monograins with S/(S+Se)=0.8 to previously studied S/(S+Se)=0.6.

This work has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement no.952982. A portion of this research used resources at the Spallation Neutron Source, a DOE Office of Science User Facility operated by the ORNL. The authors gratefully acknowledge the PSI and the SINQ for providing us beamtime at the HRPT diffractometer and Australia's Nuclear Science and Technology Organisation (ANSTO) for providing us beamtime at the ECHIDNA diffractometer.

Opto-Electrical Characterization of Back Bandgap-Graded $Cu_2Zn(Sn_{1-x},Ge_x)Se_4$ Kesterite Thin-Film Solar Cells Romain Scaffidi[1,2,3], Guy Brammertz[3,1], Jessica de Wild[3,1], Denis Flandre[2] and Bart Vermang[3,1]; [1]Hasselt University, Belgium; [2]UCLouvain, Belgium; [3]imec, Belgium

CZTSSe kesterite materials constitute a promising candidate for thin-film photovoltaics, based on abundant and non-toxic elements. Despite their high absorption coefficient and tunable bandgap for either single or tandem junctions, they suffer from significant V_{oc} losses impeding their efficiency to level with competing technologies such as CIGS, CdTe and Perovskites. Two main culprits for this large V_{oc} deficit are electrostatic fluctuations and high density of bulk defects, highly dependent on the absorber composition typically considered as ideal within well-established Cu-poor and Zn-rich ranges. An increasingly popular solution to tackle these two loss mechanisms and boost V_{oc} is the alloying of Ge to substitute Sn, leading here to $Cu_2Zn(Sn_{1-x},Ge_x)Se_4$ (CZTGSe) compounds, the bandgap of which is tunable through conduction band level following the x=Ge/Ge+Sn ratio. This work focuses precisely on the opto-electrical characterization of Sn-Ge bandgap-graded CZTGSe solar cells at both the absorber and complete device levels.

A sequential process is implemented and optimized, involving first the physical evaporation of a CZTG metallic precursor stack, then pre-annealed in N_2 and finally selenized. We obtain CZTGSe absorbers with low surface roughness and acceptable grain size within a Cu-poor and Zn-rich composition range. They exhibit an average x ratio around 45%, with a clear Sn-Ge segregation appearing naturally during the annealing step that leads to x=70% at the back surface and x=20% at the front surface. This corresponds to a back bandgap gradient which should simultaneously improve carrier collection and limit interface recombination, similarly to state-of-the-art CIGS. Yet, the low carrier lifetime is likely limited by poor top surface quality with observed surface defects and ZnSe secondary phases.

Advanced electrical characterization is performed on complete CZTGSe solar cell samples to gauge the impact of this Sn-Ge back bandgap grading approach and detect potential loss mechanisms. An efficiency of 7.2% is attained, along with values of 484 mV, 34.5 mA/cm^2 and 43.3 % for V_{oc}, J_{sc} and FF, respectively. Even though the performance is lower than record kesterite devices, the J_{sc} value is close to the Shockley-Queisser (SQ) limit for a confirmed minimum bandgap of 1.18eV, probably due to the largely enhanced carrier collection by our back bandgap gradient design. However, our devices are affected by important V_{oc} and FF deficits, i.e. about 50% of their SQ limits, for which the analysis of dark and light IV curves suggest are mainly the consequence of high-density deep defects as well as dominant electrical parasitics. This is investigated more deeply via temperature-dependent admittance spectroscopy, enabling the identification of a relatively deep defect level at the CZTGSe/CdS interface with activation energy of 260 meV and capture cross section of the order of 10^{-16} cm^{-2}. Minority carrier recombination via this defect state is likely the explanation for the poor V_{oc} and FF values observed. SCAPS-1D simulations are well in agreement with these experimental findings and allow to highlight this interface loss mechanism as the main limiting factor in our samples.

Eventually, Ge inclusion into kesterites effectively permits bandgap gradient to boost carrier collection and approach SQ limits in terms of J_{sc}. However, our study reveals that performance is still largely restrained by V_{oc} and FF losses at the CZTGSe/CdS interface which should be here the first area of improvement. This is preliminarily attempted via front surface sulfurization, but further investigations are required whether it concerns the Sn-Ge bandgap gradient design or the top interface quality using chemical treatments or alternative buffer materials.

8:15 AM EN02.09.01
A Tale of Two Siblings, i.e., Silicon and CIGS Solar Cells, and Their Rear Surface Passivation Gizem Birant[1,2,3], Jessica de Wild[4,2,3] and Bart Vermang[2,3,4]; [1]Fonds Wetenschappelijk Onderzoek – Vlaanderen (FWO), Belgium; [2]Hasselt University, Belgium; [3]EnergyVille, Belgium; [4]imec, Belgium

Since the origin of thin-film (TF) solar cells, there has been an ongoing comparison between silicon (Si) and TF solar cells. It is a fact that there is much to compare. However, we believe that the vast history of Si solar cells taught us a lot and will continue to teach, as it is currently the most efficient sibling of photovoltaic (PV) technologies. The passivation (P) concept came into play for silicon solar cells around the 1980s, and then *really* slowly, the P concept, i.e., PESC, PERC, PERL, became the standard production design for Si PV and boosted the efficiency from ~16% to 25% [1]. These remarkable achievements, of course, took the attention of the younger sibling, TF PV technology. In 2013, Vermang et al. integrated the rear surface passivation concept into CIGS solar cells and improved the solar cell performance compared to the unpassivated ones [2]. This advancement led many researchers to look further into the passivation integration to the CIGS solar cells, including me. Here, we will present the industrially viable approaches to applying a rear surface passivation layer in ultrathin-film CIGS solar cells. As a passivation layer, first, we tried aluminum oxide (AlO_x) since it has been proven to be an excellent passivation layer for Si and CIGS solar cells. One challenge, though, is that this layer blocks the current; hence there should be contact openings in the passivation layer to allow current flow to the back contact or the applied layer must be thin enough to allow tunneling. To create the openings in the passivation layer, we simply added alkali halide salt, which is proven to be beneficial for CIGS solar cells [3], via spin-coating before CIGS growth [4]. During the deposition, depending on the type of salt, we achieved nano to micron-sized openings in the dielectric layers up to 30nm thick [5]. The succession of the AlO_x passivation layer leads us to investigate another potential dielectric layer candidate, the hafnium oxide (HfO_x). As a result, with the same simple contacting approach, the solar cells' efficiency is considerably enhanced [6]. The fact that via spin-coating, randomly distributed openings have been created in the passivation layer; we investigated whether it is an ideal way to apply the salt solution or not. For this, we benefitted from hyperspectral imaging and checked the homogeneity of the process and its effect on the solar cell performance [7]. Despite the addition of various passivation techniques, the efficiency of the CIGS solar cells is still not in line with the sector leader, Si solar cells. However, it took ~20 years for Si technology to accept the passivation concept's success and integrate it into the production process; as a younger sibling, we still have close to 15 years to learn, improve and adapt the passivation approach for CIGS solar cells. Furthermore, Si solar cells require a lot of energy during their production phase due to the wafer production process. Hence, its carbon footprint, i.e., CO_2 production, is remarkably high. The TF PV technologies, e.g., CIGS, perovskite or organic, on the other hand, do not require high deposition temperature, i.e., they have a rather low carbon footprint. Considering that we need to reduce our carbon footprint for a sustainable future, we believe that TF technology has a brighter future than other siblings.

Influence of Alkali Doping on the Grain Boundaries in CIGS Studied by Electrical and Capacitive Methods Aniela Czudek[1], Aleksander Urbaniak[1], Alexander Eslam[2], Roland Wuerz[2] and Malgorzata Igalson[1]; [1]Warsaw University of Technology, Poland; [2]Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg, Germany

Although the impact of alkali doping on the properties of CIGS solar cells has been a subject of ongoing debate for many years now, most research still focuses simply on the comparison between alkali-rich and alkali-free devices, without looking into the impact of the different alkali concentrations. We are convinced that in order to better understand the pathways of change and the specific factors impacting it, one has to study them over a broad range of different samples with controlled properties.

In this work, we present a systematic study of CIGS solar cells and corresponding thin films doped with a controlled concentration of sodium and potassium spanning three orders of magnitude. In case of thin films conductivity measurements were made, and on solar cells Deep Level Capacitance Profiling (DLCP) was used to estimate the doping level. Characterization of both cells and thin films together allows for further insight into the specific pathways of alkali impact – i.e. through distinguishing between the effects taking place on the interface and in the absorber – be it in its bulk or at the grain boundaries. Moreover, as the alkalis are known to segregate primarily on grain boundaries, a series of samples prepared with different evaporation methods, resulting in different grain sizes, were studied. Among all of these sample series, the dependence of conductivity, barrier height and free hole concentration on the alkali concentration (Na or K) follow a similar trendline, suggesting a common cause. One of effects that could lead to such result is the alkali-induced passivation of defects at the grain boundaries. As such, the values of energy barriers from conductivity measurements and the hole concentrations obtained from DLCP were then confronted with the results of 1D SCAPS simulations. The influence of donor defects at the grain boundaries on the barrier height and the average concentration of holes were studied. The simulation results were consistent not only qualitatively but also with good quantitative accuracy with the conductivity barrier heights and the free hole concentration values measured by DLCP.

All of those results point to the beneficial alkali effect being primarily linked to the passivation of donor defects and subsequent reduction of the energy barriers at the grain boundaries.

Development of Wide-Bandgap $Cu(In,Ga)Se_2$ Solar Cells by In-Line Co-Evaporation Wolfram Witte, Rico Gutzler, Wolfram Hempel, Stefan Paetel and Dimitrios Hariskos; ZSW, Germany

Chalcopyrite-type thin-film solar cells with bandgap energy (E_g) above 1.5 eV are ideal candidates for application as stable inorganic top cells in tandem devices. In recent years, the power conversion efficiency (PCE) could be increased for sulfide-based $Cu(In,Ga)S_2$ to 16.0% [1] and for pure $CuGaSe_2$ to 11.9% [2]. The implementation of a state-of-the-art post-deposition treatment (PDT) with heavy alkali elements like Rb or Cs resulted in an increased open-circuit voltage (V_{OC}) on wide-bandgap $Cu(In,Ga)Se_2$ (CIGS) with Ga/(Ga+In) (GGI) ratios above 0.7 [3]. Furthermore, the addition of Ag to wide-bandgap CIGS was demonstrated as a measure to reach higher V_{OC} values [4]. All these results were achieved with laboratory deposition coaters in a static mode. However, from an industrial point of view a fast and scalable in-line deposition process would be preferable for the growth of the wide-bandgap CIGS absorber by co-evaporation.

In this study, we present our results for wide-bandgap selenide-based CIGS solar cells deposited with an industrially relevant 30 × 30 cm^2 multi-stage co-evaporation system. So far, best cells with $E_g > 1.5$ eV achieved efficiencies up to 6% without RbF-PDT. After implementation of an in-line RbF-PDT the typical boost in V_{OC} and power conversion efficiency (PCE) could be obtained and best cells resulted in PCEs above 9%.

The solar cell performance strongly depends on the substrate temperature during CIGS growth and the choice of subsequent buffer and high-resistive layers. By exchanging the standard CdS/i-ZnO buffer layers with CBD-Zn(O,S)/(Zn,Mg)O, which is a good option for CIGS [5] and $Cu(In,Ga)(S,Se)_2$ [6] with E_g in the range of 1.0 – 1.2 eV, the V_{OC} gap between CdS- and Zn(O,S)-buffered wide-bandgap solar cells increased even further. Nevertheless, (Zn,Mg)O is a good partner for CdS and with this buffer combination we achieved a high V_{OC} of 899 mV for a CIGS cell with $E_g = 1.54$ eV (GGI = 0.83), resulting in an open-circuit voltage deficit (ΔV_{OC}) of 640 mV.

Moreover, we observe a gain in PCE as a result of slight Ag addition with low Ag/(Ag+Cu) ratios < 0.1 for CIGS absorbers with GGI > 0.6. Ag was incorporated by an additional evaporation source and these wide-bandgap $(Ag,Cu)(In,Ga)Se_2$ (ACIGS) solar cells exhibit increased FF values compared to the Ag-free CIGS reference samples. This observation was also made for our ACIGS cells compared to CIGS with standard GGI = 0.3, i.e. higher FF for Ag-containing samples. For high GGI values above 0.8, the Ag incorporation shifted E_g to lower values which resulted in an increased short-circuit current density and finally in an increased PCE which was accompanied by a slight increase in FF. We observe an increasing Na content in the bulk of the absorber with increasing AAC at GGI = 0.8, possibly due to altered absorber growth during deposition when more Ag is provided. Our best fully in-line prepared cell with a wide-bandgap ACIGS ($E_g \approx 1.5$ eV) achieved a PCE of 11.4% (without ARC). The corresponding V_{OC} and ΔV_{OC} values were 829 mV and 680 mV, respectively.

A minor reduction of E_g of about 0.2 eV to 1.34 eV (corresponding to GGI = 0.61), i.e. near the 2nd theoretical PCE maximum, resulted in a Ag-free CIGS cell with 18.2% PCE (with ARC) and a good V_{OC} of 856 mV with ΔV_{OC} = 480 mV.

Chemical and Electronic Structure of $(Ag,Cu)(In,Ga)(S,Se)_2$ Absorbers with Varying Ag/(Ag+Cu) Ratios and Their Interfaces with the Molybdenum Back Contact in Thin-Film Solar Cells

Dirk Hauschild[1,1,2], Luisa Both[1,1], Ralph Steininger[1], Elizaveta Pyatenko[1], Mary Blankenship[2], Wolfram Witte[3], Rico Gutzler[3], Dimitrios Hariskos[3], Michael Powalla[3], Clemens Heske[1,1,2] and Lothar Weinhardt[1,1,2]; [1]Karlsruhe Institute of Technology (KIT), Germany; [2]University of Nevada, Las Vegas (UNLV), United States; [3]Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg (ZSW), Germany

The introduction of alkali post-deposition treatments (PDTs) for $Cu(In,Ga)Se_2$ (CIGSe)-based thin-film solar cells has paved the way for efficiencies above 23 % on a laboratory scale.[1] For the next big step in solar-cell performance, new approaches need to be pursued. In recent studies, the incorporation of silver in CIGSe, i.e., forming $(Ag,Cu)(In,Ga)Se_2$ (ACIGSe), has been identified as a promising route.[2] The addition of Ag increases the absorber band gap, which could increase the open circuit Voltage (V_{OC}).[3] However, the impact of Ag on the chemical and electronic structure of the absorber surface, in particular with a PDT, is not yet understood.

In this contribution, we investigate in-line deposited and industrially relevant RbF-PDT ACIGSe absorbers and their interfaces with the molybdenum back contact as a function of the Ag/(Ag+Cu) (AAC)-ratio. For this purpose, the deeply-buried ACIGSe/Mo interface was accessed using sample cleaving and studied by synchrotron-based soft *and* hard x-ray photoelectron spectroscopy (PES and HAXPES, respectively), as well as laboratory-based x-ray and UV PES (XPS and UPS, respectively) and inverse photoemission (IPES). A detailed picture of the chemical and electronic structure of the ACIGSe surface and the ACIGSe/Mo interface as a function of the AAC-ratio is painted and will be discussed in view of the device performance.

9:15 AM EN02.09.05

Peculiar Bond Length Dependence and its Impact on the Band Gap Bowing in $(Ag,Cu)(In,Ga)Se_2$ Thin Film Alloys

Hans H. Falk[1], Stefanie Eckner[1], Konrad Ritter[1], Sergiu Levcenco[1], Timo Pfeiffelmann[1], Edmund Welter[2], Jes K. Larsen[3], William N. Shafarman[4] and Claudia S. Schnohr[1]; [1]Leipzig University, Germany; [2]Deutsches Elektronen-Synchrotron DESY, Germany; [3]Uppsala University, Sweden; [4]University of Delaware, United States

The incorporation of Ag into $Cu(In,Ga)Se_2$ absorbers enables a reduced deposition temperature, which benefits the growth of thin film solar cells. Furthermore, Ag alloying leads to a wider optical band gap and improves the open-circuit voltage and thus the photovoltaic conversion efficiency. Contrary to other semiconductor alloys, however, the band gap increase occurs even though the crystal lattice expands with increasing Ag content. Moreover, the Ga-Se bond length of $(Ag,Cu)GaSe_2$ is predicted by theoretical calculations to decrease with increasing Ag content [1]. This prediction is counterintuitive, since in other chalcopyrite alloys, for example $Cu(In,Ga)Se_2$, all bond lengths increase as the lattice expands [2]. To unravel this mystery, we studied the atomic-scale structure, especially the element-specific bond lengths, of $(Ag,Cu)GaSe_2$, $(Ag,Cu)InSe_2$ and $Ag(In,Ga)Se_2$ alloys using extended X-ray absorption fine structure spectroscopy (EXAFS). The thin films were grown on Mo-coated soda lime glass by a single stage co-evaporation process [3]. The average Ag-Se and Cu-Se bond lengths determined by EXAFS clearly increase with increasing Ag content in both $(Ag,Cu)GaSe_2$ and $(Ag,Cu)InSe_2$, whereas the Ga-Se and In-Se bond length decreases despite the expansion of the chalcopyrite lattice. Thus, $(Ag,Cu)GaSe_2$ thin film alloys indeed exhibit the counterintuitive bond length dependence predicted by theoretical calculations and $(Ag,Cu)InSe_2$ shows the same behavior. In contrast, $Ag(In,Ga)Se_2$ exhibits a bond length dependence similar to that previously observed for $Cu(In,Ga)Se_2$. This clearly demonstrates that the peculiar behavior of a decreasing bond length with increasing crystal lattice is related to the mixing of the group-I lattice site, independent of the nature of the group-III atom. Furthermore, the element-specific bond lengths determined by EXAFS enable us to model the anion positions of the different local motifs present in the alloys and to estimate their contribution to the band gap bowing. Our study thus provides unique and systematic insight into the local structure of the $(Ag,Cu)(In,Ga)Se_2$ alloy system, including its impact on a key material property.

9:30 AM *EN02.09.06
Developments in CIGS Energy Conversion Devices—From Solar Cells to Hydrogen Evolution Shogo Ishizuka; AIST, Japan

$Cu(In,Ga)Se_2$ (CIGS) and its derivative materials are versatile, as well as resource and cost-efficient and thus, attractive for photovoltaic energy conversion device applications. To date, we have developed lightweight and flexible $Cu(In,Ga)Se_2$ (CIGS) minimodules using a monolithically interconnected structure with independently certified photovoltaic efficiency values greater than 18% (number of cells: 17, designated area: 68 cm^2, without Ag or S alloying). This accomplishment was the culmination of techniques for controlling alkali-metal doping, the activation of metastable acceptors, and a minimodule fabrication process developed on flexible substrates. Modification of surface and interface, and bulk crystal quality by alloying with Ag or S, or other elements is expected to be a promising approach for further enhancements of the photovoltaic efficiency value. In addition, it has been suggested that mechanically scribed cell edges (equivalent to the side wall of P3 in the module fabrication process) can be an important factor in the degradation of device performance; therefore, there is room for improvement with proper passivation/termination treatments in the cell separation process. In fact, significant increases in the shunt resistance, fill factor (FF), and thus, photovoltaic efficiency values, and suppression of photovoltaic performance deterioration under low irradiance conditions were observed for CIGS solar cells fabricated using a photolithography-based cell separation process in lieu of a conventional mechanical scribing process.
Wide-bandgap CIGS-based photoabsorber materials are promising candidates for photocathode applications for the splitting of water into hydrogen as well as top-cell applications in tandem solar cells. We have demonstrated an over 8% half-cell solar-to-hydrogen (HC-STH) efficiency using ternary $CuGaSe_2$ (CGS)-based thin-films. This HC-STH value was demonstrated for a photocathode that underwent surface modification of CGS layer with RbF (q.e. not a postdeposition treatment). It has also been suggested that such surface modification of CGS thin-films with a Cu-deficient phase layer (CDL) may be effective in enhancing both the HC-STH and the open circuit voltage (V_{OC}) values of corresponding CGS solar cell devices. A CGS/CdS solar cell fabricated with a CDL demonstrated an independently certified photovoltaic efficiency value of 11.05% with a V_{OC} of 0.960 V, a short circuit current density of 15.9 mA/cm^2, and a FF of 72.4% (designated area: 0.497 cm^2, without RbF). These results suggest that improving wide-bandgap CIGS-based device performance requires different approaches from those used for conventional narrow-bandgap CIGS devices.

10:30 AM *EN02.10.01
A Comparative Study of the Influence of Ag Alloying on the Performance of CZTSSe and CZTS Monograin Layer Solar Cells Maarja Grossberg-Kuusk, Idil Mengü, Jüri Krustok, Mati Danilson, Maris Pilvet, Kristi Timmo, Katri Muska, Valdek Mikli, Reelika Kaupmees and Marit Kauk-Kuusik; Tallinn University of Technology, Estonia

With the aim to reduce recombination losses in the kesterite based solar cells, the Ag alloying was performed on $Cu_2ZnSn(S,Se)_4$ monograins, leading to the formation of $(Ag_{1-x}Cu_x)_2ZnSn(S,Se)_4$ (ACZTSSe) solid solution. Ag is known to partially replace Cu in ACZTSSe, reducing the influence of Cu-Zn disordering and improving the open circuit voltage (V_{OC}) of the solar cells. Controversial results on the influence of the substitution of Cu by Ag in kesterite thin films have been reported in the literature. However, Ag alloyed kesterite thin film solar cells have been shown to have improved performance due to the reduced defect concentrations compared to the pure $Cu_2ZnSnSe_4$ and Cu_2ZnSnS_4 absorbers. Recently, Yuancai Gong et al. reported 13 % efficient thin film solar cells based on Ag alloyed kesterite CZTSSe[1].
We have previously studied the influence of Ag alloying on the properties of $Cu_2(Zn,Cd)SnS_4$ monograin powders and on the performance of the corresponding monograin layer solar cells[2]. The incorporation of Ag into the $Cu_{1.85}(Zn_{0.8}Cd_{0.2})_{1.1}SnS_4$ monograin absorber material improved the efficiency of monograin layer solar cells from 6.62% (x = 0) to 8.73% (x = 0.01) resulting from the changes in the defect structure, which led to reduced non-radiative recombination losses in the absorber.
Here, we report the influence of Ag incorporation into the $Cu_2ZnSn(S,Se)_4$ monograins on the structural, optical and electrical properties of the absorber material as well as on the performance of the monograin layer solar cells. Various ratios of [Ag]/ ([Cu] + [Ag]) were used in the synthesis process and losses of outcome Ag concentrations in the resulting material compared to the input were observed. The formation of ACZTSSe solid solutions is determined by X-ray diffraction as well as Raman spectroscopy. Changes in the defect structure and related radiative recombination mechanisms were studied by temperature dependent photoluminescence spectroscopy and correlated to the defects detected by admittance spectroscopy of the corresponding solar cells. Reduced recombination of photoexcited charge carriers as well as improved device performance of the ACZTSSe compared to the CZTSSe monograin layer solar cell devices is reported.

Controlled Li Alloying of CZTSSe Absorbers by Electrochemical Treatment Simon Moser, Abdessalem Aribia, Ayodhya N. Tiwari and Romain Carron; Empa, Switzerland

$Cu_2ZnSn(S, Se)_4$ compounds, widely known as CZTSSe or kesterte referring to their crystal structure, are a promising material for thin film solar cells due to their composition out of non-toxic and earth-abundant elements and suitable optical and electronic properties . Yet, the performance of these solar cells is limited by defect-driven recombination, with the highest-ever reported power conversion efficiency being 13.6% so far. The properties and suitability for

PV application of thin-film kesterite absorbers are improved upon alloying with light alkali elements such as Li and Na, owing to defect passivation and increased carrier concentration. Moreover, Li alloying can be used to tune the absorber bandgap. However, the presence of light alkali elements, either added intentionally or diffused from the substrate, interacts with kesterite phase synthesis during annealing at high temperatures. As a consequence, Li-alloying in $(Li, Cu)_2ZnSn(S, Se)_4$ kesterite absorbers is limited to only a few percent of Li/(Li+Cu), before degraded morphology deteriorates the solar cell performances.

In this work we present an alternative strategy to incorporate controlled amounts of Li into crystallized kesterite absorbers, bypassing the alkali concentration limitations related to absorber synthesis. The Mo back contact of the spin coated and annealed CZTSSe absorbers is electrically connected to metallic Li and both are placed in a liquid electrolyte yielding a so-called half-cell configuration. Implementing this battery-inspired approach, we demonstrate the electrochemical treatment of CZTSSe and the successful transfer of Li into the absorber layer. We show that the treatment results in the incorporation of Li into the kesterite crystal grains, yielding alloyed $Li_xCu_{2-x}ZnSn(S,Se)_4$ absorbers with modified chemical composition. Using liquid electrolyte allows us to disassemble the half-cell after the treatment and deposit subsequent layers on top of the absorber to fabricate a working solar cell device with decent performance.

We present the benefits and limitations of our novel electrochemical Li alloying strategy based on morphological, structural, electrical, and optical characterization of treated absorbers layers and devices. We further discuss how this innovative approach could be combined with conventional alkali doping and alloying strategies in order to circumvent deteriorated solar cell performances related to the absorber synthesis in presence of high Li concentrations. Furthermore, the presented electrochemical approach opens new research directions, such as the investigation of ion migration in CZTSSe absorbers.

Identification and Performance Impact of Small Process Fluctuations in the Upsizing of Thin Film CZTSe/CdS Photovoltaic Technology Pedro Vidal-Fuentes[1], Fabien Atlan[1], Jacob Andrade-Arvizu[1], David Payno[1], Enric Grau-Luque[1], Alejandro Perez-Rodriguez[1,2] and Victor Izquierdo-Roca[1]; [1]IREC, Spain; [2]Universitat de Barcelona, Spain

Renewable energy production comes hand-to-hand with the development of suitable and future photovoltaic technologies, where large scale production depends on new concept thin film materials and device architectures, based on low cost processes and critical raw materials free, where $Cu_2ZnSnSe_4$ presents as a good candidate. In this context, it is a necessity to jump from small-scale laboratory sized cells to wider adaptable sizes, to achieve a plethora of different end applications, not only extensive (solar farms) but also for delocalized production (IoT, ViPV…), where the technological flexibility of the thin film technologies for the development of cells and modules with customized design is strongly relevant. The problems and difficulties of upscaling to a larger surface reveal themselves in an increased lateral inhomogeneity due to the increased ratio of area to cover vs thickness of the layers. The devices herein explored are based on a thin film structure, for the samples to perform properly, the layers need to present high quality and maintain their properties laterally, which is indeed a challenge, especially if the production cost has to be kept low. This challenge comes as a binary problem: the understanding of the specific physical or chemical phenomena, and the measurement of the effects of these variations in the final output of the PV devices. Usually, subtle variations, like thickness oscillations or compositional shifts, are unobserved at a small scale, because the process fluctuations can happen in areas larger than the measured cell, and finally define or limit the output of a device.

In this research a set of 3 samples (5x5 cm^2) are studied as the initial step for large-scale production of $Cu_2ZnSnSe_4$ devices. Each sample is isolated in 3x3 mm^2 individual cells, which permits to achieve a complete data library that aids to obtain a considerable amount of cell by cell information to implement statistical analysis. In those devices (3x3 mm^2), several characterization techniques are employed comprising: Raman spectroscopy (RS) with λ_{ex} = 442 and 532 nm; photoluminescence (PL) with λ_{ex} = 325, 442 and 532 nm, temperature dependent PL (PL-T) with λ_{ex} = 442 nm; current voltage characteristics (J-V); and image analysis. With the combination of those techniques, we can extract how the physicochemical properties of the front interface layers CZTSe/CdS/ZnO/ITO in the device architecture affect the final output of the device or influence each other. The data library is then composed of 3 x 196 cells that are analyzed as one complete dataset, where statistical correlations and small variations arise between the cells with some insightful results. Fluctuations are found in the CdS buffer layer as small thickness variations, bandgap changes and non-uniform defect energies. These variations of the CdS layer turn out to be strongly correlated to the final efficiency of the individual cells and define the observed patterns in optoelectronic performance along the surface of the 5x5 cm^2 samples, which also reflects in the visual appearance of the sample. These small changes, intrinsic to the processes, otherwise unseen in a discrete set of small samples or a set with strong variations in one of the fabrication steps (i.e. different samples with different absorber synthesis temperatures), imply strong modifications in the final efficiency of the individual devices, which are usually not perceived due to the low statistical significance of the data sets, this could potentially shadow or misguide the results of experiments and thus hamper progress in the development of these complex structures. In addition, the correlations found can be used as a quality control parameter in the fabrication of CZTSe modules, with simple approaches like visual inspection, applied in-line in the process.

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 952982 (Custom-Art)

Enhanced Carrier Collection in Cd/In-Based Dual Buffers in Kesterite Thin Film Solar Cells from Nanoparticle Inks Stephen Campbell[1], Guillaume Zoppi[1], Leon Bowen[2], Matthew Naylor[1] and Yongtao Qu[1]; [1]Northumbria University, United Kingdom; [2]Durham University, United Kingdom

Increasing the power conversion efficiency (PCE) of kesterite $Cu_2ZnSn(S,Se)_4$ (CZTSSe) solar cells has remained challenging over the last decade, in part due to V_{oc}-limiting defect states at the absorber/buffer interface. Previously, we found that substituting the conventional CdS buffer layer with In_2S_3 in CZTSSe devices fabricated from nanoparticle inks produced an increase in the apparent doping density of the CZTSSe film and a higher built-in voltage arising from a more favourable energy band alignment at the absorber/buffer interface. However, any associated gain in V_{oc} was negated by the introduction of photo-active defects at the interface (Campbell *et al.*, J. Appl. Phys 127, 205305, 2020). This present study incorporates a hybrid Cd/In dual buffer in CZTSSe devices which demonstrate an average relative increase of 11.5% in PCE compared to CZTSSe devices with standard CdS buffer, with the best performing dual buffer device ($CZTSSe/CdS/In_2S_3$) achieving 7.8% PCE (compared to 5.9% PCE in the $CZTSSe/In_2S_3/CdS$ hybrid buffer device). Spectral response measurements of hybrid buffer devices confirmed the presence of photo-active interface defects when the In_2S_3 buffer is adjacent to the CZTSSe absorber. Current density-voltage analysis using a double diode model revealed the presence of i) a large recombination current in the quasi-neutral region (QNR) of the CZTSSe absorber in the standard CdS-based device, ii) a large recombination current in the space charge region (SCR) of the hybrid buffer $CZTSSe/In_2S_3/CdS$ device and iii) reduced recombination currents in both the QNR and SCR of the $CZTSSe/CdS/In_2S_3$ device. This accounts for the notable 9.0% average increase in J_{sc} observed in the $CZTSSe/CdS/In_2S_3$ in comparison to the CdS-only CZTSSe solar cells.

Energy dispersive X-ray (EDX), secondary ion mass spectroscopy (SIMS) and grazing incidence X-ray diffraction (GIXRD) compositional analysis of the CZTSSe layer in the three types of kesterite solar cells suggests there is diffusion of elemental In into the absorbers with a hybrid buffer. In incorporation into the CZTSSe absorber increases the doping density of the SCR in the absorber. In diffusion arises from the post-deposition heat treatment (PDHT) of the hybrid buffer layers following their successive chemical bath depositions. When the In_2S_3 buffer is adjacent to the absorber of the hybrid buffer devices it is subjected to a double PDHT which greatly increases In incorporation into the absorber. As a result, the doping density in this absorber reaches 10^{17} cm^{-3} which negatively affects device performance. However, in the $CZTSSe/CdS/In_2S_3$ device, the single PDHT of the In_2S_3 layer is sufficient to increase the doping density of the SCR region of the CZTSSe without adversely affecting overall device performance.

It is expected that optimisation of the thickness of the hybrid buffer layers will lead to further improvements in device performance. These hybrid In_2S_3/CdS buffers provide a promising way to boost the efficiency of kesterite CZTSSe solar cells.

SESSION EN02.11: Tandem II
Session Chairs: Jessica de Wild and Johan Lauwaert

1:30 PM *EN02.11.01
Design and Optimization of Perovskite / CIGS Tandem Solar Cells Philip Schulz; Centre National de la Recherche Scientifique, France

Tandem photovoltaic devices based on CIGS and perovskite solar cell (PSC) sub-cells offer the implementation of all-thin-film tandems with all the advantages of thin-film technology, together with the possibility to achieve high efficiencies above the thermodynamic limit of single-junction solar cells. More precisely, the CIGS/perovskite tandem solar cell technology allows for low cost, light-weight, large area roll-to-roll fabrication and lower integration and installation costs, finally promising lower energy costs compared to current technologies. To this date, record power conversion efficiencies of over 24% and 27% have been achieved for monolithic two-terminal (2T) and stacked four-terminal (4T) tandems, respectively.
The crucial step for coupling CIGS and PSC devices in one tandem cell lies in the optimization of the layer stack with respect to light management and current collection, which include the growth of the transparent electrode layers. These requirements become even more stringent in monolithic 2T tandems, where cell performance requires current matching between top and bottom cells. This means that in particular for the CIGS cell we need to tailor the photoactive band gap to make optimum use of the partial illumination in the spectral region above ~750 nm wavelength, which is transmitted through the perovskite cell stack. One means to realize a beneficial trade-off between gains in the open circuit voltage and losses due to reduced photoabsorption is by the design of band gap grading, i.e. Ga in-depth distribution in the CIGS absorber film.
Hence, our approach to achieve high performance monolithic interconnected perovskite/CIGS 2T tandem solar cells rests on four major building blocks. (i) The adaptation of the CI(G)S bottom cell including control over the surface roughness, (ii) growth and optimization of the PSC layer stack on top, notably with focus on the hole transport layer, (iii) the design of the tunneling/recombination junction connecting the two sub-cells, and (iv) the implementation of light management structures for improved current matching.
All these tasks involve a dedicated focus on the control and analysis of the interfaces in each sub-cell and between the two cells, which will be the focus on my talk. I will lay out our methodology to assess the interface chemistry and the effect on its optoelectronic properties and functionality in the device. This point is particularly relevant for the optimized PSC and significantly affects the overall device performance and stability.

2:00 PM EN02.11.02
Perovskite/CIGS Tandem Solar Cell with an Efficiency Over 25% via Optimization of CIGS Bandgap Grading Hojin Lee, Passarut Boonmongkolras, Jaehyuk Koh, Chaeyoun Kim and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

By stacking two or more solar cells in a tandem configuration, the solar cell can more efficiently utilize the solar spectrum, and power conversion efficiency (PCE) is much higher than the Shockley-Quessier limit of single junction solar cells can be obtained. Theoretical calculations on tandem solar cells have predicted an ideal combination of ~1.1 eV and ~1.7 eV as suitable bottom and top cells, respectively. Wide bandgap perovskite and Cu(In, Ga)Se_2 (CIGS) are ideal materials for tandem solar cells, which carried out the theoretical calculations assuming that both the efficiencies of top and bottom cells reach the Shockley-Quessier limit. However, in reality, deviation from the Shockley-Quessier limit is more significant for a wider bandgap perovskite. Therefore, we adopted perovskite with a narrower bandgap than the ideal value (~1.7 eV) for tandem solar cells with CIGS. As the bandgap of perovskite was reduced, a CIGS bottom cell's bandgap must also be reduced for better current matching. Ga content can lower the overall bandgap of CIGS by precise control during deposition. Typical high-performing CIGS includes the so-called double grading bandgap profiles in which the bandgap first reduces with the thickness and opens up towards the front interface with n-type CdS buffer layer; however, it has not been confirmed whether the double-grading, which was optimized for single-junction CIGS solar cells, is still the best option for tandem solar cells. In this study, we controlled the bandgap profile of CIGS and compared single- and double-grading configurations of CIGS with a similar overall bandgap for applications to tandem solar cells with perovskite. Our investigation on the CIGS bottom cell under red light-filtered (i.e., wavelength smaller than 825 nm) illumination to mimic actual conditions during the operation of perovskite/CIGS solar cells showed that single-graded CIGS have a higher fill factor value than the double-graded counterpart. With further optimization of the monolithic tandem devices, we achieved PCE of 25.1% using perovskite of 1.65 eV and CIGS of 1.04 eV. Our study highlights the importance of bandgap tuning perovskite/CIGS tandem solar cells.

2:15 PM EN02.11.03
Steric Engineering Enables Efficient and Photostable Wide-Bandgap Perovskites for All-Perovskite Tandem Solar Cells Jin Wen and Hairen Tan; Nanjing University, China

Metal-halide perovskites are of tremendous interests for both single-junction and multi-junction photovoltaic devices due to their easy bandgap tunability via composition engineering. Perovskites possess long carrier diffusion lengths and high defect tolerance, enabling low-cost and solution-processed solar cells. To date, the power conversion efficiency (PCE) of single-junction perovskite solar cells (PSCs) has reached a certified value of 25.7%, which approaches that of crystalline silicon solar cells.
Monolithic all-perovskite tandem solar cells have the promise to deliver higher PCEs than do single-junction PSCs while maintaining the benefits of low-cost solution processing. Wide-bandgap (WBG, ≈1.8 eV) perovskite is a crucial component to pair with narrow-bandgap perovskite in low-cost monolithic all-perovskite tandem solar cells. However, the stability and efficiency of WBG PSCs are constrained by the light-induced halide segregation and by the large photovoltage deficit.
In this presentation, I will discuss our recent progress on a steric engineering that obtains high-quality and photostable WBG perovskites (≈1.8 eV) suitable for all-perovskite tandems. By alloying dimethylammonium and chloride into the mixed-cation mixed-halide perovskites, wide bandgaps are obtained with much lower bromide contents while the lattice strain and trap densities are simultaneously minimized. The WBG PSCs, with a considerably improved PCE of 17.7% and an increased Voc of 1.26 V, exhibited superior operational stability and maintain 90% of their initial PCEs after 1000 h operation at the maximum power point (MPP). With the triple-cation/triple-halide WBG perovskites enabled by steric engineering, a stabilized power conversion efficiency of 26.0% in all-perovskite tandem solar cells is further obtained. The strategy provides an avenue to fabricate efficient and stable WBG subcells for multijunction photovoltaic devices.

2:30 PM BREAK

SESSION EN02.12: Novel and Emerging II
Session Chairs: Byungha Shin and Andriy Zakutayev
Thursday Afternoon, April 13, 2023
Moscone West, Level 2, Room 2002

3:30 PM *EN02.12.01
Novel (Sb,Bi)(S,Se)(Br,I) van der Waals Chalco-Halide Thin Film Photovoltaics—Current Status and Future Perspectives Ivan Caño Prades, Alejandro Navarro, Edoardo Maggi, Maykel Jiménez Guerra, Cibrán López Álvarez, Sergio Giraldo, Marcel Placidi, Zacharie Jehl Li-Kao, Claudio Cazorla, Josep-Lluís Tamarit, Joaquim Puigdollers and Edgardo Saucedo Silva; Universitat Politècnica de Catalunya, Spain

Quasi one-dimensional (Q1-D) structures based on van der Waals materials such as $(Sb,Bi)_2(S,Se)_3$ have demonstrated impressive progresses over the past 5 years. These types of materials typically form nano/micro-ribbons with strong covalent bonding in one direction, and at the same time, weak van der Waals bonding in the others two. This fingerprint feature confers unusual optoelectronic properties to these materials when properly oriented, and has allowed fast progresses in terms of conversion efficiency of solar cell devices, with a current record exceeding 10%. Beyond Sb and Bi-chalcogenide compounds, there is a limited body of knowledge on other Q1-D systems such as mixed chalco-halide van der Waals compounds, that combine chalcogens (S,Se) with halogens (Br,I) in the same structure. In fact, recent theoretical studies suggests that mixed chalco-halides can simultaneously achieve the robustness and stability of chalcogenide materials, along with the excellent optical and electrical properties of halides, and in particular showing high defect tolerance similarly to halide-perovskites.

This presentation will introduce a novel family of materials based on mixed Sb and Bi chalco-halides [(Sb,Bi)(S,Se)(Br,I)]. The first part will be devoted to reviewing the most relevant results reported so far for the few examples available in the literature, that have reached encouraging conversion efficiencies around 5% within a very limited timeframe, with a meso-porous solar cell configuration. In addition, the fundamental properties of these compounds obtained by DFT modelling will be discussed. The calculation of the bandgaps, band structures, optical and transport properties will be presented, discussing the trends of these properties depending on the chalcogen or the halogen introduced into the structure. The results will show that all these compounds can be relevant for different thin film photovoltaic applications, with bandgaps ranging from 1.6 eV for SbSeBr up to 2.3 eV for BiSBr.

In the second part of the presentation, the complexity of the synthesis of mixed chalco-halides will be discussed, and a new methodology for their synthesis, developed by the authors of this work, and based on the combination of co-evaporation of chalcogenides and high-pressure reactive annealing under halogen atmosphere, will be presented. This methodology allowed for the first time the demonstration of working solar cells with absorbers produced by vapor deposition techniques with these compounds. The tunability of the Q1-D structures by changing the synthesis temperature and pressure will be demonstrated. It will be shown that the synthesis of bromine-based compounds requires higher temperatures and pressures than iodine ones, due to the thermodynamics associated with the incorporation of Br and I in the chalcogenide phase. A detailed analysis of the mechanisms behind the formation of the different compounds will be presented by implementing interrupted-synthesis processes, and supported by the combination of thermo-gravimetric analysis, differential scanning calorimetry, and advanced structural/compositional characterizations.

The last part of the presentation will be devoted to the challenges and possible technological solutions for the fabrication of planar-heterojunction solar cell devices with these innovative photovoltaic absorbers. The use of different electrons and holes transport layers will be discussed, demonstrating for the first-time conversion efficiencies with these architectures between 1-5% and with very encouraging Voc values above 600 mV in some cases. Finally, the perspective of these materials and the possible advantages with respect to current chalcogenide and halide technologies, will be presented and discussed.

4:00 PM EN02.12.02
Bismuth Oxyiodide as a Nontoxic, Air-Stable Perovskite-Inspired Material for Energy Harvesting and Solar Fuels Robert Hoye; University of Oxford, United Kingdom

Although halide perovskites have taken the photovoltaics field by storm, concerns over the toxic and easily accessible lead content have prompted a search for lead-free alternatives. Bismuth-based compounds have particularly gained attention, owing to their electronic similarities to lead, but advantages of being free from the same toxicity limitations [1]. This talk focuses on our recent work on one of these materials: BiOI.

BiOI is not a perovskite, but replicates important features of the electronic structure of lead-halide perovskites that are believed to be conducive to defect tolerance. We show through computations and experiment that BiOI indeed tolerates the dominant vacancy and anti-site defects. Whilst the bandgap of BiOI (1.9 eV) is too wide for single-junction photovoltaics, we show that it is optimal for indoor light harvesting for sustainably powering Internet of Things (IoT) devices [2], and also suitable for solar energy harvesting as a photocathode for water splitting [3]. In the latter work, we develop a device structure that improves the operational stability of BiOI photocathodes from minutes to months, and combine these devices with $BiVO_4$ photoanodes to realise the first demonstration of all-oxide-based bias-free syngas production [3]. We also show this device structure to be beneficial for other novel halide photocathodes, such as lead-halide perovskites [4]. We finish off with a discussion of the key factors limiting charge-carrier transport and Urbach energies in BiOI, and how these could be overcome by tuning the composition and structure of this material.

4:15 PM EN02.12.03
Aerosol-Assisted Chemical Vapour Deposition of $BiVO_4$ Photoanodes for Light-Driven Water Splitting Thom Harris-Lee[1,2], Matthew Surman[3], Andrew L. Johnson[1] and Frank Marken[1]; [1]University of Bath, United Kingdom; [2]Monash University, Australia; [3]ASM International, Finland

Bismuth vanadate ($BiVO_4$) is an outstanding candidate for visible-light driven water splitting due to its low production cost, high stability, low toxicity, and reasonable band gap with well-placed conduction and valence band edges relative to both hydrogen and oxygen evolution potentials.[1] In this presentation, the development and application of new and novel precursor systems tailor-made for the dual-source aerosol-assisted chemical vapour deposition

(AACVD) of highly nanostructured, phase-pure monoclinic-scheelite BiVO$_4$ thin films is outlined. Having identified the 'best in show' precursors for AACVD application, the BiVO$_4$ thin film deposition conditions are optimised for the most suitable precursor ratios and deposition temperatures for high quality films, with variations in nanostructure as a function of deposition time also being investigated in parallel by scanning electron microscopy (SEM). Light-driven water splitting performance is then evaluated using standard techniques including UV/Vis spectroscopy, linear sweep voltammetry under simulated sunlight irradiation, incident photon-to-current efficiency (IPCE) measurements, chronoamperometry, and electrochemical impedance spectroscopy (EIS). Pristine BiVO$_4$ films yielded photocurrent densities of 1.23 mAcm^{-2} at 1.23 V vs RHE, the highest photocurrent density of any CVD-grown BiVO$_4$ film to date.

The potential of AACVD for semiconductor doping and hybridisation studies are discussed, most importantly the compatibility of new metal precursors with existing ones. This is exemplified by the facile deposition of W-doped BiVO$_4$ without adding complexity or steps to the process. This work provides a roadmap in which an effective 'toolbox' of cross-compatible metal precursors can be rapidly deployed with AACVD to fabricate a range of doped and/or mixed-metal materials with high photocatalytic performance.

Cation Disorder in Emerging Ternary Chalcogenides Absorbers (I-III-S$_2$; NaBiS$_2$ & AgBiS$_2$) Seán R. Kavanagh[1,2], Yi-Teng Huang[3], Robert Hoye[2], David O. Scanlon[1] and Aron Walsh[2]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]University of Cambridge, United Kingdom

I-V-VI$_2$ ternary chalcogenides have recently attracted growing attention as earth-abundant, nontoxic, and air-stable absorbers for photovoltaic applications.[1,2] In particular, our recent work on the NaBiS$_2$ & AgBiS$_2$ members of this family has revealed ultra-strong optical absorption for these compounds – *the highest of all current PV materials*.[3] A key benefit of such intense light absorption is that it allows for ultrathin (<100 nm) solar cell devices, dramatically reducing material consumption, weight and manufacturing demand, directly lowering the cost and facilitating applications in space for example, in addition to benefitting quantum efficiency and photovoltaic (PV) performance.

Our collaborative work on AgBiS$_2$[3] showed the crucial importance of controlling cation distribution and disorder in these materials, yielding record-breaking efficiencies >9% – the highest of any Bi-based solar absorber.[3] However, the impact of disorder on the charge-carrier properties in these materials is remains poorly understood. Herein, we investigate the key properties which dictate the relationship between disorder on the cation sublattice and carrier transport in these materials. We find the band-edge orbital character to be a crucial factor in the sensitivity of carrier localisation (and thus solar cell efficiency) to cation disorder, resulting in ultra-fast carrier trapping, despite slow carrier recombination, in NaBiS$_2$.[4] We extend this analysis by explicitly calculating the phononic properties of these compounds, alongside Inelastic Neutron Scattering (INS) measurements, to probe the carrier de-population process in these compounds.

This work reveals the critical role of cation disorder in the photovoltaic performance of these disordered inorganic PV compounds, alongside key considerations for future research in this area.

4:45 PM EN02.12.05

Innovative Low Dimensional SbSeI Micro-Scale Devices for Photovoltaics Ivan Caño Prades[1,2], Alejandro Navarro[1,2], Edoardo Maggi[1,2], Simon A. Svatek[3,4], José Ignacio Delgado Castaño[3], Carlos Bueno Blanco[3,4], Elisa Antolín Fernández[3,4], Shunya Yan[5], Esther Barrena[5], Joaquim Puigdollers[1], Marcel Placidi[1] and Edgardo Saucedo Silva[1,2]; [1]Universitat Politècnica de Catalunya, Spain; [2]Barcelona Research Center in Multiscale Science and Engineering, Spain; [3]Universidad Politécnica de Madrid, Spain; [4]Instituto de energía solar, Spain; [5]Institut de Ciència de Materials de Barcelona, Spain

The recent success of the van der Waals Sb$_2$(S,Se)$_3$ system has put low dimensional semiconductors in the spotlight to develop high efficiency photovoltaics (PV). Indeed, their performance has increased consistently, triplicating in less than a decade, and they also possess many benefits compared to other PV thin film systems, including earth-abundancy, low toxicity, thermal stability, and anisotropic crystal structure – resulting in unique electrical properties when the material is correctly oriented. However, van der Waals semiconductors beyond Sb$_2$(S,Se)$_3$ have been scarcely investigated, constituting an open field for research. Amongst this family of largely overlooked materials, antimony chalcohalides (*Sb[S,Se]X, X = Br, I*) are highly attractive due to their wide bandgaps in the 1.6-2.0 eV range (ideal for tandem and semi-transparent applications), customizable optical properties by using different halides or chalcogenides while retaining their quasi-1D structure, defect-tolerance, and ferroelectric properties, which might offer new opportunities (an alternative to perovskites) to improve electron-hole separation and achieve high photovoltages.

The first attempts to synthesize these materials for PV implementation have been essentially focused on low temperature (< 300^{o}C) and atmospheric pressure solution-based chemical routes, although PV performance of the resulting devices has been overall low. Aiming towards a more controlled, reproducible and versatile system, in this work, SbSeI has been synthesized by a novel procedure based on the selective iodination of co-evaporated Sb$_2$Se$_3$ films at pressures above 1 atm, developing an extremely uniform morphology consisting in single-crystal micro-columnar structures, which can reach lengths up to tens of microns, and which height and density can be finely tuned by adjusting the annealing temperature and pressure. Structure and crystalline quality have been characterized by advanced microscopy imaging techniques, Raman spectroscopy and X-ray diffraction. Also, Kelvin probe microscopy has been used to determine the local work function of these micro-columnar structures, revealing a work function variation among the exposed crystalline facets.

In addition to the excellent crystalline quality and low dimensional structure, SbSeI crystals show an overwhelmingly high photoluminescence (PL) signal, significantly larger than that of Sb_2Se_3 thin films, suggesting that they might have the capability of developing a remarkable PV effect. Indeed, electrical and optoelectronic measurements have been performed on micro-scale devices by transferring micro-columnar crystals to a SiO_2/Si wafer, and connecting them to Pt and Au contacts, yielding a clear diode response with the Au-Au and Au-Pt electrodes, which is greatly enhanced under illumination. Memory effect, capacitance-voltage and ferroelectric measurements have also been performed. Finally, solar cell prototypes have been prepared using a substrate configuration, resulting in high open-circuit voltages around to 600 mV.

Overall, this work presents a general study of synthesis and characterization of novel chalcohalide-based micro-scale solar cells, showing their compatibility with scalable physical vapor deposition techniques. We report the formation of highly crystalline SbSeI micro-columnar structures, showing excellent PL response, bandgap of 1.7 eV, and diode performance of micro-scale devices. These results demonstrate the potential of low dimensional chalcohalides to be implemented into innovative architectures and advanced functionalities (such as for enhanced carrier collection and light trapping), pointing the way to develop defect-tolerant and ferroelectric absorbers with anisotropic electrical properties for the next-gen PV, photo-electrocatalysis, piezo- and thermo-electric applications.

SESSION EN02.13: Poster Session II

Anatase Thin Film Growth—Optimizing Grains and Facets for Photoelectrochemical Applications Faven Berhane and Andrew Ichimura; San Francisco State University, United States

Reducing our dependence on fossil fuels for energy is important to eliminate greenhouse gas emissions. First-generation solar cell production is not sustainable, as manufacturing crystalline silicon is resource intensive. Anatase TiO_2 is a wide band-gap semiconductor oxide that has applications in third-generation solar cells and photoelectrocatalysis for water splitting and may become part of the portfolio of materials for clean energy production. One approach to improve devices based on TiO_2 thin films is to use crystallographic anisotropy to induce space-charge separation of photogenerated charge carriers. Exploiting the space-charge anisotropy intrinsic to the crystallographic directions and facets of anatase may improve both the reactivity and charge transport for photocatalytic and charge transport applications. It has been found that the (001) and (101) anatase facets are preferentially oxidizing and reducing, respectively. In addition, charge transport has lower resistance along the [001] direction. Therefore, anatase thin films for PEC should be designed with the c-axis normal to the conducting substrate and (001) facets at the surface to improve both charge transport and reactivity, respectively. Previously, we reported a synthesis for anatase thin films with [001] texture (Ichimura 2012). In this study, we examine thin film growth systematically to determine the conditions that maximize the [001] orientation and (001) facet expression of anatase thin films.

This work aims to optimize a one-pot hydrothermal synthesis of anatase TiO_2 thin films as a function of reagent concentration, pH, and temperature for photoelectrochemical applications. In this research, TiF_4 is the titanium source and HF is a structure-directing agent used to promote (001) facet growth. The TiO_2 thin films are synthesized in batches to reliably control concentration and pH. Preliminary syntheses have revealed that pH is an important factor to control grain size while temperature has a large effect on the growth of the (001) facets. The thin films are characterized by field emission scanning electron microscopy (FESEM), atomic force microscopy (AFM), and grazing incidence X-ray diffraction (GIXRD). The TiO_2 film parameters (grain size and statistics, film thickness, and extent of orientation) will be correlated with reagent concentration, pH, and temperature. Preliminary PEC measurements that employ a Ni(II) based catalyst for the oxygen evolution reaction will also be reported. Additionally, ^{19}F NMR will be used to correlate film structure and solution composition.

5:00 PM EN02.13.04

Importance of Titanium Dioxide (TiO_2) Phase Control for Application as a Partner Layer in Antimony Selenide (Sb_2Se_3) Solar Cells Christopher Don and Jon Major; University of Liverpool, United Kingdom

Despite the successful history of CdS/Sb_2Se_3 heterojunction devices, cadmium toxicity, parasitic absorption from the relatively narrow CdS band gap (2.4 eV) and multiple reports of inter-diffusion at the interface forming Cd(S,Se) and $Sb_2(S,Se)_3$ phases present significant limitations to this device architecture. Among the options for alternative partner layers, the wide band gap (3.0-3.2 eV), non-toxic titanium dioxide (TiO_2) has demonstrated the most promise. FTO/TiO_2/Sb_2Se_3/P3HT/Au devices have achieved 7.3% PCE, compared with 10.6% for an FTO/CdS/Sb_2Se_3/spiro-OMeTAD/Au device structure. TiO_2/Sb_2Se_3 device structures deliver competitive J_{sc} and V_{oc} with these record PCE devices, however the devices are severely hindered by comparatively low FF (~52% and ~%68 respectively).

It's typically assumed that the meta-stable anatase phase of the polymorphic TiO_2 is attained for processing temperatures <500°C, since the anatase-rutile phase transition is commonly reported to be >600°C, however there is generally a lack of rigorous analysis of how the phase of TiO_2 may influence the device performance. In this study we correlate TiO_2 phase differences attained via low-temperature processed (500°C) RF magnetron sputtered and solution spin-cast TiO_2 window layers with 'S-Shape' 'kinks' in current-voltage measurements of TiO_2/Sb_2Se_3 solar cell device structures, which act to severely reduce FF in these devices. The S-Shape current-voltage curve under illumination is attributed to an interfacial charge barrier, highlighted by calculated J_{sc} discrepancy between JV and EQE measurement.

This work reports approaches to distinguish between TiO_2 polymorphic phases using both surface and bulk characterisation methods. We also demonstrate the impact that phase changes may have on both the front contact/TCO and antimony chalcogenide band alignment. A device fabricated with a rutile-TiO_2 window layer (FTO/r-TiO_2/Sb_2Se_3/P3HT/Au) achieved a PCE of 6.88% and near-record 32.44 mA cm^{-2} J_{sc}, which is comparable to established solution based TiO_2 fabrication methods which produced a highly anatase partner layer with 6.91% PCE. S-shape current-voltage curves are attributed to multi-phase TiO_2 films with a pure rutile surface and anatase bulk which generates a valley in conduction band minima alignment and drastically impedes electron extraction.

This result has implications for groups attempting to transition either from CdS partner layers to TiO_2, or even for transition from one TiO_2 deposition method to another. The work presented here shows that TiO_2 phase control is reliant on more factors than simply sintering temperature, which is significant considering TiO_2 phase is not always confirmed in Sb_2Se_3 device literature, especially in the context of our result which indicates TiO_2 phase differences alone can reduce PCE from ~7% to ~2% as a result of severe fill-factor losses in the face of this interfacial charge barrier. This is perhaps one of the reasons comparatively few groups are reporting high efficiency TiO_2/Sb_2Se_3 heterojunction devices, despite the clear limitations of CdS/Sb_2Se_3 structures.

5:00 PM EN02.13.05

Synthesis of Ag_3SX (X = Br, I) Chalcohalide Anti-Perovskites Thin Films Ivan Caño Prades[1,2], Jonathan Turnley[3], Marcel Placidi[1], Rakesh Agrawal[3] and Edgardo Saucedo Silva[1,2]; [1]Universitat Politècnica de Catalunya, Spain; [2]Barcelona Research Center in Multiscale Science and Engineering, Spain; [3]Purdue University, United States

Metal chalcohalides constitute an extended family of semiconductor materials encompassing different compositions, structural and optoelectronic properties. Indeed, since the 1960s, several chalcohalide materials have been reported to possess photoconductive, electro-optical and ferroelectric effects, and their wide variety of compositions and structures could lead to a broad bandgap range, potentially suitable for photovoltaics (PV). However, these semiconductors have been largely overlooked among the PV field, likely shadowed by the prevalence of Si in the solar cell market, and the success of other thin film technologies such as $Cu(In,Ga)Se_2$ and halide perovskites. Nevertheless, recent studies have reported excellent performance of several chalcohalide materials such as SbSI and SbSeI, reaching efficiencies up to 5% in a very short period of time, benefited by their quasi-1D structure, which favors a high mobility and excellent transport properties. But the chalcohalide family includes other members which have properties suitable for PV, as well as being constituted by low-toxicity and earth-abundant elements.

Among these, silver chalcohalides stand out for their crystalline structure analogous to the successful perovskite, suggesting that they could possess great tolerance to defects. Indeed, their structure corresponds to that of a perovskite, switching cation sites by anions, and anion sites by cations; hence denominated an anti-perovskite. Also, theoretical calculations have reported that silver chalcohalides have bandgaps in the 0.9-2.0 eV range, making them ideal for single-junction or tandem PV devices. Despite these promising properties, there is no published information on their implementation in solar cells, and so far, they have only been synthesized by solid-state reactions (powder) and laser ablation at high temperatures (ultra-thin films).

In this work, we present a procedure to prepare Ag_3SBr and Ag_3SI by low-temperature solution-based methodologies, using the amine-thiol solvent to dissolve Ag_2S and AgX (Br,I) precursors, followed by solution deposition by blade or spin-coating to obtain polycrystalline thin films on Mo and Al_2O_3-coated glass substrates. The structural properties of these films have been characterized by X-ray diffraction, confirming the formation of the anti-perovskite phase. Also, a series of samples have been subjected to different annealing treatments to determine the optimal synthesis conditions, whereby it has been observed that the anti-perovskite phase starts to form at 200ºC coexisting with Ag_2S (which decreases upon increasing temperature). Likewise, formation of AgBr has been detected at temperatures above 250ºC, bounding the range of optimum growth. Ag_3SBr and Ag_3SI films have also been characterized by scanning electron microscope imaging, Raman and transmission spectroscopies measurements.

Thus, this work demonstrates for the first time the viability of solution-processing methods to prepare Ag chalcohalide anti-perovskite thin films, using the amine-thiol ("alkahest") solvent. Importantly, this methodology has reduced the synthesis temperature to 200ºC, opening the door to its implementation with different substrates and the manufacture of solar cells. In addition, this versatile chemical system tolerates different cation and anion substitutions, offering a viable approach for bandgap tuning. Strategies to incorporate Cu_2S to the precursor solutions to prepare $(Cu,Ag)_3SX$ films and replace S by Se will also be presented and discussed.

5:00 PM EN02.13.07

Synthesis of Calcohalides by Sequential Co-Evaporation and High-Pressure Annealing Process for Photovoltaic Applications Alejandro Navarro[1], Ivan Caño Prades[1], Edoardo Maggi[1], Xavier Alcobé[2], Joaquim Puigdollers[1] and Edgardo Saucedo Silva[1]; [1]Polytechnic University of Catalunya, Spain; [2]Centres Científics i Tecnològics de la Universitat de Barcelona, Spain

The interest in low-dimensional materials has been regained due to the re-discovery of the high potential of these materials as absorbers for high-efficiency photovoltaic conversion. In particular, recent progresses in research on the quasi-1D material $Sb_2(S,Se)_3$, whose efficiency has been steadily increasing over the last decade, has attracted the interest of the scientific community to this class of materials. Among other interesting properties, these materials have the advantage of being constituted by abundant elements of low or no toxicity. Theoretical modelling has shown the very interesting properties of a new class of semiconductors based on semi-metal chalcohalides ([Bi,Sb][S,Se]X, with X = Br, I). Among them, they present unique electrical properties due to their anisotropic crystalline structure, potential defect tolerance and ferroelectricity similarly to the perovskite family. The potential applications of these materials range their implementation in tandem, semitransparent PV technologies and photocatalysis due to their bandgaps ranging from 1.6 to 2.3 eV.

In this work the properties of SbSeBr synthesized by co-evaporation of Sb_2Se_3, followed by a reactive annealing under halide atmosphere at different pressures above 1 atm that allows a better control on the incorporation of the halogen element into the crystal structure. A wide range of synthesis conditions are explored by modifying the reactive annealing pressure, temperature and duration. The first findings reveal that both the pressure and the temperature have a great effect on the size of the small irregular grains. Compared to analogous material such as SbSeI, this material requires relatively long process times to achieve a complete transformation of Sb_2Se_3 to SbSeBr. It is interesting to note that, so far, no reports on the synthesis of this particular material by means of the versatile, effective and easily scalable chemical routes are published.

The composition and crystal structure are characterized by combining X-Ray Fluoresence, X-Ray diffraction, Raman spectroscopy, and Energy-dispersive X-ray spectroscopy. The first results show that by the method developed in our lab it is possible to obtain a single-phase material with a very high degree of both purity and crystallinity. An identification of the main Raman modes will also be presented.

The absorber layers have been used to fabricate solar cells, reporting the first working devices for this material with efficiencies above 0.5% and with a very encouraging Voc (>600 mV). The main current limiting factor for the efficiency of the devices is the complex morphology of the SbSeBr layers, suggesting that a proper optimization of the novel synthesis process and an appropriate choice of Hole Transport Layer and Electron Transport Layer can boost the efficiency of these promising materials.

Finally, once the processing conditions are fully optimized, solar cell devices will be completed in both substrate and superstrate configurations, opening promising pathways for the development of highly efficient solar cells based on quasi-1D materials by a proper selection of device configuration, transport layers and material synthesis conditions.

5:00 PM EN02.13.08

Fine-Tuning Energy Levels and Molecular Packing of Asymmetric End Group Non-Fullerene Acceptor for Efficient and Stable Organic Solar Cells Huijeong Choi[1], Peddaboodi Gopikrishna[1], Do Hui Kim[2], Shinuk Cho[2] and BongSoo Kim[1]; [1]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); [2]University of Ulsan, Korea (the Republic of)

Organic solar cells (OSCs) have emerged as promising photovoltaic technology because of low-cost, lightweight, flexibility, and transparency. Recently, the power conversion efficiencies (PCEs) of OSCs have exceeded 18% with the development of non-fullerene acceptors (NFAs). Reported Y6 which has an A-DA’D-A structure, various Y-series derivatives have been designed. However, a trade-off between an open-circuit voltage (V_{OC}) and a short-circuit current density (J_{SC}) remains a problem even though the PCEs of OSCs based on the Y-series derivatives have increased rapidly. Hence, it is crucial to finely tune the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of photoactive materials for balance between V_{OC} and J_{SC}. In this work, we report efficient and stable OSCs based on a new asymmetric NFA, IPC-BEH-IC2F. This asymmetric NFA is comprised of a weak electron-donating core dithienothiophen[3,2-*b*]-pyrrolobenzothiadiazole (BEH) and two kinds of end groups having strong electron-accepting ability 9*H*-indeno[1,2-*b*]pyrazine-2,3-dicarbonitrile (IPC) with tricyclic fused ring and 2-(5,6-difluoro-3-oxo-2,3-dihydro-1*H*-inden-1-ylidene)malononitrile (IC2F) which used as an end group in Y6. The IC2F-BEH-IC2F (or Y6) and IPC-BEH-IPC having symmetric structures were also characterized to compare with asymmetric IPC-BEH-IC2F. The IPC moiety significantly affects the optical properties and electronic structures of the NFAs. The asymmetric IPC-BEH-IC2F shows the highest extinction coefficient among the three NFAs due to its strong dipole moment and highly crystalline feature. Its HOMO and LUMO energy levels are successfully tuned between those of the IC2F-BEH-IC2F and IPC-BEH-IPC through the asymmetric structure. Besides, the IPC moiety promotes strong intermolecular π-π stacking due to their tricyclic fused system, which is beneficial for charge transport. Inverted type OSCs based on polymer:NFA blends were fabricated. Among all these polymer:NFA based OSCs, the asymmetric IPC-BEH-IC2F based OSC blended with PBDB-T showed a balance between V_{OC} and J_{SC}, leading to the highest PCE of 12.70% with a high V_{OC} of 0.85 V and a J_{SC} of 22.29 mA cm^{-2}. In addition, the PBDB-T:IPC-BEH-IC2F based OSC also exhibited the best long-term stability under ambient conditions due to the strongly interacting IPC moiety, which forms the densely packed morphology and prevents penetration of Ag atom into the photoactive layer. These results demonstrate that using asymmetric NFAs can be useful for improving the photovoltaic performance and stability of OSCs.

5:00 PM EN02.13.09
High Crystalline Regioregular Polymer by Thermal Treatment for Thickness-Insensitive Organic Photovoltaics Jiwoo Yeop[1], Kwang Hun Park[2], Bogyu Lim[2] and Jin Young Kim[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

To successfully develop a regioregular polymer, poly[4,8-bis(5-(2-hexyldecyl)thiophen-2-yl)benzo[1,2-*b*:4,5-*b*’]dithiophene][5,5’-bis(7-(4-(2-butyloctyl)thiophen-2-yl)-6-fluorobenzo[*c*][1,2,5]thiadiazol-4-yl)-2,2’-bithiophene] (PDBD-FBT), symmetric monomer synthesized in high yield by tin homo-coupling reactions. PDBD-FBT is suitable as donor material in organic photovoltaics (OPVs) because it shows high crystallinity and strong face-on packing properties. These properties were amplified by thermal annealing (TA). It causes power conversion efficiency (PCE) enhancement in PDBD-FBT-based OPVs. Using PDBD-FBT as polymer donor and 2,2'-((2*Z*,2'*Z*)-((12,13-bis(2-heptylundecyl)-3,9-diundecyl-12,13-dihydro-[1,2,5]thiadiazolo[3,4-*e*]thieno[2",3’':4’,5']thieno[2',3':4,5]pyrrolo[3,2-*g*]thieno[2',3':4,5]thieno[3,2-*b*]indole-2,10-diyl)bis(methanylylidene))bis(5,6-difluoro-3-oxo-2,3-dihydro-1*H*-indene-2,1-diylidene))dimalononitrile as electron acceptor, PCE of 7.91% was achieved without any additive and TA treatment at optimized film thickness approximately 100nm. After TA treatment, PCE of 12.53% was achieved with 58% increase compared with the reference devices. Owing to the strong crystallinities, trap-assisted recombination occurs by excessively formed grain boundaries; however, enhanced exciton dissociation probability covers these drawbacks. Even thick film condition approximately 340nm, this tendency is more pronounced (73% of PCE enhancement by TA treatment is observed). Although thick film’s OPVs are difficult to achieve high efficiency, it shows similar efficiency as the device with optimized film thickness. Our study demonstrates that it is possible to manufacture thickness-insensitive OPVs based on regioregular polymers with strong crystallinity and face-on characteristics, thereby providing a solution to the thickness variation of large-area organic solar cell modules.

5:00 PM EN02.13.10
Molecular Structure-Property Relation, Molecular Dynamics Simulation, and Charge Dynamics in Nonfullerene-based Organic Solar Cells Min Hun Jee[1], Dohun Yuk[2], Chang Woo Koh[1], Sungnam Park[1], Jin Young Kim[2] and Han Young Woo[1]; [1]Korea University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

In Organic solar cells, Y6 derivatives have a good candidate due to dominant face-on orientation, high electron mobility, and low energy loss with high electroluminescent quantum efficiency. However, Y6 derivatives have a long and complicated synthetic procedure to synthesize dithieno[2″,3″:4′,5′]thieno[2′,3′:4,5]pyrrolo[3,2-e:2′,3′-g] [2,1,3]benzothiadiazole (BTP) core. So, we designed two new Y6 derivatives (YBO-2O/-FO) with a simplified synthetic procedure by moving solubilizing alkyl substituents on the BTP to the terminal (3-oxo-2,3-dihydro-1H-inden-1-ylidene)malononitrile (INCN) groups. We investigated the intermolecular packing characteristics when the bulky alkyl side chain on the core of Y6 is removed through molecular dynamics (MD) simulation. YBO-2O/-FO are more formed in the core-core and terminal-terminal (CC-TT) with tighter packing structure than Y6 which coincides with GIWAXS (tighter packing than Y6) and SCLC (faster electron mobility than Y6). The HOMO and LUMO energy level was upshifted by the electron-donating terminal group (INCNO2). YBO-FO has an adequate HOMO energy level with that of the polymer donor PM6 which is a good hole transfer rate at the interface between donor and acceptor. In blend films, the hole transfer from YBO-2O/-FO to PM6 is investigated by transient absorption spectroscopy (TAS), demonstrating efficient hole transfer from YBO-FO to PM6. Despite the simplified synthesis, YBO-FO shows a power conversion efficiency of 15.01% similar to Y6.

5:00 PM EN02.13.12
Dimerized Small-Molecule Acceptors Afford High-Performance and Stable Organic Solar Cells with High Open-Circuit Voltage and Long Life-Time Jinwoo Lee[1], Cheng Sun[2], Soon-Ki Kwon[2], Yun-Hi Kim[2] and Bumjoon Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Gyeongsang National University, Korea (the Republic of)

The power conversion efficiencies (PCEs) of small molecule acceptors (SMAs)-based organic solar cells (OSCs) have remarkably increased in recent years, but their thermal and long-term stabilities should be significantly enhanced for the commercialization. In addition, relatively lower open-circuit voltages (V_{oc}) of OSCs compared to other types of solar cells (*e.g.*, perovskite solar cells) should be addressed to further improve their PCEs. Here, we demonstrate that dimerizing a SMA with a properly-designed conjugated linker resolves the critical issues associated with the stability and V_{oc} of OSCs. The dimerized SMA (DYBO) connected by a benzodithiophene (BDT) conjugated linker affords OSCs with excellent PCEs (> 18%), which outperform those of the reference OSCs (PCE = ~17%) based on a monomer-type SMA (MYBO) with the identical SMA building block. The incorporation of the electron-donating BDT linker in DYBO effectively upshifts the lowest unoccupied molecular orbital energy level and reduces the voltage loss, synergistically increasing the V_{oc} of the devices. Importantly, the DYBO-based OSCs have excellent thermal and photo stabilities. For example, the DYBO-based OSCs retain more than 80% of the initial PCE even after 6000 hr of thermal exposure at 100 °C, whereas the MYBO-based OSCs sharply degrade their PCE to ~80% of the initial value after only 36 hr exposure. The main origins of the improved stabilities in the DYBO-based OSCs are (1) the significantly increased glass transition temperature (T_g) from 80 to 179 °C by the dimerization, which stabilizes the blend morphology during thermal stresses; (2) the improved miscibility of DYBO with a BDT-based polymer donor. Thus, we highlight the importance of the molecular design of dimerized SMAs for achieving OSCs with excellent PCEs and stabilities.

5:00 PM EN02.13.13
Perovskite Microcells Fabricated Using Swelling-Induced Crack Propagation for Semi-Transparent and Colored Solar Windows Jinhong Park and Dae-Hyeong Kim; Seoul National University, Korea (the Republic of)

Perovskite microcells have a great potential to be applied to diverse types of optoelectronic devices including light-emitting diodes, photodetectors, and solar cells. Although several perovskite fabrication methods have been researched, perovskite microcells without a significant efficiency drop during the patterning and fabrication process could not be developed yet. We herein report the fabrication of high-efficiency perovskite microcells using swelling-induced crack propagation and the application of the microcells to colored solar windows. The key procedure is a swelling-induced lift-off process that leads to patterned perovskite films with high-quality interfaces. Thus, a power conversion efficiency (PCE) of 20.1 % could be achieved with the perovskite microcell, which is nearly same as the PCE of our unpatterned perovskite photovoltaic device (PV). The semi-transparent PV based on microcells exhibited a light utilization efficiency of 4.67 and a color rendering index of 97.5 %. The metal–insulator–metal structure deposited on the semi-transparent PV enabled to fabricate solar windows with vivid colors and high color purity.

5:00 PM EN02.13.14
Modifying Additive Engineering with 2D-MXene in Perovskite Layer for Highly Efficient Inverted Perovskite Solar Cells Exceeding 23% Efficiency Hye Seung Kim, Ju-Hyoung Han, Soon-Yong Kwon and Myoung Hoon Song; Ulsan National Institute of Science and Technology, Korea (the Republic of)

On account of the excellent photovoltaic properties (e.g. tunable bandgap, long carrier diffusion length, and high absorption coefficient) and solution processability of the perovskite, a number of studies have been conducted on the perovskite as a next-generation solar cell. The rapid increase of the power conversion efficiency (PCE) of the perovskite solar cells (PSCs) has been achieved in the last decade, however, it has been implemented only in the conventional (n-i-p) structure of the PSCs. The inverted (p-i-n) structure, which has low-temperature processability, negligible hysteresis effects, and better device stability than n-i-p structure, is in the spotlight. Furthermore, p-i-n structure is suitable for fabricating tandem solar cells that can overcome the Shockley-Queisser limit (S-Q limit) of single junction solar cell.
In order to catch up with the efficiency of the n-i-p structure, numerous efforts have been made in the p-i-n structure. Due to the ionic nature of perovskite, which generates defect states, a typical method is to use an additive to passivate the defects in the perovskite layer. The perovskite crystal can be passivated during crystal growth process with incorporated additive, or prevent halide ion migration which leads to decrease efficiency of solar cells and device stability with placing additive material between perovskite and electron transporting layer (ETL).
A new family of 2D materials, called MXene, has emerged as a great candidate for additives in PSCs replacing other materials due to its outstanding electrical conductivity, tunable optical properties, and robust physical, chemical properties. Since MXene's surface has negatively charged groups (e.g. -OH, -O, -F, and -Cl), it is reasonable to expect that interaction of MXene with Pb^{2+} ion in perovskite not only passivates the defect sites of the perovskite but also affects to the crystal growth of perovskite. Moreover, MXene would decrease the charge transfer resistance in PSCs by its high electrical conductivity, increase the thermal stability by its good thermal conductivity. Lastly, incorporation of MXene in the perovskite cause the change of work function of perovskite to improve the device performances.
Herein, we demonstrate the affect of MXene as an additive in the p-i-n PSCs by engineering two different incorporating methods. We compared the difference in the mechanism of each crystal growth when MXene is added by two different methods, following compare the differences in morphology of perovskite and device performance according to each method. Consequently, the short-circuit current density (Jsc) and open-circuit voltage (Voc) are greatly improved, so that obtain over 23% of PCE.

5:00 PM EN02.13.15
Self-Encapsulated Semitransparent Perovskite Solar Cells for Long-term Stability via Thermocompression Bonding Process Heeyun Jeong and Taeyoul Yang; Chungnam National University, Korea (the Republic of)

Organic-inorganic hybrid perovskite solar cells (OIHPs) have attracted the PV community due to low cost and high power conversion efficiency, but still have suffered from poor stability. In order to shield perovskite solar cells (PSCs) from extrinsic degradation factors such as oxygen and moisture and assure long-term stability, effective encapsulation technology is indispensable. Here we designed a facile process to build glass-glass encapsulated semitransparent PSCs by laminating two half cells where a perovskite layer is formed on a hole transport layer (HTL, p-type) and an electron transport layer (ETL, n-type), respectively, with a transparent conducting oxide (TCO) glass substrate. By laminating the half cells through a thermocompression bonding process, the device is self-encapsulated during manufacturing. Soft mechanical characteristics and atomic migration nature of the perovskites enable the lamination between the perovskite layers with minimizing voids and good adhesion properties. During the lamination process, surface of the perovskite transformed into bulk with enlarged grains, and the interfaces has much smoother and denser morphology. Through surface iodine extraction experiments and TRPL analysis, it was confirmed that defects and trap density decreased in the laminated perovskite. The thermcompression increases hydrophobicity on interfaces of the perovskite. Therefore, the laminated perovskite has higher stability against moisture. The self-encapsulated semitransparent PSCs with a wide bandgap perovskite (E_g ~ 1.67eV) is performed with the PCE of 17.24 %, and thermal stability at 85 °C is secured for over 3,000 hours.

5:00 PM EN02.13.16
Vapor-Transport-Deposited SnSe for Thin-Film Solar Cells Pravin S. Pawar, Raju Nandi, KrishnaRao E. Neerugatti, Jae Yu Cho and Jaeyeong Heo; Chonnam National University, Korea (the Republic of)

The binary chalcogenide-based thin-film solar cells (TFSCs) have attracted great attention due to their low-cost and nontoxic constituents, simple structure, and ability to exhibit high power-conversion efficiency (PCE). The orthorhombic tin selenide (a-SnSe), a binary chalcogenide, is a potential candidate for the low-cost TFSCs due to its appropriate optical bandgap, high optical absorption coefficient (α〉 10^5 cm^{-1}) in the visible region, intrinsic p-type conductivity, and high hole mobility (200 cm^{2}V^{-1}s^{-1}). However, the reported PCE for SnSe TFSCs is significantly low (less than 1%) in most cases due to poor crystallinity, small grains, and a large number of defects. Herein, we report the highest cell efficiency of 2.51% and a high short-circuit current density of 28.07 mA cm^{-2} for a-SnSe TFSCs grown via vapor-transport-deposition (VTD). The effect of evaporation temperature and duration was studied on the performance of SnSe TFSCs. The grain size and surface roughness of the SnSe thin films were mainly affected by the evaporation temperature and duration and were found to be the main parameters to influence the shunt properties of the device. Significantly large shunt losses are detected in the case of both small and extremely large grains. The shunt losses for SnSe thin film with small grains are associated with high grain-boundary scattering. The presence of extremely large grains results in increased surface roughness of the SnSe thin film, which causes nonuniform deposition of the CdS buffer layer and, consequently, higher shunt losses. The SnSe thin film with moderate-sized grains and inferior surface roughness exhibits improved shunt properties owing to uniform deposition of the CdS buffer layer and subsequent layers and significantly improved the device performance. Detailed studies on the morphological and structural properties of the orthorhombic VTD-SnSe thin films and their impact on the photovoltaic device performance will be discussed.

5:00 PM EN02.13.17
PbS Quantum Dot Solar Cell with Reduced Hysteresis by Controlling Interface and Thickness of Hole Transport Layer Using Transfer Printing Hyungcheoul Shim[1,2], Areum Kim[1] and Seungmin Hyun[1,2]; [1]Korea Institute of Machinery and Materials (KIMM), Korea (the Republic of); [2]University of

Science and Technology (UST), Korea (the Republic of)

We fabricated a hole transport layer (HTL) using transfer printing to fabricate high efficiency PbS quantum dot solar cell with minimized hysteresis. We applied PbS-EDT(1,2-ethanedithiol) as an HTL and controlled the adhesive properties between the donor substrate and the HTL through the UVO process in order to effectively transfer the HTL to the PbS layer, which enabled multilayer transfer printing as a result.
During the transfer printing process, a densly packed gradient solid-solution layer without pinholes was created at the interface with the existing PbS layer to reduce the hysteresis phenomenon, and to improve the power conversion efficiency to about 10% according to the HTL thickness optimization.
In addition, the use of the EDT solvent can be remarkably reduced by using the transfer printing when forming the PbS-EDT layer. This can reduce the amount of organic solvent consumed in the process and improve the potential of environmentally friendly processes.

Hybrid Pulsed Laser Deposition Growth of Chalcogenide Semiconductors Mythili Surendran, Shantanu Singh, Huandong Chen, Boyang Zhao and Jayakanth Ravichandran; University of Southern California, United States

Chalcogenide semiconductors, especially 2D transition metal dichalcogenides, are extensively studied owing to their intriguing physical properties for electronic and photonic applications. However, in the past few years, ternary chalcogenide semiconductors such as chalcogenides perovskites have gained substantial interest as a new class of semiconductors due to their tunable chemistry, structure, and opto-electronic properties. For instance, $BaZrS_3$ (BZS) (band gap = 1.9 eV), a prototypical chalcogenide perovskite, is promising as an ultra-thin absorber in tandem solar cells[1-3], whereas $BaTiS_3$ (BTS) (band gap = 0.27 eV) exhibits a giant birefringence and large optical anisotropy in the infrared region[4]. Growth of thin-film chalcogenide perovskites is a critical step to enable investigations into their fundamental properties and also device applications. But the thin-film growth of chalcogenide perovskites is challenging due to a large mismatch in the vapor pressure of the cations and chalcogens, corrosive and reactive nature of most chalcogen precursors, the propensity to oxidize easily in the presence of oxygen at high temperatures and the lack of suitable non-reactive substrate surfaces for epitaxial growth.

Recently, we have demonstrated direct, single-step, epitaxial growth of BZS[1] and BTS[5] thin films on oxide substrates by pulsed laser deposition (PLD) using Argon-H_2S background gas. H_2S is a toxic, hazardous, and flammable gas and reacts with many materials, and the ionized Argon and/or H_2S lead to significant degradation of the crystallinity of both the surface and film at the high growth temperatures. Here, we report an alternative hybrid PLD approach using organo-sulfur precursors as sulfurizing agents to grow chalcogenide semiconductors. To demonstrate the efficacy of this approach, we have demonstrated epitaxial growth of 3D binary chalcogenides such as BaS and SrS (wide band gap) and 2D binary chalcogenides such as TiS_2 (metallic) and ZrS_2 (semiconducting). The potential of these binary sulfides as suitable candidates for transparent and conducting layers in chalcogenide-based photovoltaic devices will be discussed. We have also realized epitaxial BZS and BTS films using hybrid PLD and a comparison of this approach to PLD using Ar-H_2S will be provided. Further, we will also discuss our future growth efforts and the applications of this novel growth method.

8:30 AM EN02.14.01
Highly Transparent ITO/Ag/ITO Sandwich Structure with an Ultra-Thin Silver Layer for Solar and Display Applications Thanh P. Tran[1], Maheshwar Shrestha[2] and Qi Hua Fan[1,1]; [1]Michigan State University, United States; [2]Scion Plasma LLC, United States

A highly and evenly transparent conductive electrode is fabricated on glass substrate thanks to the ability to produce stable continuous ultra-thin silver films, the computational global search of optical properties on ITO/Ag/ITO (IAI) sandwich structures using the transfer matrix method (TMM), and annealing process in the air at high temperature. First, ion beam treatment and aluminum cap layer enable the depositing of stable ultra-thin silver films at 6 and 7 nm. Particularly, ion beam treatment helps to prepare a surface with better wettability toward silver, and the aluminum cap layer help to protect silver film by impeding the movement of silver surface atoms. Secondly, the film thicknesses are then used as the inputs for the simulation of the ITO/Ag/ITO sandwich structure and we found the optimum design of ITO (45 nm)/ Ag (6-7 nm)/ITO (50 nm)/ Glass. Finally, the stable silver film allows further processing of annealing at high temperatures (200C) in the vacuum and in the air, which is not possible for a stand-alone silver film. The resulting 7 nm film on glass substrate has a sheet resistance of 10 Ohm/ sq. an average transmittance in the range of 400-800 nm of 89%. This process can be implemented in other substrates as well as other transparent conductive oxides such as SnO_2, AZO, TTO, and TiO_2. Therefore, a couple of TCOs were taken into consideration for a similar sandwich structure to compare the optical performance showing potential replacements for ITO in optoelectronic applications in the circumstance that indium is getting costly.

The Renaissance of Selenium Thin-Film Solar Cells – The Elemental High Bandgap Photoabsorber Rasmus Nielsen, Tobias Hemmingsen, Andrea Crovetto, Ole Hansen, Ib Chorkendorff and Peter C. Vesborg; Technical University of Denmark, Denmark

In the pursuit of lowering the cost and increasing the penetration of solar energy technologies, a family of inorganic thin-film photovoltaic materials is

emerging. The oldest member of this family, selenium, is experiencing renewed interest due to its high bandgap of 1.95 eV in its trigonal phase, as well as its irresistible monoatomic simplicity. The high bandgap makes selenium a potential partner in tandem photovoltaic devices featuring e.g., silicon as the lower bandgap photoabsorber, but high-efficiency selenium thin-film solar cells have yet to be realized.
We present selenium thin-film solar cells with power conversion efficiencies exceeding 5% and following a novel optimization of the carrier-selective contacts, we demonstrate a record open-circuit voltage of 0.99V and highly encouraging fill-factors beyond 60%. These state-of-the-art devices are investigated in a combined experimental and first-principles study to reveal the origin of the still-significant photovoltaic losses [1]. In view of these results, we set forth strategies for continued improvements to the photovoltaic performance by means of non-equilibrium growth and defect engineering.

Challenges and Prospects Towards Developing Emerging Antimony and Bismuth-Based Chalcogenide for Next Generation, Earth Abundant Photovoltaics Nicolae Spalatu, Sajeesh Vadakkedath Gopi, Mykhailo Koltsov, Robert Krautmann, Malle Krunks and Ilona Oja Acik; Tallinn University of Technology, Estonia

The emergence of new PV applications in the society requires the design of materials and devices with a different set of properties. At this scale, for a new photovoltaic (PV) technology is not sufficient to be only competitive with the Si and CdTe technologies in efficiency and reliability but one should also rely on green, environmentally friendly, and earth-abundant materials. An emerging class of highly promising PV materials currently under widespread investigation in the PV community are the inorganic antimony-and bismuth-based chalcogenide compounds. The excellent intrinsic material properties of these compounds allowed to rapidly approach 8-10% conversion efficiency, opening a new chapter in PV research, full of new possibilities but also scientific challenges. This talk will discuss the latest achievements in bismuth- and antimony-based thin film solar cell technology with the main emphasis on Sb_2Se_3 and Bi_2S_3 compounds. I will summarize the knowns and unknowns of their defect chemistry, including highlights of unique optoelectronic characteristics that are not yet fully explained. The discussion will highlight the progress achieved in our group, toward growth of high-quality Sb_2Se_3 and Bi_2S_3 absorber films and solar cells by rapid, high-volume, and in-line close-spaced sublimation and vapor transport deposition techniques. Special emphasis will be put on the key processing strategies to optimize absorber material properties (doping and alloying), understanding of buried interfaces and push the boundaries of understanding and performance. A thorough look at the formation chemistry and shed light on some of the synthesis and doping challenges, potential doping elements, the impact this has on carrier density and the impact on solar cell performance.

9:15 AM EN02.14.04
Experimental and Computational Studies of Solution Processed $CuSbSe_2$ for Photovoltaic Applications Yuchen Fu[1], Hugh Lohan[1], Yi-Teng Huang[2], Marcello Righetto[1], Szymon Zelewski[2,3], Chang-woo Cho[4], Young Won Woo[5], Harry Demetriou[6], Martyn A. McLachlan[6,6], Sandrine Heutz[6,6,6], Benjamin Piot[4], Akshay Rao[2], Laura Herz[1,7], Aron Walsh[6] and Robert Hoye[1]; [1]University of Oxford, United Kingdom; [2]University of Cambridge, United Kingdom; [3]Wroclaw University of Science and Technology, Poland; [4]Université Grenoble Alpes, France; [5]Yonsei University, Korea (the Republic of); [6]Imperial College London, United Kingdom; [7]Technical University of Munich, Germany

The exploration of novel absorber materials composed by earth-abundant and low-toxicity elements is important for thin-film solar cells. Among these materials, $CuSbSe_2$ is promising because of its suitable optical and electrical properties such as ≈ 1.1 eV bandgap and high absorption coefficient. However, the practical application of the reported hydrazine solution process is limited by the hazardous nature of hydrazine, and more detailed investigations into charge-carrier transport properties of $CuSbSe_2$ is needed. In this study, a novel thiol-amine solution processing route is used to fabricate $CuSbSe_2$ thin films. The fundamental properties of $CuSbSe_2$ thin films are investigated, including phase purity, absorption coefficient and bandgap, to demonstrate the feasibility of the thiol-amine route. Next, the charge-carrier kinetics are studied by transient absorption (TA) and optical-pump terahertz-probe (OPTP) spectroscopy, which reveal that, in contrast to other heavy pnictogen-chalcogenide compounds studied recently [1], $CuSbSe_2$ avoids carrier localisation. To further study the carrier-phonon coupling and carrier transport properties, the temperature-dependence of the mobility is determined through Hall-effect measurements, and compared with DFT calculations to show that Fröhlich coupling dominates in $CuSbSe_2$. The coupling to acoustic phonons is weak, owing to low deformation potentials. The cause of the low deformation potential is studied by investigating how the lattice distorts along the dominant phonon modes. The combined experimental-computational studies shown in this work lead to new insights into how materials avoiding carrier localisation could be designed in the future.

Antimony Trichalcogenide Materials for Short-Wavelength Infrared Photovoltaic (SWIR-PV) Devices Jitendra Kumar, Yaniv Dror, Anchal Vashishta and Eran Edri; Ben-Gurion University of the Negev, Israel

Coupling a short wavelength infrared (SWIR) PV device with a bandgap of 0.6-0.7 eV to tandem PV technologies can improve overall power conversion efficiency (PCE) by 5-11%. Alternatively, a SWIR device can be used in a thermophotovoltaic system and (ideally) furnish a PCE > 50%. However, there is a limited variety of low-cost light absorbers for the SWIR region. Antimony trichalcogenides, such as Sb_2Se_3, exhibit a large absorption coefficient (~10^5) and a long diffusion length (~1.7 µm). Made of earth-abundant materials and by rapid and low-cost deposition methods, Sb_2Se_3 solar cells with PCE > 10% were recently reported. Three other qualities make Antimony trichalcogenides promising SWIR-PV materials: i) Due to the unique quasi-one-dimensional crystal structure, certain grain boundaries in Sb_2Se_3 thin films are expected to be electronically benign. ii) due to the antibonding states at the top of the valence band, Sb_2Se_3 is expected to be (point) defect tolerant. iii) The bandgap of Sb_2Se_3 can be tuned to the SWIR region by alloying with Bi. Here we report a method for making thin films and solar cells of Bi-alloyed PV. By using closed space sublimation, we successfully incorporated Bi in Sb_2Se_3 up to 40%At. without forming secondary phases. The absorption edge extended from 1050 to 1370 nm. Proof-of-concept solar cells will also be presented.

9:45 AM EN02.14.06
Beyond 6 % Efficient Ultrasonic Spray Deposited Sb_2S_3 Solar Cells from 100 nm Thick Pristine Absorbers for Semi-transparent Applications Sreekanth Mandati, Atanas Katerski, Jako S. Eensalu, Nicolae Spalatu, Malle Krunks and Ilona Oja Acik; Tallinn University of Technology, Estonia

Antimony sulphide (Sb_2S_3) is an emerging semiconductor material with excellent promise for future photovoltaic (PV) technologies owing to its superior optoelectronic properties coupled with earth-abundant and environmentally friendly elements. The relatively wide bandgap of Sb_2S_3 (1.7 eV) makes it wiser choice for application in semi-transparent PV and tandem solar cells. Although the material has potential even for single junction cells with a Shockley-Queisser efficiency limit of ≈ 28 % but the open circuit voltage deficiencies arising from defects and/or self-trapping of photogenerated carriers by lattice deformation limit the maximum efficiency to ≈ 16 %. Therefore, despite numerous attempts and various device architectures, the efficiency of

Sb_2S_3 solar cells is still considerably low with an achieved maximum of 8 %, even for an absorber thickness ranging from 200 nm to over 2 µm. And, most of the high efficiency devices (7-8 %), which utilize an absorber thickness of at least 200 nm, are fabricated by either spin coating, chemical bath deposition (CBD) or vacuum deposition techniques. While CBD has the promise for large area upscaling, its throughput is relatively low and requires longer deposition time (≈ 4 hours). In this context, the study herein demonstrates 6.2 % efficient Sb_2S_3 solar cells from an absorber thickness of ≈ 100 nm deposited using industrially benign and scalable ultrasonic spray pyrolysis (USP) with high throughput (deposition time ≈ 20 min). The solar cells are apt for semi-transparent applications with an average visible transmittance of 27 % (400-800 nm) for the device stack with P3HT as hole transport material without the back metal contact. To the best of authors' knowledge, the efficiency of 6.2 % is a reasonable record achieved for pristine 100 nm Sb_2S_3 absorbers devoid of any doping or post deposition treatment. The individual layers and solar cells are comprehensively characterized using advanced characterization techniques like photoelectron emission spectroscopy, photoluminescence, TRPL, and DLTS to understand the band energetics, device physics, defects and interfaces. The USP process parameters towards obtaining high quality absorbers leading to record efficiencies will be discussed in detail while emphasizing the role of defects on the performance of Sb_2S_3 solar cells. In addition, the roadmap towards complete semi-transparent Sb_2S_3 solar cells by replacing back metal contact, which is being pursued, will be presented.

10:30 AM EN02.15.01
Spatio-Temporal Mapping Uncouples Exciton Diffusion from Singlet-Singlet Annihilation in the Electron Acceptor Y6 Giulia Lo Gerfo M.[1], Luca Bolzonello[1], Francisco Bernal-Texca[1], Jordi Martorell[1] and Niek F. van Hulst[2]; [1]ICFO - The Institute of Photonic Science, Spain; [2]ICREA -Institució Catalana de Recerca i Estudis Avançats, Spain

Understanding the spatial dynamics of nanoscale exciton energy transport beyond the temporal decay is at the core of photosynthesis and essential to provide a better framework for further improvements of nanostructured optoelectronic devices, such as solar cells. The diffusion coefficient (D) of photovoltaic films has so far only been determined indirectly, from transient singlet-singlet annihilation (SSA) experiments.
Here, we present the full picture of the exciton distribution dynamics, adding the spatial domain to the temporal one, by spatio-temporally resolved photo-luminescence microscopy. In this way, we directly track diffusion and we are able to decouple the real spatial broadening from its overestimation given by SSA. We measured the diffusion coefficient, $D = 0.017 \pm 0.002$ cm^2/s, of the non-fullerene electron acceptor Y6, which combined with an exciton lifetime of $\tau = 840$ ps, gives a Y6 film diffusion length of $L = (D\tau)^{1/2} \approx 35$ nm. Thus, we provide an essential tool that enables a direct and free-of-artifacts determination of diffusion coefficients, which we expect to be at the core of further methodical studies on exciton dynamics in energy materials.

10:45 AM EN02.15.04
Improvement of Stability of Perovskite Solar Cells with a PbS Buffer Layer Formed by Solution Process Sooah Kim and Taeyoul Yang; Chungnam National University, Korea (the Republic of)

Perovskite solar cells (PSCs) have not yet been commercialized due to their low stability against external factors such as light, moisture, and heat. The migration of iodide ions out of the perovskite is also one of the critical mechanisms of the poor stability of PSCs. In order to inhibit the degradation of PSCs due to external factors and ion migration, it is necessary to form an inorganic buffer layer by surface treatment on the surface of the perovskite. We introduced an inorganic PbS buffer layer by spin coating of Na_2S solution on surface of the perovskite. A PbS buffer layer prevent direct contact of moisture to perovskite and diffusion of the iodide ions. As a result, the PSCs with the PbS buffer layer maintained higher efficiency than those without PbS buffer layer under light and in the moist air and 85 °C heat test. In addition, PbS buffer layer improves charge transfer at the Perovskite/Spiro-OMeTAD interface, so increases power conversion efficiency of PSCs.

11:00 AM EN02.15.05
Halide Perovskite Improved Diffusion Length by AlON Passivation, as Measured by Steady-State Optoelectronic Measurements Anat Itzhak[1], David Keller[1], Tatyana Bendikov[2], Adi Kama[1], Oded Millo[3], Isaac Balberg[3] and David Cahen[1,2]; [1]Bar Ilan University, Israel; [2]Weizmann Institute of Science, Israel; [3]The Hebrew University of Jerusalem, Israel

Metal oxides (MO) are sturdy materials; therefore, MO selective contacts can substantially improve PSCs' stability. However, MO surfaces are reactive, and thus they tend to react at the interface with HaPs and harm both stability and reproducibility of HaP-based electronic devices. ZnO is an extreme case of a reactive MO due to its highly alkaline surface, which readily reacts with HaP. We used steady-state measurements to understand the passivation of ZnO-HaP interface by Aluminum oxynitride (AlON) sub 2 nm layer deposited by atomic layer deposition (ALD). The effect of AlON passivation on the diffusion length of HaP under steady-state conditions, mimic real-life operation conditions for most solar cells. Yet, steady-state measurements require as high as possible photoconductivity (σ_{ph}), which is typically restricted to the absorber. To enable a steady-state charge transport measurement, we used ALD to grow a conformal, ultra-thin (~4 nm) ZnO electron transport layer that is laterally insulating due to its thickness. The formation of ultra-thin continuous inorganic films enables steady-state measurements on stacks of layers. We show that the presence of the AlON layer prevents HaP degradation caused by the interaction with the ZnO layer, improves the HaP σ_{ph}, and doubles the HaP carrier diffusion lengths.

11:15 AM EN02.15.06
Study of Phase Formation of Oxide Derived Cu-Bi-S Compounds Daniely R. Santos[1,2], Lorenzo Milano[3,2], Bjorn Joos[1,2], Jan D'Haen[1], Hans-Gerd Boyen[1], Sudhanshu Shukla[2,1] and Bart Vermang[1,2]; [1]Hasselt University, Belgium; [2]imec, Belgium; [3]Politecnico di Milano, Italy

Copper-based oxides ($Cu_xBi_yO_z$) with a p-type character comprise wide band gap. However, these compounds suffer from the phenomenon of photocorrosion (leading to self-oxidation or self-reduction) and insufficient light absorption, which limits their usage and long-term durability for different applications. To address these limitation, copper-based chalcogenide has shown a prospective alternative. Copper-bismuth chalcogenides, Cu-Bi-S, have been explored as a promising material for solar energy conversion. Recently, devices based on wittichenite-type (Cu_3BiS_3) compound has spurred interest for photovoltaics and water splitting application[1,2], due to its favorable optoelectronic properties, such as p-type conductivity and direct band gap (Eg ≈ 1.10–1.86 eV) with high optical absorption coefficient (>10^5 cm) in the visible region[3]. The aforementioned properties imply that the $Cu_xBi_yS_z$ could be suitable for different applications, however, CBS is still largely unexplored as photo absorber in photovoltaic devices (maximum 1.281% PEC)[4] and as a semiconductor/photocatalyst. This is largely due to the lack of control over different Cu-Bi-S phases, such as Cu_3BiS_3 and $CuBi_3S_5$, for which the stability domains are quite narrow in the phase diagram[5]. In this work, we obtain CBS phases by sulfurization of $Cu_xBi_yO_z$ (CBO) precursor films, with varying Cu:Bi stoichiometry (1:3, 3:1) in the optimized temperature range (350-425°C). The films were characterized by SEM, RAMAN, XRD, optical absorption spectroscopy. XPS studies were performed in order to identify the stoichiometry and oxidation states of the 3:1 and 1:3 (Cu:Bi) precursor sulfurized at the best temperature condition. The results confirmed the total conversion of CBO to CBS. Although mixed phases were identified for both Cu:Bi ratio at different sulfurization temperature, 3:1 (Cu:Bi) precursor film sulfurized at 350°C yields Cu_3BiS_3 single phase, which is corroborated by Raman peaks at 279 and 470 cm^{-1} corresponding to Cu3BiS3 phase. Sulfurization of 1:3 (Cu:Bi) precursor film at 425°C leads to $CuBi_3S_5$ phase; while at 350°C both Cu_3BiS_3 and $CuBi_3S_5$ phases are observed, however, Cu_3BiS_3 is more evident, which is in agreement with Raman. Optical measurements showed that 1:3 and 3:1 (Cu:Bi) precursor sulfurized at 350°C presented similar Eg (1.61 and 1.54 eV, respectively); while 1:3 sulfurized at 425°C has low Eg (1.0 eV), indicating that the presence of $CuBi_3S_5$ phase decreases the band gap energy. Band-edges from XPS confirmed that CBS is promising for different applications.

2:00 PM EN02.16.01

2D and 3D Phases of Chalcogenide Perovskites Giulia Longo[1], Prakriti Kayastha[1], Lucy Whalley[1], Devendra Tiwari[1] and Ken Durose[2]; [1]Northumbria University, United Kingdom; [2]University of Liverpool, United Kingdom

Chalcogenide perovskites have been recently under the researchers' spotlight as novel absorber materials for photovoltaic applications. $BaZrS_3$, the most investigated compound of this family, shows high absorption coefficient, a bandgap of around 1.8 eV, and excellent environmental and thermal stability.[1-3] Despite the high temperature synthesis that has been traditionally employed to prepare this material, milder conditions have been successfully applied recently, opening the possibility for its deposition in thin film and device integration.[4] In addition to the 3D perovskite $BaZrS_3$ the Ba-Zr-S compositional space contains 2-D Ruddlesden-Popper phases $Ba_{x+1}Zr_xS_{3x+1}$ (with x= 1, 2, 3) which have recently been reported. [5, 6] It is important to note that, differently from hybrid lead halide perovskites in which RP phases are achieved through the addition of a bigger cation, these lower dimensional phases can be obtained only through stoichiometric variation of the 3D elements. Consequently, 3D-2D mixtures, with different optoelectronic properties compared to the pure phases, can be easily created, requiring a deep understanding and control of the mechanisms to avoid the formation of secondary phases.
In this paper we report solid state synthesis and characterization of Ba-Zr-S phases. In order to avoid the use of the easily oxidised metals the starting materials used were BaS and ZrS_2. We report the protocols for synthesis at 900°C in quartz capsules, changing the precursor ratio BaS: ZrS_2 and revealing the formation of a mixture of 3D and 2D chalcogenide perovskite phases. To carefully resolve the composition, we complemented the XRD, SEM and EDS characterization of the synthetic products with the analysis of the Raman-IR spectra. For this purpose, we calculated the phonon mode, deriving the Raman and IR spectra, for the 3D and 2D Ba-Zr-S chalcogenide perovskites and for the binary precursors. This thorough characterization will show how complex can be to distinguish between different phases in the Ba-Zr-S compositional space, stressing the importance of the use of multiple techniques to soundly resolve the composition of these materials.

Liquid Flux Assisted Growth Mechanism for The Chalcogenide Perovskite – $BaZrS_3$ Kiruba Catherine Vincent, Shubhanshu Agarwal, Jonathan Turnley and Rakesh Agrawal; Purdue University, United States

Chalcogenide perovskites are emerging photovoltaic materials with attractive optoelectronic properties including a high absorption coefficient, tunable bandgap, and high dielectric constant. In contrast to their halide counterparts, these materials have been shown to be stable, and earth-abundant with nontoxic constituents. However, the current rudimentary synthesis techniques have limited the growth of these materials. Traditional solid-state and vacuum processing methods demand temperatures in excess of 800-1000 °C bringing up difficulties in identifying suitable substrates and subsequent device fabrication. Hence, gaining insights into the growth mechanism of these materials becomes integral for engineering robust fabrication methodologies.
To address this, we systematically studied the growth mechanism of the $BaZrS_3$ perovskite through our earlier reported hybrid precursor route utilizing barium thiolate and zirconium hydride precursors. Preliminary findings demonstrate that the high-temperature requirements are related to mass transfer

barriers between precursors rather than thermodynamic limitations. We also identified an accessible liquid phase capable of overcoming these diffusional barriers and driving the reaction towards lower temperatures as well as assisting in grain growth.
In conclusion, this work is focused on understanding the growth mechanism of the $BaZrS_3$ perovskite and identifying the potential liquid phase to drive low-temperature synthesis and support subsequent thin film fabrication.

Optoelectronic Characterization of Solution-Processed $BaZrS_3$, $BaHfS_3$, and Ruddlesden-Popper Phases Synthesized Using Dithiocarbamates and Dithiocarboxylates Apurva A. Pradhan, Madeleine Uible, Daniel C. Hayes, Shubhanshu Agarwal, Jonathan Turnley, Suzanne C. Bart and Rakesh Agrawal; Purdue University, United States

Chalcogenide perovskites have recently garnered great interest for photovoltaic applications due to their predicted and experimentally verified high stabilities compared with halide perovskites while retaining their excellent optoelectronic properties. One of the greatest challenges with using chalcogenide perovskites for applications in solar cells is that they have historically required high synthesis temperatures, making them incompatible with the glass substrates and the conductive rear-contact layers required to create a photovoltaic device.
Our group has recently published two routes of synthesizing $BaZrS_3$ and $BaHfS_3$ using solution-deposited routes utilizing inks with solid suspensions. However, both synthesis routes resulted in island growth of these materials. In this work, we explore methods to create continuous films of $BaZrS_3$ and $BaHfS_3$ using inks containing fully dissolved molecular precursors consisting of metal dithiocarbamates and metal dithiocarboxylates. By adjusting the barium to transition metal ratios in the inks, this solution processed synthesis route was also extended to the synthesis of Ba-Zr-S and Ba-Hf-S Ruddlesden-Popper phases, a class of materials that has not been extensively studied. Analytical characterization of the molecular precursors and optoelectronic characterization of the ternary phase materials were then carried out to determine their properties.

Radically Reimagining III-V Compound Semiconductor Photovoltaics: Epitaxy-Free Approach to Scalable Synthesis of Flexible Low-Cost Thin Film Solar Cells Phillip Jahelka, Andrew Nyholm, Sara Anjum, Michael Kelzenberg and Harry A. Atwater; California Institute of Technology, United States

For III-V compound semiconductor solar cells to achieve scalability for very large-scale photovoltaics, we need to radically reimagine how they are fabricated. We outline an approach for scalable synthesis of GaAs thin film solar cells that bypasses epitaxial growth and eliminates or minimizes vacuum processing. Starting with thin film absorbers that are formed by mechanical exfoliation from GaAs bulk ingots, we demonstrate that high efficiency cells are possible using methods adopted from silicon and perovskite thin film photovoltaics, such as use of diffused junctions formed at ambient pressures, and solution processing of ohmic contacts and passivation layers using earth-abundant materials. We demonstrate diffused junction GaAs solar cells with 1-Sun AM1.5G efficiencies as high as 23.5%.

Thin-film GaAs photovoltaic pn junction structures were synthesized from bulk GaAs crystals by diffusion doping and spalling to mechanically exfoliate 3-micron thick films of GaAs. The p/n junction is fabricated with a simple zinc-diffusion doping technique, which has yielded open circuit voltages > 960 mV. The films are spalled onto electroplated nickel stressor layers that also serve as the mechanical support for the film. Using 110 oriented GaAs crystals results in large-area mirror-smooth spalled films with 0.1 nm RMS roughness. Preliminary fabrication of thin film diodes yielded implied V_{oc} values over 830 mV, with ideality factor of two, and an absence of parasitic shunts. The diodes are supported on a Kapton tape, demonstrating their potential application for lightweight photovoltaic manufacturing and deployment. These diodes represent the first steps toward high-efficiency low-cost, epitaxy-free, III-V photovoltaics. Finally, we also performed a technoeconomic analysis indicating a scalable pathway for epitaxy/vacuum-free III-V photovoltaics to achieve LCOE parity with future silicon photovoltaics, with a capital cost of 8cent/Watt for module manufacturing.

Bifacial CdTe Photovoltaics: Studies, Progress, and Next Steps Adam Phillips[1], Kamala Khanal Subedi[1], Dipendra Pokhrel[1], Aesha Patel[1], Manoj Jamarkattel[1], Abdul Quader[1], Prabodika N. Kaluarachchi[1], Jared Friedl[1], Tyler Brau[1], Dengbing Li[1], Jialiu Ma[2], James Becker[2], Chungho Lee[2], Gang Xiong[2], Bill Huber[2], Wyatt Metzger[2], Abasi Abudulimu[1], Zhaoning Song[1], Robert W. Collins[1], Nikolas Podraza[1], Yanfa Yan[1], Ebin Bastola[1], Michael J. Heben[1] and Randy Ellingson[1]; [1]University of Toledo, United States; [2]First Solar, United States

The increased energy yield of bifacial PV reduces $/kWh costs and accelerates solar PV adoption. Successful interface passivation at c-Si contacts has enabled excellent bifacial performance for that technology. In contrast, poor electronic and chemical passivation at the back contact of thin film solar cells have thus far prohibited commercially viable bifacial CIGS and CdTe PV technologies, which utilize a p-type polycrystalline absorber. In these devices, the product of electron density and interface recombination velocity yields high recombination current density at the back contact. We review recent progress towards improved experimental and computational understanding and control of the CdTe back contact properties using viable transparent interface materials. As just one example of many, we have studied $CdCl_2$-treated CdTe devices subjected to low-temperature annealing following deposition of copper and chromium nitrate solutions intended to form Cu_xCrO_y as a p-type buffer layer. The approach has demonstrated backside illuminated devices with high current density and high fill factor, with performance that persists even for thicker absorber layers, showing efficient charge collection even without a fully-depleted device. Our modeling efforts aim to delineate whether passivation consists of reduced downward band-bending (electronic passivation), reduced back-contact defect density (chemical passivation) and back surface recombination velocity (BSRV), or both types of passivation. Devices with 8% back-illuminated efficiency and >50% bifaciality have been demonstrated, but significant progress remains in order to demonstrate high-efficiency state-of-the-art devices with beneficial energy yield. Future bifacial performance gains rely on improved understanding and control of the back contact interface, remediating defects to reduce BSRV, and engineering band-bending which propels electrons away from the back contact region. We will also discuss the implications for bifacial CdTe devices of transitioning from Cu-doped to As-doped absorbers.

4:15 PM *EN02.17.03

High-efficiency Flexible Chalcogenide Photovoltaics and Their Tandem Cell Applications Donghyeop Shin[1], Awet Mana Amare[1], Inyoung Jeong[1], Inchan Hwang[1], Soomin Song[1], Young-Joo Eo[1], Ara Cho[1], Jun-Sik Cho[1], Joo Hyung Park[1], Seung Kyu Ahn[1], Jinsu Yoo[1], SeJin Ahn[1], Jihye Gwak[1], Hojin Lee[2], Byungha Shin[2], Jae Ho Yun[3] and Kihwan Kim[1]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Korea Institute of Energy Tecnology, Korea (the Republic of)

<p>Cu-based chalcogenide thin films such as chalcopyrite, kesterite, and etc. have drawn significant attentions as a photovoltaic absorber since the Cu(In,Ga)Se_2 (CIGSe) record cell achieved the power conversion efficiency of 23.35% on a glass substrate. In recent years, there is high demand on lightweight and flexible photovoltaic devices to realize BIPV and VIPV applications. As a result, flexible solar cells have been studied using various flexible substrates such as stainless steel (STS), polyimide (PI), and etc. Furthermore, ultra-thin glass (UTG) is being considered as an emerging potential for flexible solar cells. Despite the successful achievement of high-efficiency flexible CIGSe solar cells (> more than 20%), each flexible material has advantages and disadvantages. The STS substrate contains detrimental Fe element that leads to formation of deep-level defects. Besides, they have a rough surface compared to flat glass substrate. On the other hand, the PI substrate is vulnerable to high-temperature processes so that it is hard to adopt commonly applied conditions (ex. high-temperature process of >550C) for glass substrate to produce high-quality CIGSe films. Presumably, the performance gap between rigid and flexible cells originates from limitations on the material properties and/or high-temperature process. In order to overcome these drawbacks, UTG is also attempted as a flexible substrate of CIGSe solar cells. In this work, we have developed compatible deposition process for high-efficiency CIGSe solar cells on various flexible substrates: STS and PI as well as UTG. Their efficiencies of PV devices on STS, PI, and UTG yielded more than ~19% which was higher than CIGSe solar cells on the rigid glass substrate (~17%). It means that UTG could be also suggested as a novel flexible substrate for CIGSe solar cells. In addition to flexible solar cells, the CIGSe PV devices can be used as a bottom cell in tandem configuration combined with a highly efficient perovskite-based top cell. To maximize use of the full spectrum of incident light, we fabricated monolithic perovskite/CIGSe tandem solar cells. The best tandem cells showed higher than 20%. Consequently, the obtained results indicate that chalcogenide solar cells still possess versatile potential to demonstrate flexible and tandem applications</p>

4:45 PM EN02.17.04
High Performance Bifacial Cu(In,Ga)Se_2 Thin Film Solar Cells and its Application in Tandem Devices with High Power Generation Density Shih-Chi Yang[1], Huagui Lai[1], Tzu-yin Lin[2], Mario Ochoa[3], Radha K. Kothandaraman[1], Ayodhya N. Tiwari[1], Fan Fu[1] and Romain Carron[1]; [1]EMPA, Switzerland; [2]National Tsing Hua University, Taiwan; [3]University of Cantabria, Spain

Thin film solar cells based on polycrystalline Cu(In,Ga)Se_2 (CIGS) have reached efficiencies of 23.35% on glass and 22.2% on flexible substrates to date. It becomes more and more appealing to develop advanced device architectures like bifacial or semi-transparent devices. However, transparent electrical back contacts (TBC) required in these applications typically suffer from unfavorable transport properties due to the formation of detrimental GaO_x at the CIGS/TBC interface after high temperature CIGS deposition process. The combination of short diffusion length of carriers and high rear interface recombination results in low performance under rear illumination. As a result, efficiencies of devices with TBC remain below that of Mo back contact counterparts, with the highest reported efficiency of 16.1%. The highest efficiency of bifacial devices measured under front and rear illuminations are 9.0% and 7.1%, respectively. Therefore, further development of TCO-based devices including bifacial, bifacial tandem, semi-transparent, and ultra-thin rear-back-contact (RBC) devices remained stagnant.

To overcome those challenges, we investigated prospects of reducing the absorber deposition temperature by adding a small amount of Ag (equivalent of few nanometers) in CIGS to get rid of the detrimental GaO_x interface layer while maintaining the high quality of the absorbers. In this work, absorbers were grown by co-evaporation method on Ag-coated ITO/glass substrates at nominal temperatures ranging from 300°C to 450°C. We identify an optimal process temperature of around 350°C, which gives rise to GaO_x-free interface, high absorber quality, high transmittance of ITO back contact and suitable GGI back gradings. A bifacial CIGS solar cell was obtained with efficiencies of 19.77% and 10.89% under front and rear 1-sun illumination, as independently certified by Fraunhofer ISE. To the best of our knowledge, both values are the highest efficiencies reported for a chalcopyrite-based TBC structure.

Finally, we demonstrate high performance 4-terminal bifacial perovskite/CIGS tandem solar cells. We achieved a power generation density of 28.0 mW/cm^2 $BiFi_{300}$ with a gain of 8.9 mW/cm^2 as compared to the performance of the stand-alone CIGS cell. Further improved performance will be presented. Another promising application is all-thin-film 2-terminal bifacial perovskite/CIGS tandem solar devices. Due to higher J_{SC} in the bottom cell resulting from the additional albedo light, the current matching condition allows perovskite top cell with a reduced bandgap, which generally has less stability issue from halide segregation. Therefore, anticipated high performance and improved stability of bifacial monolithic perovskite/CIGS tandem solar cells could feature a prominent place in future photovoltaics markets.

Our study provides insights into the key limiting factors for bifacial CIGS thin film solar cells. It paves the way for the development of not only TBC-based chalcopyrite solar cell architectures but also next generation of PV technologies toward high-energy yield.

Characterization and Modelling of Thin Dielectric Layers for Advanced PV Cells Denis Flandre; UCLouvain / ICTEAM / ELEN, Belgium

Thin dielectric layers are widely introduced as passivation, tunneling or carrier-transport layers in advanced photovoltaic (PV) cells, implemented in Si as well as more recently other thin-film semiconductor materials.

Specific characterization techniques and physical models need to be considered to identify and assess their electrical properties of importance for the performance of the PV cells.

The main concepts and their significance will be reviewed based on study cases incorporating different reference or innovative materials.

1) The electrical passivation performance (i.e. fixed oxide charges, interface traps and carrier lifetimes) of different Al_2O_3/SiO_2 thin dielectric stacks

realized on monocrystalline Si substrates have been extracted from ac measurements of capacitance (C) and conductance (G) over wide ranges of frequencies and temperatures, with an analytical model comprising a 6-element equivalent circuit [1, 2]. The dc leakage current (I) at low voltage was furthermore related to the trap-assisted tunneling. The effective carrier lifetimes were measured by the contactless photoconductance decay method [3]. Lifetimes of almost 1 ms were obtained at low excess carrier density for the dielectric stack featuring the lowest values of oxide charges, interface states and trap-assisted tunneling current. Bias temperature instability was lately investigated on MOS capacitors, before and after annealing, towards optimizing the process conditions for long-term reliability [4].

2) Such extensive electrical characterization methodology, supported by modelling via numerical simulations (SCAPS, Silvaco Atlas), has been extended to Al_2O_3, HfO_2 and SiO_x layers implemented as a rear passivation layer for ultra-thin (UT) CIGS PV cells [5-7]. Extraction of intrinsic cell parameters from the dark current and ac measurements can be correlated with the PV performance under light [8]. Subsequently, the measured parameters have been introduced in a 2D model of rear-passivated UT-CIGS cells in ATLAS. The model has been exploited to understand and optimize the trade-off between passivation quality and series resistance (related to the ratio of passivated area versus the sizes of the rear opening contacts) that impacts gains or losses of cell performances, confirming experimental trends [9].

3) A third category of materials include TiO_2 or SnO_2 metal oxides that we have studied as electron-transport layers on Si, CIGS or perovskite substrates [10-11]. For such doped oxides, the C-V characteristics often show large variations and unexpected behaviors. Based on simulations that fairly reproduce our main observations and provide new physical insight, the results have been related to full or partial depletion effects, depending on the oxide doping level and thickness.

Effects of Growth Conditions on Formation Behavior of the Recombination Center in $ZnSnP_2$ Bulk Crystals Isshin Sumiyoshi and Yoshitaro Nose; Kyoto University, Japan

Zinc tin diphosphide (ZTP) is an alternative material for commercialized thin-film photovoltaics due to of the non-toxic and earth-abundant constituent elements, the suitable bandgap, and the high absorption coefficient[1,2]. Our group has reported the ZTP bulk crystal-based solar cell with the record conversion efficiency of 3.87% which is still lower than the theoretical limit[3]. In particular, the short circuit current density of 12.1 mA cm^{-2} is lower compared with that of CIGS solar cells, which is probably due to the really short minority carrier lifetime of sub-nanosecond[4].
We prepared ZTP bulk crystals by solution growth method using Sn as flux. In our previous work, the starting composition was on the line of the Sn–ZnP_2 pseudo–binary system[5], while it is well known that the formation behavior of intrinsic defects which could be carrier traps depends on the chemical potentials of constituent elements. In this study, we thus attempted to enhance the minority carrier lifetime of ZTP crystals by the control of composition, namely chemical potentials in the system. We actually performed the crystal growth in the compositions with 1.3 and 4 mol% of Zn (Zn-rich and P-rich) in addition to the conventional composition, and the other conditions were the same in the previous report[5].
We characterized the ZTP crystal grown under the conventional condition by deep-level transient spectroscopy (DLTS) in which Schottky diodes with Ag (Schottky) /ZTP / Cu_3P / Cu (ohmic) were used. DLTS measurement showed that ZTP had two traps for electrons and five traps for holes within the bandgap. Particularly, the nearest electron trap level to conduction band minimum (CBM), E1, had extremely high capture cross section of ~10^{-11} cm^2 compared with other traps. Furthermore the time constant for electron capture from CBM to E1 was estimated to be ~10^{-4} ns, which was equivalent to the reported minority carrier lifetime[4], indicating that the trap E1 might be the recombination center of ZTP.
We also evaluated the influence of growth condition on the properties of recombination. The fluorescence lifetimes of minority carriers were characterized by time-resolved photoluminescence (TRPL) at the photon energy of 1.69 eV under room temperature. The net fluorescence lifetime of samples of Zn-rich, conventional, and P-rich conditions were estimated to be 0.39, 0.066, and 0.065 ns, respectively. The lifetime of Zn-rich sample is higher than others and the results in the literature[4]. Steady–state PL spectra were also measured at 77K and found to be contained several emissions with energy of around 1.28, 1.52, and 1.77 eV. The emission at 1.77 eV might come from Band-to-Band transition and its intensity in the sample of Zn-rich condition was higher than that of others. This indicates that the concentration of the active recombination center E1 is low in Zn-rich sample, which is consistent with the results of TRPL.
In spite of the change of defect properties by growth conditions, the compositions of all the obtained ZTP were stoichiometric. Therefore, it was implied that the compositional difference of a few mole could affect the formation of intrinsic defects, especially related to E1. We consider two contributions of this phenomena from the viewpoint of thermodynamics: entropy and enthalpy. Both of them depend on chemical potentials of constituent elements in the system during crystal growth, where ZTP and liquid are in thermodynamic equilibrium. Hence, we evaluated the chemical potential of elements in liquid phase using sub-regular solution model, and clarified the precipitation temperature is lower in Zn-rich condition. In the presentation, we will discuss more quantitatively the effects of the entropy and the enthalpy on the formation of defects in ZTP.

Multiwavelength Excitation Raman Scattering Study of Sb_2S_3: Fundamental Vibrational Properties and Application in the Evaluation of Crystallographic Orientation Victoria Rotaru[1], Pedro Vidal-Fuentes[1], Alex J. Lopez-Garcia[1], Tariq Jawhari[2], Xavier Alcobé[2], Alejandro Perez-Rodriguez[1,3], Victor Izquierdo-Roca[1] and Maxim Guc[1]; [1]Catalonia Institute for Energy Research (IREC), Spain; [2]Centres Científics i Tecnològics de la Universitat de Barcelona (CCiTUB), Spain; [3]Departament d'Enginyeria Electrònica i Biomèdica, Universitat de Barcelona, Spain

Sb_2S_3 has become popular in several research fields [1,2] and most prominently among the PV community, achieving efficiency values close to 8% in short time. One of the key aspects of this compound is its high structural anisotropy, where the atoms are bonded by covalent bonds along one crystallographic axis forming ribbons, which are attached together by van der Waals forces along the other two directions [3]. This translates into highly anisotropic properties that are, in fact, an important parameter to control when implementing Sb_2S_3 in optoelectronic devices, where, for example, increased mobility is achieved along the covalently bonded axis. Likewise, this anisotropy is expected to have a strong impact on the vibrational properties of Sb_2S_3.
Being a material that attracted significant interest in the last years, the vibrational properties of this anisotropic compound are still not properly understood in the literature. In order to establish a clearer understanding of the discrepancies between Raman spectra of Sb_2S_3 in existing articles, an investigation of the fundamental vibrational properties of the Sb_2S_3 compound by Multiwavelength Raman spectroscopy was performed. As a starting point, in order to fully identify the features present in the Raman spectra of Sb_2S_3, a single crystal grains powder sample was analyzed in order to minimize the possible influence of the crystallographic orientation, with a multiwavelength approach using eight excitation wavelengths in the range from 325 up to 1064 nm.

Resonance and pre-resonance effect yielded changes in the intensity of several Raman peaks, highlighting them in dependence on the excitation laser employed. Furthermore, low temperature (~20 K) measurements were also carried out with λ_{ex} = 632.8 nm excitation on the powder sample, reducing the thermal agitation of the material and reducing the width of the peaks, which allowed to better resolve the low intensity peaks. Finally, polarization dependent Raman scattering measurements have been also performed on a Sb_2S_3 single crystal mineral, which not only enrich the knowledge about the specific peaks, but also give rise to some changes in peak intensities in the different configurations. As a result, the deconvolution of the obtained Raman spectra for each wavelength, polarization and temperature was performed, thus enabling the generation of a complete fitting function using a combination of Lorentzian curves. This permitted us to establish the position of up to 19 Raman active optical modes from the 30 theoretically predicted, which serves as an important stepping stone for the correct interpretation of the experiments through all the research fields interested in the material.
The study is completed by a deeper analysis of the Sb_2S_3 single crystal mineral. X-ray diffraction analysis allowed to identify the specific crystallographic orientation of these facets, and Raman scattering measurements showed a clear difference in the spectra measured at different fundamental crystallographic planes. The found variations allow the implementation of Raman spectroscopy, a non-invasive technique with lateral micrometric precision, to be used as a quality control tool for the in-situ and in-sample crystallographic orientation assessment of Sb_2S_3 thin films that are proposed as emerging PV technologies with a relevant cost-efficient potential. Finally, application of Raman scattering in device grade layers and finished solar cells corroborates the potential of the technique for the identification of the potential presence of secondary phases and the crystalline assessment of the layers, which provides with a powerful non-destructive characterization tool for device optimization.

This work is part of the R+D+i MaterOne project Ref. PID 2020-116719RB-C42 funded by MCIN/AEI/10.13039/5011000110033.

Engineering a Thin-Film Absorber of Silver Antimony Sulfur Selenide Solar Cells Sanghyun Lee[1] and Kent Price[2]; [1]University of Kentucky, United States; [2]Morehead State University, United States

Silver Antimony Sulfur Selenide, $AgSb(S_xSe_{1-x})_3$ thin-film solar cells have been emerging as third-generation photovoltaic devices with promising properties of the tunable bandgap (0.7 - 1.9 eV), good doping concentration (10^{16} cm^{-3}), high absorption coefficient (>10^4 cm^{-1}), and simplified processing conditions with high vapor pressure and low melting point (550 C). There have been several studies about $AgSb(S_xSe_{1-x})_3$ thin-film absorbers by depositing $Sb_2(S_xSe_{1-x})_3$, Ag, and Se thin-film precursors, followed by the heat treatment. With the favorable optical bandgap of $AgSb(S_xSe_{1-x})_3$ thin-films (x=0.53, 0.58, and 0.61), the efficiency has been improved with >2.77 %. In another approaches, $AgSbSe_3$ thin-film absorber devices demonstrate <0.1 %, whereas $AgSbS_3$ thin-films devices show approximately 0.27 %. Since Antimony Sulfur Selenide, $Sb(S_xSe_{1-x})_3$ thin-films have demonstrated good optical and electronic properties as an absorber layer, further optimization of thin-film absorber layers could be achieved by utilizing both $Sb(S_xSe_{1-x})_3$ and $AgSb(S_xSe_{1-x})_3$ thin-films. As we reported earlier, substituting Ag in $Sb(S_xSe_{1-x})_3$ thin-films tends to increase the bandgap of the absorber layer by lowering the valence band based on studies of other thin-film absorber layers such as Copper Indium Gallium Diselenide (CIGS) and Copper Zinc Tin Sulfur Selenide (CZTSSe) thin-films.

In this study, we have conducted a theoretical study on thin-film absorbers of $AgSb(S_xSe_{1-x})_3$, $Sb(S_xSe_{1-x})_3$, and the combination of $AgSb(S_xSe_{1-x})_3$ and $Sb(S_xSe_{1-x})_3$ thin-films from the electronic band structure perspective. To fully utilize the promising properties of both $Sb_2(S_xSe_{1-x})_3$ and $AgSb(S_xSe_{1-x})_3$ films, we investigated different compositions and concentrations of Sulfur and Selenium with proposed empirical equations for electron affinity and bandgap energy. Furthermore, we varied the doping of thin-film absorbers to search for the optimal conditions for the band alignment to Molybdenum metal back contact films. For our analytical simulation, we have used in-house MATLAB modeling suites that have been developed in our group.

Four different structures of thin-film absorbers have been modeled above Molybdenum metal thin-films. The workfunction of Molybdenum metal thin-films is 4.9 eV and an inevitable MoS_xSe_{1-x} interlayer was inserted during our simulation throughout this study. For both $AgSb(S_xSe_{1-x})_3$ and $Sb(S_xSe_{1-x})_3$ thin-films, the electron affinity and bandgap energy increase as Sulfur (x) composition increases. However, the increased bandgap is not directly translated into improved solar cells efficiency due to the alignment of thin-film electronic structures. For example, the best efficiency was achieved with 2 um $AgSb(S_{0.4}Se_{0.6})_3$ thin-film devices (18.4 %) at sulfur concentration, x = 0.4. However, once we combine two $AgSb(S_xSe_{1-x})_3$ and $Sb(S_xSe_{1-x})_3$ thin-films while keeping a total thickness, 2 um (1 um/1 um), an interface between $AgSb(S_{0.4}Se_{0.6})_3$/ $Sb_2(S_{0.4}Se_{0.6})_3$ and Molybdenum metal thin-films is preferably formed due to reduced effective Schottky hole barrier. If we assume the same amount of defect states at the interface, the improved effective Schottky hole barrier is 128 mV due to the favorable band alignment, which is approximate 4.3 times better than a $AgSb(S_{0.4}Se_{0.6})_3$ thin-film structure. With a bi-layer $AgSb(S_{0.4}Se_{0.6})_3/Sb_2(S_{0.4}Se_{0.6})_3$ thin-film absorber, we studied various doping concentrations impact on device efficiency based on the modified electronic band structure of each thin-film. The doping concentration of a $AgSb(S_{0.4}Se_{0.6})_3$ thin-film mainly increases the photogenerated current while a $Sb_2(S_{0.4}Se_{0.6})_3$ thin-film improves open circuit voltage.

Double In and Ga Donor Doping and Self-Compensating Process in ZnO Nanocrystal Films Tetyana v. Torchynska[1], Brahim el Filali[1], Georgiy Polupan[1] and Lyudmyla Shcherbyna[2]; [1]Instituto Politecnico Nacional, Mexico; [2]4V.Lashkaryov Institute of Semiconductor Physics at the NASU, Ukraine

Zinc oxide has attracted attention for decades due to its important optical, electrical, chemical and microstructural properties, interesting for optoelectronic applications in light emitting devices, transparent conduction oxide (TCO) in solar cells, gas sensors, flat screens and touch panel displays, in vacuum fluorescent displays, in photovoltaics or thermal mirrors. But the n-type conductivity of non-doped ZnO films is not high enough to be used in devices. Group–III atoms (Al, Ga, In) are very important donors for ZnO film–based technology. However, the free electron density in doped ZnO films was revealed to be limited to 10^{19} - 10^{21} cm$^{-3.}$ due to the self-compensating effect, related to generation of the acceptor-type defects to counteract of donor doping. The nature of these acceptor type defects and the factors that stimulate the self-compensating effect still remain to be investigated.
It was supposed that one reason for the self – compensating effect can be connected with a high level of elastic stresses in the doped ZnO films with high donor contents. In the present work, the variation of the optical, structural and electrical parameters of the ZnO nanocrystal (NC) films doped with Ga and In atoms has been investigated. ZnO films of 2 groups were grown by ultrasonic spray pyrolysis with the In contents 1.0 at% (1) or 2.0 at% (2) and the different concentrations of Ga from the range 0.5-3.0 at %. Using co-doping by Ga and In atoms with lower (Ga) and higher (In) ionic radii compared to the Zn ions, it is expected to lower the stresses in the films and gain insight into the factors favored to the self-compensating effect.
The ZnO films have been studied using scanning electron microscopy (SEM), energy dispersive X ray spectroscopy (EDS), X ray diffraction (XRD), photoluminescence (PL) and X-ray photo electronic spectroscopy (XPS). Non-monotonic changes in the morphology of films were revealed that correlates with non-monotonic changes of oxygen and indium contents in ZnO films with variation of Ga contents. Compressive stresses arising due to In doping prevent effective oxidation at the film crystallization. The Ga doping up to 1.5 at% allows to compensate the compressive stresses in the films that is favored to the effective ZnO oxidation and the dissolution of In ions in the thermal annealing. High donor doping was shown to be accompanied by the

appearance of a new near band edge (NBE) emission band, related to carrier recombination in the shallow donor-acceptor pairs (DAPs), which is a "fingerprint" of a beginning of the self-compensating process. Simultaneously, the effective charges of the Ga (In) ions decrease and the rate of electrical resistivity reduction slows down. The nature of shallow donors and acceptors in DAPs, as well as the impact of co-doping by Ga and In atoms on the self-compensating effect have been discussed.

Growth of $SrHfS_3$ and $SrZrS_3$ Thin Film by Magnetron Sputtering Haolei Hui[1], Zhonghai Yu[2], Chang Huai[1], Thomas Hahn[1], Sen Yang[2] and Hao Zeng[1]; [1]University at Buffalo, The State University of New York, United States; [2]Xi'an Jiao Tong University, China

Chalcogenide perovskite is an emerging class of semiconductor materials with potential applications in electronics and optoelectronics. $SrHfS_3$ in the distorted perovskite structure is shown to be a direct gap semiconductor with strong green photoluminescence. Together with its high stability defect tolerance, it many find applications such as LEDs. In this work we report the synthesis of $SrHfS_3$ and $SrZrS_3$ thin films by magnetron sputtering using metal targets, followed by CS_2 sulfurization. Salts was used improve the film crystallinity. Sample growth on conductive substrates was also attempted, with an eye for device fabrications. Our work demonstrates a new way of fabricating $SrHfS_3$ and $SrZrS_3$ thin films with controllable composition.

Surface Photovoltage Spectroscopy to Evaluate Rear Passivation Strategies in CdTe Photovoltaics Nathan D. Rock[1], Mike Scarpulla[1], Kristopher O. Davis[2] and Amit Munshi[3]; [1]University of Utah, United States; [2]University of Central Florida, United States; [3]Colorado State University, United States

We present developments in surface photovoltaic spectroscopy (SPS), aimed at characterizing passivation strategies for CdTe cell interfaces, particularly the rear contact. Effective rear contact passivation has been predicted to increase device efficiency by as much as 3.5% when coupled with a hole selective contact. We demonstrate how SPS is a critical tool in evaluating novel solutions to eliminate voltage loss at interfaces. We examine the effect of known wet etchant strategies on SPS signal, correlating and contrasting the information gained with that available via TRPL. We also explore passivating interface layers in CdTe and Si based devices. SPS signals are evaluated via SCAPS 1D modeling and analytical modeling and the effects of surface recombination velocity, band bending, and recombination in bulk and SCR are extracted.

Silver-Alloying in Wide-Gap CIGS Absorbers—Challenges and Latest Advances Toward Application in a Tandem Device Jan Keller, Lars Stolt, Patrick Pearson, Kostiantyn Sopiha and Marika Edoff; Uppsala University, Sweden

This presentation summarizes our latest research on wide-gap, silver-alloyed $Cu(In,Ga)Se_2$ (CIGS) solar cells (i.e. forming ACIGS). The processed absorber layers had band gap values (E_G) in the range of 1.40 to 1.65 eV, making them attractive for application in top cells of tandem devices. To reach this high E_G level, the [Ga]/([Ga]+[In]) (GGI) ratio needs to be at least 0.65. For pure CIGS solar cells, such high Ga concentrations not only lead to a large deficit in open-circuit voltage (V_{OC}), but also to a distinct deficit in short-circuit current density (J_{SC}) and fill factor (FF). The main problem seems to be a deteriorating absorber quality with increasing GGI. However, since the application of alternative buffer layers can mitigate the V_{OC} loss, wide-gap CIGS devices with standard CdS buffers must be partly limited by interface recombination as well.

Alloying silver into wide-gap CIGS has been explored by several groups before [1-3]. Although the performance gap to low-E_G devices could not be closed completely, the results highlight the potential for solar cells with $E_G > 1.4$ eV.

In our recent works [4-8], we first focused on identifying the optimum compositional window for high-performance ACIGS solar cells, while keeping the GGI level above 0.65. Calculations based on density functional theory show that the conduction band shifts downwards with Ag addition. A beneficial positive conduction band offset with CdS is predicted for an [Ag]/([Ag]+[Cu]) (AAC) value of at least 0.3 (increasing with increasing GGI). Our experimental results, with highest efficiencies for AAC = 0.5 at a band gap of 1.45 eV (GGI = 0.72), confirmed this trend. The champion device with a (Zn,Sn)O buffer exhibited an efficiency of 15.1% without anti-reflection coating (ARC) [4]. However, for higher GGI and AAC values (i.e. $E_G > 1.5$ eV), the efficiency starts to decline significantly.

To investigate the limitations for ACIGS solar cells with higher E_G, the effect of the absorber stoichiometry was studied for a constant GGI = 0.85 and AAC = 0.8, yielding $E_G = 1.62$ eV (i.e. sweet-spot for tandem applications) [5]. It was found that already a minor group-I deficiency leads to a substantial formation of ordered vacancy compounds (OVCs). For too off-stoichiometric ACIGS, OVC patches form at the back interface, leading to a significant FF drop. The highest efficiency of 10.2% (no ARC) is reached for a reverse voltage sweep (hysteresis found).

Next, the AAC and GGI ratios were simultaneously reduced again to about 0.60 and 0.75, respectively. Although the OVC formation was mitigated, our analysis of a large sample set proved a clear stoichiometry effect on the solar cell characteristics [6]. It was revealed that near-stoichiometric absorbers approach full depletion, whereas off-stoichiometric materials have doping densities "common" for CIGS absorbers. Due to the generally low diffusion length, this results in a low carrier collection (but higher V_{OC}) for off-stoichiometric, and perfect carrier collection (but lower V_{OC}) for stoichiometric samples. Consequently, the highest V_{OC} of 916 mV was measured for an off-stoichiometric sample ($E_G = 1.46$ eV, CdS buffer). By applying an RbF post-deposition treatment, the V_{OC} could be further increased to 926 mV and an efficiency of 16.3% (no ARC) was achieved [7].

Finally, the Mo back contact was exchanged by an In_2O_3:H film, with almost complete near-infrared transparency [8]. After fine-tuning the sodium supply, an efficiency of 12% (no ARC) was reached, using a stoichiometric ACIGS absorber with $E_G = 1.44$ eV.

Characterisation of Electronic Defects on the Sub-Micron Scale of the Absorber-Buffer Interface between $Cu_2ZnSn(S,Se)_4$ and ZnSnO Alice Sheppard, Raphael E. Agbenyeke, Jude Laverock, Neil A. Fox and David J. Fermin; University of Bristol, United Kingdom

Transitioning into global carbon neutrality by 2050 is vital to ensure the health and future of Earth. The fabrication of a low-cost, high efficiency thin film photovoltaic (PV) material for building-integrated PV will help fulfil the need for renewable energy sources moving forward. $Cu_2ZnSn(S,Se)_4$ (CZTSSe) is an earth-abundant, non-toxic thin film solar absorber with a theoretical power conversion efficiency (PCE) of 20%, [1] and can help fulfil this PV requirement. Severe voltage deficits due to deep-level defects and interfacial recombination have plagued the performance of a CZTSSe/CdS device, where little is known about the surface electronic landscape of the key absorber-buffer interface. This study replaces the use of toxic CdS with ZnSnO (ZTO) as the buffer material, deposited using atomic layer deposition, due to ZTO having a larger, tuneable bandgap between 3.3 to 3.7 eV. The electronic structure of the CZTSSe/ZTO interface will be probed using energy-filtered photoemission electron microscopy (EF-PEEM) to identify possible harmful features hindering performance. Furthermore, band alignment studies, using ultraviolet photoelectron spectroscopy, will investigate the suitability of ZTO as a buffer layer.

Mapping the Energetics of Bulk and Surface Defect States in Solution-Processed Cu_2ZnSnS_4 Thin-Film David J. Fermin[1], Devendra Tiwari[2], Alice Sheppard[1] and Raphael E. Agbenyeke[1]; [1]University of Bristol, United Kingdom; [2]Northumbria University, United Kingdom

Inorganic solar cells based on $Cu_2ZnSn(S_xSe_{1-x})_4$ thin-film absorbers have reached power conversion values of 11.5% [1] and 13.0 % [2] in the sulfide and sulfo-selenide forms, respectively. Although these performance levels are some of the most promising in In-free *substrate* device configuration, they remain far below their theoretical limit.[3] It is widely recognised that cell voltage is the key limiting factor in these devices, and a variety of strategies have been investigated including doping and alloying the absorber layer.[4-6]

The complexity in the composition of these compound semiconductors offers key advantages such as tuneable band energetics, but also brings about significant challenges in terms of secondary phases and point defects which can be detrimental to device performance.[7] For instance, voltage loss has been linked Cu/Zn antisites as well as Sn defect.[3,7,8] In this contribution, we investigate the position and distribution of defect states in the bulk and at the surface of Cu_2ZnSnS_4 (CZTS) thin films prepared by solution based methods, employing variable temperature photoluminescence (PL) spectroscopy and high-resolution energy-filtered photoemission of electron microscopy (EF-PEEM), a technique which can unravel valuable information on variations of the surface electronic properties of these complex materials.[9,10,11]

Variable temperature PL spectra are dominated by emission from quasi-donor acceptor pairs (QDAP) with activation energy values strongly affected by the introduction Sb and Na:Sb as dopants.[12] Indeed, we will show that incorporation of Sb in the range 0.05% wt leads to a clear transition from localized to non-localized QDAP emission. EF-PEEM also reveals significant changes in the surface electronic landscape upon doping, with mean local effective work function decreasing by more than 0.2 eV upon Sb doping. PL and EF-PEEM clearly show that Na can regulate Sb doping levels, keeping the same PL characteristics of CZTS without any added dopants but with a smoother surface electronic landscape as probed by EF-PEEM.[10,12] We will also correlate variable temperature PL of the thin-films with variable temperature admittance spectroscopy of full devices. This analysis allows linking spectroscopic signatures associated with Cu/Zn and Sn defect states with admittance responses of the device. We will show that dopants such as Na and Sb can affect not only carrier density, but also decrease the density of defects associated with elemental disorder in the film as well as the relative position of the band edges, which can have a profound defect in device performance.

Tails States, Voc Loss and Semiconductor Compensation Susanne Siebentritt and Omar Ramirez; Univ of Luxembourg, Luxembourg

It has been shown for many solar cell absorbers that Voc loss correlates with the Urbach energy, that describes the decay of tail states into the band gap. In chalcopyrites it was furthermore observed that heavy alkali postdeposition treatments reduce both: Urbach energy and Voc loss. This behaviour has been attributed to passivation of grain boundaries [1]. However, recently we have shown, that alkali treatment in single crystalline films without grain boundaries also leads to a reduction of Voc loss and Urbach energies [2]. This behaviour can be traced back to a reduced compensation by increasing the doping level [3]. It is to be expected that a similar mechanism plays a role in polycrystalline films.
Part of the dependence of the Voc loss on Urbach energy can be attributed to radiative and non-radiative recombination in and through tail states [4]. However, the dependence is stronger than would be expected from the increased recombination. We now understand that this is due to a simultaneity: increasing doping has a simultaneous effect, increasing Voc and decreasing tail states.
Thus, we propose, that one effect of heavy alkali treatment is due to the observed increase of Na doping inside the grains, because it increases the net-doping, reduces tail states and thereby reduces radiative and non-radiative recombination. All this increases Voc.

UV and X-ray Stability of CsPbBr$_3$ Perovskite Nanocrystals Azmat Ali[1], Fredrik O. Johansson[1,2], Mariam Ahmad[3], Hervé Cruguel[1], Erika Giangrisostomi[4], Ruslan Ovsyannikov[4], Lenart Dudy[5], Mathieu G. Silly[5], Morten Madsen[3], Emmanuel L'Huillier[1] and Nadine Witkowski[1]; [1]Sorbonne Université, France; [2]KTH Royal Institute of Technology, Sweden; [3]University of Southern Denmark, Denmark; [4]Institute for Methods and Instrumentation in Synchrotron Radiation Research, Germany; [5]Synchrotron SOLEIL, France

Understanding of electronic band structure and charge carrier dynamics of halide perovskites and their interface is critical for the advancement of perovskite photovoltaics[1,2]. Inorganic Cesium lead bromide (CsPbBr$_3$) perovskite nanocrystals (NCs) with a bandgap of 2.3 eV are regarded as one of the potential candidates as an active layer in solar cells devices, thanks to significant progress made recently in terms of improving its intrinsic properties and stability under environmental conditions. However, stability under UV and X-ray exposure remains an open question[3-6]. The stability of spin-coated CsPbBr$_3$ NCs deposited on gold (Au) substrates is investigated here under the impact of the UV laser light and X-rays. Under the UV laser pulse, the NCs exhibit distinctly different behavior depending upon the energy of the laser pulse, its fluence and time NCs exposed to it. When the NCs are exposed to UV laser pulses with the photon energy of 3.6 eV (greater than the bandgap), the NCs are modified irreversibly. Both metallic lead and ionic lead with a new component of Pb4f are detected in the Pb4f core-level spectra. Similarly, when NCs exposed exclusively to X-ray with high flux, same components of Pb4f were found in Pb4f spectrum. The modification is more or less similar in either case; however, under UV laser exposure, a large chemical shift of 0.69 eV towards higher binding energy observed after the exposure, which is not the case with X-ray exposure alone. The chemical shift could be attributed to the accumulation of charge carriers at the interface under UV laser and getting trapped by the metallic lead (donor-type surface states) [6]. Therefore, depending on the type of radiation exposure either UV laser or X-rays, the CsPbBr$_3$ NCs show different behavior and thus the energy level alignments. We show that the chemical properties of NCs are sensitive to UV laser and X-rays irradiation, and investigation of these changes under the type of radiation exposure might help us understand the underlying phenomenon that governs these changes.

Thermal Management in Caloric Devices Andrej Kitanovski, Katja Klinar, Katja Vozel and Nada Petelin; University of Ljubljana, Slovenia

Caloric energy conversion is an emerging field of cooling, heat-pumping and power-generation technologies. The potentially high energy efficiency and use of environmentally friendly and safe solid-state working substances has stimulated increased research activity in the past two decades. Most of today's caloric devices use so-called active regeneration, in which the working fluid oscillates through the matrix of the caloric material - the caloric regenerator. This is associated with irreversible viscous and heat-transfer losses and limits the operating frequency and related power density of the device.

Thermal Control Devices (TCDs) represent an alternative thermal management technique to active regeneration processes, which are widely used as a heat transfer principle in caloric technologies. TCDs allow non-linear, switchable and active control of the heat, similar to the control of electrical current by their electrical counterparts. Their integration in the form of thermal diodes, thermal switches, thermal regulators, and thermal conductors in caloric energy conversion system has the potential to significantly increase power density through rapid and oscillatory heat transfer from/to the caloric material and the heat sink/source while maintaining high energy efficiency, thus meeting the most important market condition and facilitating the commercialization of caloric technologies.
Despite some research activities on TCDs integrated in caloric technologies, research in this particular area is still at an early stage. There is a great lack of knowledge and experience regarding the operational performance of the different types of TCDs as well as their performance when integrated into caloric

devices. On the other hand, the scientific community dealing with materials should focus on various possible (new) materials or their composites, whose thermal properties correspond to the desired properties of thermal diodes, and approach them systematically with proper data collection on their thermal properties.

In this work, we provide a critical and an up-to-date review on the research activities and applications of TCDs in all types of caloric devices, as well as an overview of various mechanisms that have not yet been applied in calorics. Based on this, we provide guidelines and target characteristics for future research activities in the field of caloric technologies.

Materials Design for Fe-Based Magnetic Refrigerants from the Perspective of Utilization for the AMR-Type Modules Asaya Fujita; AIST Chubu, Japan

Among various types of caloric phenomena, magnetocaloric effect is relatively easy to control in a non-contact external field, and therefore, external-field sources are installed by keeping thermal insulation from the heart of the thermal cycle. Meanwhile, attenuation of magnetic flux according to the Coulomb law leads to "gigantic" scales in both the size and cost of the magnetic field generators, such as the electromagnetic or permanent-magnet circuits. For the portability and cost-reduction of the magnetic heat-pump systems, a central issue imposed on materials is a compatibility between realization of highly sensitive magnetocaloric response against smaller magnetic fields, and superior workability for forming compact and efficient beds.
Our recent benchmark in an isothermal entropy change $\triangle S_M$ reaches about 20 J/kg K under 1 T for $(La,Pr)(Fe,Mn,Si)_{13}H$ compounds around 300 K. However, in the active magnetic regenerator (AMR)-type system, which is considered as a most viable technology, no isothermal process is incorporated but only iso-field and adiabatic temperature changes construct the heat cycle. Accordingly, the critical metrics are amount of latent heat η under (even) zero magnetic field and a span of adiabatic temperature change $\triangle T_{ad}$. In this work, we will introduce recent achievements in the materials design, in addition to the theoretical aspect, to improve and analyze η and $\triangle T_{ad}$. We also evaluate the durability of magnetocaloric performance against various fabrication techniques of the bed with integrated microchannel structures. In this regard, careful attention must be paid on the metallographic aspects such as the peritectic reaction in phase diagram, and affinity for (contaminating) light elements. We will discuss the advantages and disadvantages of each method for the bed fabrication.

A Material Study on Magnetocaloric Liquefaction of Hydrogen Tino Gottschall, Eduard Bykov, Timo Niehoff, Marc Strassheim and Catalina Salazar-Mejia; Helmholtz-Zentrum Dresden-Rossendorf, Germany

Magnetic cooling is a refrigeration technique that is based on the so-called magnetocaloric effect, the change of temperature caused by a magnetic field [1]. It can be utilized to construct environmentally friendly cooling devices, air conditioners, and heat pumps [2]. Originally, magnetic cooling was used to achieve ultra-low temperatures by adiabatic demagnetization of magnetic salts. Recently, low temperatures have once again become the focus of attention as an area of application for magnetocaloric cooling namely for hydrogen liquefaction [3,4].

Hydrogen is light, energy dense and clean. If produced from sustainable resources, it represents the ultimate energy carrier for many of our needs. Liquid hydrogen has more than twice the energy density of the gas at 700 bars. What is more, it can be transported in conventional, unpressurised dewars. However, conventional liquefaction means we use 40 % of the energy content of the gas we are compressing, just to liquefy it! Magnetocaloric materials enable an alternative and more efficient approach. A large number of compounds are already known that show magnetocaloric effects in the desired temperature range and new candidates are constantly being added. In this work, we would like to discuss our current progress for the creation of a materials library for cryogenic applications. The basis for this is our characterization infrastructure for materials research at the Dresden High Magnetic Field Laboratory in static and pulsed fields. With this, we want to able to understand these materials in order to further optimize the magnetic-cooling performance near the boiling temperature of hydrogen.

Caloric Effects Owing to Elastic Coupling at Electronic Phase Transitions Peter Littlewood[1], Charles Liang[2] and Gian Guzman-Verri[3]; [1]U Chicago, United States; [2]University of Chicago, United States; [3]University of Costa Rica, Costa Rica

All electronically driven phase transitions are coupled to local ionic displacements, sometimes as their principal manifestation (e.g. charge density waves, ferroelectrics) and sometimes as a side effect (e.g. magnetism, metal to insulator transitions).
The coupling to the lattice induces elastic strain fields, which have intrinsic long-range interactions, which deform the metric of space and cannot be screened. When strain fields are produced as a secondary order parameter in phase transitions - as for example in ferroelectrics - this produces unexpected consequences for the dynamics of order parameter fluctuations.
I will discuss the consequences of electro-strictive coupling in Mott insulators such as the nickelates[1] and phase change materials such as GeTe[2], and flexoelectric coupling for the so-called quantum paraelectrics such as strontium titanate[3].

Elastocaloric Measurements of Quantum Materials—The Case of $TmVO_4$ and the Prospect of Cryogenic Elastocaloric Cooling Ian R. Fisher; Stanford University, United States

We have developed an AC method to probe the elastocaloric effect and have applied it to a variety of quantum materials. The technique can be used to study the entropy landscape associated with continuous phase transitions, but is especially useful for the study of materials for which strain couples to order parameter fluctuations in non-trivial ways. In particular, I will discuss the elastocaloric signature of nematic fluctuations, and the observation of a giant elastocaloric effect in $TmVO_4$, a material that provides a prototypical example of the cooperative Jahn-Teller effect at low temperature.

The Origin of Functional Fatigue in Shape Memory Alloys Huseyin Sehitoglu and Ahmed Sameer Khan Mohammed; University of Illinois, United States

There are a large number of elasto-caloric shape memory alloys (SMAs) with considerable future potential. However, the functionality of SMAs degrades with cycling and this is common to all shape memory alloys with no exception. The degradation of functionality means that the transformation strains decrease and the transformation domains reduce with cycling. The degradation results in changes in hysteresis and transformation stress as well. If the loops shakedown to an elastic state in the limit, the forward and reverse transformation no longer occurs and elasto-caloric effect would disappear. The presentation will explain the underlying causes of the cyclic-induced degradation in shape memory alloys from theoretical considerations. In particular, we will focus on generation of dislocations from crystallographic misfit at interfaces using advanced theory, including first principle calculations, anisotropic elasticity, and theory of martensitic transformations. This understanding at the lattice level will allow refined phenomenological models to be developed that can be utilized in engineering applications.

Twist-Based Refrigeration, Actuation, and Mechanical Energy Harvesting Using Twisted, Coiled, and Plied Yarns Ray H. Baughman; The University of Texas at Dallas, United States

Higher efficiency, lower cost refrigeration is needed for both large- and small-scale cooling. We show that high cooling results from twist changes for twisted, coiled, or supercoiled fibers, including those of natural rubber, NiTi, and polyethylene fishing line. By using opposite chiralities for twist and coiling, supercoiled natural rubber fibers and coiled fishing line fibers result that cool when stretched. Similar mechanics involving twist transfer between yarn twist and coiling are here used to make compact, energy-efficient refrigerators, thermal and electrochemical artificial muscles, and twistron electrochemical mechanical energy harvesters. For harvesting between 2 and 120 Hz, our most recent twistron carbon nanotube harvesters have higher gravimetric peak power and average power than previously reported for any prior-art, material-based mechanical energy harvester.

4:00 PM EN03.02.05
Improving Efficiency of Elastocaloric Cycles by Applying Novel Thermodynamic Cycles and Proper Training Regime Parham Kabirifar[1], Ichiro Takeuchi[2] and Jaka Tusek[1]; [1]University of Ljubljana, Slovenia; [2]University of Maryland, United States

Vapor-compression technology emerged nearly a century ago by utilizing natural refrigerants, which had inherent problems, i.e., low efficiency, inflammability and toxicity. Consequently, stable and more efficient synthesized refrigerants such as chlorofluorocarbons (CFCs) and hydrofluorocarbons (HFCs) were developed, nevertheless, CFCs depleted the ozone layer and HFCs had high global warming potential. Therefore, due to significant environmental impact, vapor-compression technology should soon revert to natural refrigerants. As a result, caloric cooling/heating technologies that use environmentally benign solid-state refrigerants have been considered as serious alternatives to vapor-compression technology, among which, elastocaloric technology, which is based on the latent heat of phase transformation of shape memory alloys (SMAs), has been nominated as the most promising one by the US Department of Energy and the EU Commission. Accordingly, elastocaloric effect of different SMAs has been investigated, and several elastocaloric devices using different geometries and thermodynamic cycles have been designed and tested with promising results. Developing durable elastocaloric devices that are more efficient than their vapor compression counterparts is still the main focus of the ongoing research. However, some of the basics of the elastocaloric cycle have been either overlooked or have not been investigated thoroughly. This study investigates the effects of training (stabilization of thermomechanical response) and the parameters of the elastocaloric cycle on the elastocaloric response of NiTi wires under tensile loading. Multiple training regimes with different stress amplitudes and strain rates have been applied to NiTi thin wires and the elastocaloric response of the samples has been evaluated subsequently. A typical elastocaloric cycle consists of an adiabatic loading and an adiabatic unloading segment each of which is followed by a holding period throughout which the heat can be transferred to/absorbed from the heat transfer medium or a contact heat sink/source. The parameters of the holding period have been systematically investigated by applying constant stress and constant strain throughout the holding period resulting in isostress and isostrain thermodynamic cycles respectively[1]. In addition to the applied training regime, the parameters of the holding period can significantly affect the generated elastocaloric effect and alter the nature of the applied thermodynamic cycle. While the typically applied isostrain cycle results in a Brayton thermodynamic cycle, applying the isostress cycle with partial phase transformation changes the thermodynamic cycle and shifts it toward the Carnot cycle, which has the maximum theoretical efficiency. In addition to the efficiency of the cycle, the isostress cycle generates larger adiabatic temperature changes under lower applied stress levels that can enhance the tensile fatigue life of the wires and reduce the size of the actuators that are needed in practical devices. In multielement configurations like elastocaloric regenerators[2], lower stress levels needed in isostress cycles allow for increasing the number of elastocaloric elements that improves the performance of the regenerator by increasing its heating/cooling power.

Characterization of Natural Rubber Tubes for Elastocaloric Cooling Applications Giulia Lombardi[1], Gael Sebald[1,2], Gildas Coativy[2], Jacques Jay[2] and Atsuki Komiya[1]; [1]Tohoku University, Japan; [2]Institut National des Sciences Appliquées de Lyon, France

The elastocaloric effect of natural rubber (NR) was first studied at the beginning the 19th century, by John Gough in 1805, and James Joule in 1850, giving rise to what is today known as the Gough-Joule effect [1]. This describes the property of NR to give out heat when stretched and to contract when heated. Despite these findings now date back to more than 170 years ago, it was only recently that this elastomer gained interest among the scientific community for space cooling applications. Contrary to most caloric materials, NR is non-toxic, abundant and low-cost.
When stretched between elongation of 1 to an elongation to 6, it was proved experimentally an adiabatic temperature change up to 10~15 K with rather low

mechanical losses leading to a ratio between potential heat exchange and the mechanical work around 3~5 (also known as COP_{mat}) [2]. This attractive elastocaloric activity is however not applicable because of the excessive geometry change during operation. For example, the surface at an elongation of 1 might be too small for fast heat exchange compared to the fully elongated one (change of exchange area combined with the large increase of the thickness). Therefore, up to now, we can mention only two works that explored the development of elastocaloric cooling based on NR: the single-tube system developed by Sebald *et al.* in 2020 [3] and the membrane-inflation system developed by Greibich *et al.* in 2021 [4]. This is highly in contrast with the number of published works of caloric cooling systems based on other elastocaloric materials, the most used being NiTi-based shape-memory alloys (SMAs) mainly due to its high adiabatic temperature (between 15 K and 40 K). However, these materials require high values of applied tensile force (300 MPa or more), which are not ideal for system scale-up.
The objective of this work is devoted to the experimental evaluation of the elastocaloric activity of elastocaloric elastomers, that will be presented in detail. As a focus, we demonstrate that NR is indeed a good candidate for elastocaloric cooling applications, despite the limited adiabatic temperature exhibited by the material when subjected to cyclic elongations. Cyclic elastocaloric properties of NR tubes were studied by imposing trapezoidal cycles at 0.1 Hz under various elongations. The maximum temperature variations on the material were recorded for elongations between 400% and 600% of its initial length, giving a ΔT of 4 K. The main advantage of NR lies on the applied tensile stress, two orders of magnitude lower than that required by SMAs. We recorded, in fact, a maximum stress on the NR tubes of 2 MPa for cyclic elongations at 0.1 Hz between 350% and 550% of its initial length. The corresponding mechanical losses were found to be equal to 0.27 MJ m^{-3}. In order to estimate the material efficiency for elastocaloric cooling, we calculated the material coefficient of performance COP_{mat} , defined as the potential absorbed heat divided by the hysteresis loss. We found a COP_{mat} value of 22 when considering the first 50 cycles, which is one of the highest recorded values among elastocaloric materials. As the characterization proceeded until 10^4 cycles, the COP_{mat} reached 53, thanks to a drop of the mechanical losses of the material. These values, along with the low tensile force required, demonstrate the high elastocaloric potential of NR, a future key material to be used in cooling applications, given that further improvements both on the material and on the system side are achievable.

Elastocaloric Response of Isotropic Liquid Crystalline Elastomers Jeremy Herman and Timothy White; University of Colorado Boulder, United States

Liquid crystalline elastomers (LCE) are anisotropic, soft materials that align or reorient to deformation. The order of LCE has led to both theoretical and experimental consideration of their potential as elastocaloric materials. Elastocaloric responses in materials are typified by an association of deformation, change in entropy, and an associated temperature change. We have recently reported that mechanotropic phase changes (e.g., mechanically induced liquid crystalline phases) exhibit temperature changes of 2°C upon deformation (100% strain). Here, we examine the elastocaloric response of what we refer to as "isotropic" LCE (iso-LCE). Iso-LCE are materials that exhibit nematic to isotropic transition temperatures (T_{NI}) below room temperature. Accordingly, at room temperature, they are in the isotropic (paranematic) state. Enabled by the utilization of a two-step thiol-Michael/thiol-ene chemistry, we examine iso-LCE that exhibit enhanced elastic recovery to deformation while exhibiting low hysteresis. The deformation of these materials induces orientational order (entropy change) that result in elastocaloric temperature changes (> 3°C) in response to minimal stress (<< 1 MPa) and strain (< 200%). The responsivity of these materials exceeds natural rubber and shape memory alloys.

Large Negative Electrocaloric Effect in $BiFeO_3$-$BaTiO_3$ Solid Solution Ceramics Gangsan Kim, Yerok Choi, Jeong Seog Kim and Chae Il Cheon; Hoseo University, Korea (the Republic of)

The electrocaloric effect (ECE) has attracted considerable interest due to the possible application for new environmental-friendly solid-state cooling devices. The ECE is an adiabatic temperature change or isothermal entropy change induced by an external electric field in (anti)ferroelectric materials. A material with a high ECE in a broad temperature range near room temperature (RT) is favorable for efficient refrigeration. The cooling devices with EC materials have not been realized for many decades due to small ECEs in most ferroelectric materials. In recent years, very large adiabatic temperature changes over 10 ^oC have been reported in several (anti)ferroelectric and relaxor thin films such as $Pb(Zr,Ti)O_3$, $(Pb,La)(Zr,Ti)O_3$, and $(Bi,Na)TiO_3$-$BaTiO_3$. Most ferroelectric materials show positive ECE that the heat is released and absorbed by applying and removing electric field alternately. The performance of an ECE-based cooling device has been reported to be improved by adopting a positive and a negative EC material together. However, the negative ECE has been reported only in a few EC materials. Giant negative ECE over wide temperature range has been observed in a few antiferroelectric and relaxor ferroelectric thin films recently. In most reports, the giant positive and/or negative ECEs have been observed in thin film EC materials by applying much larger electric fields than those for saturated polarizations. The practical application of a thin film EC material for cooling devices is, however, restricted due to its small thermal mass. Lately, very large negative ECE with an adiabatic temperature change of 11.5 ^oC has been reported in $(Pb,La)(Zr,Sn,Ti)O_3$ antiferroelectric bulk ceramics. And the negative ECE with an adiabatic temperature change of 2 ^oC was reported in eco-friendly lead-free $0.68BiFeO_3$-$0.32BaTiO_3$ ceramics with coexisting ferroelectric rhombohedral and non-polar cubic phases. Several interpretations for the negative ECE in (anti)ferroelectrics and relaxor ferroelectrics have been suggested: non-collinearity between electric dipoles and an applied electric field, electric field-induced phase transition to a high entropy phase and so on., but the origin is still controversial.
In this work, ECE were investigated in lead-free $(1\text{-}x)BiFeO_3$-$xBaTiO_3$ (BF-xBT) (x = 0.1-0.5) solid solution ceramics. The samples were fabricated by a conventional ceramic process. The crystal structure changed from a ferroelectric rhombohedral (R3c) to relaxor-like pseudo-cubic as the BT content increased. Two phases were coexisted in samples with the composition range of x = 0.25 to 0.4. Polarization-electric field (P-E) hysteresis curves were measured at temperatures from RT to 150 ^oC. The temperature changes due to ECE were calculated indirectly with the Maxwell relation, using the temperature dependence of polarization. Polarization increase with increasing temperature and very large negative ECE with an adiabatic temperature change over 10 ^oC were observed in the sample with a rhombohedral ferroelectric phase. The origin for polarization change and the large ECE will be discussed.

Comparison of the Antiferromagnetic and Magnetocaloric Properties of Rare-Earth Chromites Jianhang Shi[1,1], Mohindar S. Seehra[2], Gayanath Fernando[1], Jacob Pfund[1] and Menka Jain[1,1]; [1]University of Connecticut, United States; [2]West Virginia University, United States

The magnetocaloric effect (MCE) is a thermodynamic phenomenon being exploited for the next generation of highly efficient refrigeration technologies. MCE is an intrinsic property of the magnetic materials where the temperature change and the magnetic entropy change are caused by the application or removal of magnetic field under adiabatic and isothermal conditions, respectively. High magnetic moment values associated with the rare-earth ions in rare-earth chromites, $RCrO_3$ (R= Gd, Tb, Dy, Ho, Er, and Tm), lead to the large changes in isothermal magnetic entropy near their magnetic transition temperatures and hence large MCE. In this work, we present magnetic properties of $RCrO_3$ in a temperature range of 4 – 300 K and present the effect of ionic radii on the ordering temperatures, symmetric exchange constant, spin canting angle, and MCE. Bulk powder samples of $RCrO_3$ are synthesized using a citrate gel combustion technique. First-principles calculations based on density-functional theory within the generalized gradient approximation (GGA) of Perdew- Burke- Ernzerhof and strongly constrained-and-appropriately normed (SCAN) meta-GGA are also employed to calculate the structural and electronic properties of $RCrO_3$. The ground-state energy, lattice constants, electronic structure, and density of states (DOS) of $RCrO_3$ are also calculated. The experimental dc magnetization data are fitted with modified Curie-Weiss law including the Dzyaloshinsky-Moriya antisymmetric exchange interaction, and the symmetric exchange constant and spin canting angle are obtained. Magnetic entropy change ($-\Delta S$) for a given change in magnetic field (ΔH) and the corresponding adiabatic temperature change (ΔT_{ad}) are calculated. Among $RCrO_3$, $GdCrO_3$ shows the largest value of ($-\Delta S/\Delta H$), and its magnitudes of ($\Delta T_{ad}/\Delta H$) and ($-\Delta S/\Delta H$) compare well the reported values for the perovskites $GdFeO_3$ and $GdCoO_3$. These comparisons presented here provide useful information on the potential use of these materials in magneto-refrigeration technology.

Tailoring Pyroelectricity in Internally Biased Thin Film $BaTiO_3$ via Polarization Reversal Joshua W. Adkins[1,2,3], Ignasi Fina[4], Florencio Sanchez[4], Saidur R. Bakaul[2] and Jeremiah Abiade[1,1,3]; [1]University of Illinois Chicago, United States; [2]Argonne National Laboratory, United States; [3]Laboratory for Oxide Research and Education, United States; [4]Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Spain

The ability to simultaneously take advantage of controllable polarization reversal and built-in electric fields offers an interesting opportunity to tailor pyroelectric effects in ferroelectric nanomaterials. To explore this opportunity, we examined the sensitivity of the magnitude of a $BaTiO_3$ thin film's pyroelectricity to the film's extent of polarization reversal. Using a modified indirect method that utilizes variable write-read pulses to control polarization reversal, we found that the pyroelectric response of the sample is less than -3×10^{-5} C/m^2 K at low fractions of switched polarization and grows monotonically to greater than -2×10^{-4} C/m^2 K as larger fractions of polarization are reversed. This apparently 'tailorable' pyroelectric behavior is the result of a persistent internal built-in field induced by asymmetric Pt/LSMO electrodes, which destabilizes low fractions of switched polarization and produces a diminished pyroelectric effect after calculations. Greater fractions of switched polarization are more stable against backswitching and permit a larger pyroelectric response. Our findings provide insight into indirect examinations of pyroelectric behavior in relatively simple ferroelectric materials and highlight the ability to utilize an otherwise unfavorable device characteristic to tailor pyroelectric/electrocaloric behavior in a device via purely electric means.

Electrocaloric Effects in Epitaxial Films of $SrTiO_3$ Neil D. Mathur; University of Cambridge, United Kingdom

I will describe electrocaloric effects near the 243 K ferroelectric phase transition in epitaxial films of $SrTiO_3$ on $DyScO_3$ substrates. Results will be compared with (1) bulk $SrTiO_3$ and (2) the canonical Landau description of this system.

9:00 AM *EN03.04.02
Electrocaloric Properties of Defect-Engineered $0.9Pb(Mg_{1/3}Nb_{2/3})O_3$–$0.1PbTiO_3$ Ceramics Upon Neutron and Gamma Radiation Barbara Malic[1,2], Ankita Sarkar[1], Anze Jazbec[1], Matej Šadl[1,2], Hana Uršič Nemevšek[1,2] and Luka Snoj[1,3]; [1]Jozef Stefan Institute, Slovenia; [2]Jozef Stefan International Postgraduate School, Slovenia; [3]University of Ljubljana, Slovenia

The heating of electronic components has been identified as a severe deficiency in consumer electronics, and even more in professional electronics, where harsh conditions, such as radiation or elevated temperature, add additional requirements to the stability of operation. Application areas include medical diagnostics and therapy, such as proton therapy, space technologies, particle colliders, or nuclear fusion and fission reactors. Electrocaloric (EC) cooling – technology based on the EC effect, i.e., temperature change triggered by the change in applied voltage, could be used to cool electronic components. Relaxor ferroelectrics, exemplified by $0.9Pb(Mg_{1/3}Nb_{2/3})O_3$–$0.1PbTiO_3$ (PMN–10PT), represent a material system that exhibits high enough EC temperature changes of a few K in a broad enough temperature interval of a few 10 K. However, the peak EC values not only increase until we reach the breakdown field but also shift towards higher temperatures as we increase the field amplitude. By introducing defects into the perovskite lattice via aliovalent doping, the temperature range of the peak EC response may be shifted and/or broadened, as shown in the case of Mn-doped PMN-10PT [1]. When considering using EC-based cooling in harsh conditions, the radiation hardness of the EC material is one of the criteria that need to be fulfilled. Neutron and gamma radiation are expected to affect the functional properties of the irradiated materials and, thus, the performance of the entire component or device. We show that PMN-10PT ceramics exhibit similar dielectric, ferroelectric and EC properties after exposure to doses up to 10^{17} neutrons / cm^2 as the pristine samples [2]. But what about PMN-10PT ceramics in which defects are introduced by donor or acceptor doping and contribute to changes in the dielectric, and ferroelectric properties? How do such materials respond to neutron and gamma radiation?
We prepared undoped, acceptor (Mn) and donor (La) doped PMN-10PT ceramics and irradiated them in the TRIGA Mark II research reactor [3]. The ceramics were exposed to 1 MeV equivalent neutron fluence for silicon of 10^{16} cm^{-2} and 10^{17} cm^{-2} of and gamma ray dose of 145 kGy and 1200 kGy. In the lecture, we discuss the influence of neutron and gamma radiation on crystal structure, microstructure, dielectric, ferroelectric and EC properties of defect-engineered PMN-10PT ceramics and compare them with those of undoped material used as reference.

Towards Spatially Resolved Mapping of the Electrocaloric Effect with Nanoscale Resolution using Scanning Thermal Microscopy Olivia Baxter, Amit Kumar, Marty Gregg and Ray McQuaid; Queen's University Belfast, United Kingdom

The electrocaloric effect is a well-known phenomenon where adiabatic application of an external electric field to a material results in a reversible temperature change. Interest in using these materials for environmentally friendly solid-state refrigeration applications has been rejuvenated by the discovery of this effect in commercially available multilayer ceramic capacitors and of giant electrocaloric effects in thin films. While the electrocaloric effect can be well described macroscopically through a thermodynamic approach and is understood to arise from changes in dipolar configurational entropy, the effect at the microscopic scale is not as well characterised. To date, infrared cameras represent the best spatial resolution available for in-situ imaging of temperature fields associated with electrocaloric effects, but features are limited in detail to the level of a few microns.
In this work, we build on previous Scanning Thermal Microscopy studies of electrocaloric materials and demonstrate how this imaging mode can be adapted to measure local electrocaloric response with sub-micron resolution, here demonstrated in a multilayer ceramic capacitor. At a given point on the surface, the tip monitors the temperature while an electric field applied via the capacitor electrodes is cycled on and off. Once the measurement is complete, the tip moves to a neighbouring location and the field cycling and temperature recording process is repeated. Iterating this process across the surface allows for an MxN grid of temperature versus time plots to be created. From this data, the electrocaloric heating and cooling can be extracted to create 2D maps of the electrocaloric response, here demonstrated using a multilayer ceramic capacitor. We intend to use this technique to elucidate the behaviour of other electrocaloric materials and to examine the influence of microstructural inhomogeneity on electrocaloric response.

Solid-State Compact Cooling Devices Based on Electrocaloric Polymers Qibing Pei; University of California, Los Angeles, United States

Electrocaloric cooling may offer important advantages over traditional cooling in compactness, flexibility, COP, and voidance of greenhouse gases. Major technical challenges remain to realize these potentials. We have examined the solution processing and thermal annealing to fabricate poly(vinylidene fluoride-trifluoroethylene-chlororfluoroethylene) terpolymer thin films for high electrocaloric temperature change. Introducing an electrostatic actuation mechanism allows compact, solid-state cooling device designs with high COP and cooling power. The technical approach, results, remaining challenges, and opportunities will be presented.

11:00 AM *EN03.04.06
Electrocaloric Effect in Substrate-Supported and Freestanding Relaxor Ferroelectric Thin Films Jiyeob Kim, Djamila Lou, Abel Fernandez and Lane Martin; University of California, Berkeley, United States

There is a new demand for the next generation cooling system with the limited use of fluorinated gases that are widely used as coolants in the conventional cooling system that contributes to global warming. There is a growing interest in caloric studies based on solid-state phase transitions that can meet the new demand for cooling in compact spaces such as integrated circuits and batteries. Electrocaloric materials are considered relatively easy to drive with an electric field. They are often studied in thin-film form to achieve a large breakdown field. Thin films have a small thermal mass that limits from direct measurement and many studies use indirect method to report electrocaloric effects. However, this could lead to erroneous values due to substrate clamping and heat dissipation to the substrate.

In this work, we explore indirect and direct methods to study the electrocaloric effect in relaxor ferroelectric $0.68PbMg_{1/3}Nb_{2/3}O_3$-$0.32PbTiO_3$ (PMN-32PT) thin films. PMN-32PT is known to have an extremely high electromechanical coupling, especially with compositions near morphotropic phase boundary (MPB). $Ba_{0.5}Sr_{0.5}RuO_3$ (30 nm) ‖ PMN-32PT (150 nm) ‖ $Ba_{0.5}Sr_{0.5}RuO_3$ (30 nm) heterostructures were grown on $NdScO_3$ (110) substrates via pulsed-laser deposition providing -0.5% strain on PMN-32PT. Subsequently, a 6-terminal electrothermal testing platform, adapted from a 3-omega device configuration, was fabricated via photolithography. This device allows us to apply an electric field to PMN-32PT and measure polarization and temperature change to study electrocaloric effect using both indirect and direct methods, respectively. Furthermore, we have successfully prepared freestanding versions of these same heterostructure and fabricated them into the testing platform to explore how the removal of the substrate constraints (clamping) impacts the evolution of these properties. This study should clarify the elements that contribute to discrepancies in indirect and direct electrocaloric studies in thin films and provide a guide for indirect studies for accurate calculations.

11:30 AM EN03.04.07
From Electrocaloric Cooling to Pyroenergy Harvesting using Lead Scandium Tantalate Multilayer Capacitors Pierre Lheritier[1], Alvar Torelló[1,2], Tomoyasu Usui[3], Youri Nouchokgwe[1,2], Ashwath Aravindhan[1,2], Junning Li[1], Uros Prah[1], Veronika Kovacova[1], Olivier Bouton[1], Sakyo Hirose[3] and Emmanuel Defay[1]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]University of Luxembourg, Luxembourg; [3]Murata Manufacturing Co., Ltd., Japan

Electrocaloric (EC) materials display a reversible change in temperature with a varying electric field, which could be utilized for solid-state cooling. To enhance the performance of electrocaloric coolers, it is crucial to improve the intrinsic EC effect of the material and develop appropriate heat management strategies. Torelló et al. [1] developed a fluid-based active EC regenerator based on lead scandium tantalate (PST) multilayer capacitors (MLCs). In addition to the sharp first-order transition of PST, they also took advantage of the multilayer structure to increase the active volume of the material to obtain a temperature span of 13 K. Due to their strong electrothermal coupling, PST MLCs can also be used to convert heat into electricity for pyroelectric energy harvesting (thermodynamic converse of the EC effect). Similar ideas have also been realized in magnetocaloric materials by exploiting the change in magnetization with temperature to produce electrical energy [2]. Here we developed a macroscopic pyroelectric harvester using 42 g of active PST-MLCs, which produces 11.2 J of energy per thermodynamic cycle [3]. One PST-MLC can generate an electrical energy density of 4.4 J cm^{-3} during one cycle. In addition, we also built an autonomous pyroelectric harvester comprising of microcontrollers, low-voltage converter, and temperature sensors which is powered by the energy harvested from 0.3 g of active PST-MLCs. Finally, we show that 40% of Carnot efficiency could be achieved in PST-

MLCs for a temperature span of 10 K near their phase transition temperature.

11:45 AM EN03.04.08
How Highly-Efficient Power Electronics Transfers High Electrocaloric Material Performance to Heat Pump Systems Stefan Moench[1], Richard Reiner[1], Patrick Waltereit[1], Michael Basler[1], Rüdiger Quay[1,2], David Bach[3], Roland Binninger[3] and Kilian Bartholomé[3]; [1]Fraunhofer IAF, Germany; [2]Universität Freiburg, Germany; [3]Fraunhofer IPM, Germany

Electrocaloric heat pumps are an emerging solution for emission-free cooling and heating with high performance. The material performance of some known electrocaloric ceramics or polymers can exceed that of today's vapor compression systems. However, the system performance of published prototypes still lacks significantly behind. This talk presents ultra-efficient power electronics as a solution to this fundamental problem: First, a simple half-bridge switched-mode power converter topology based on gallium nitride transistors is used to demonstrate 99.3% efficient charging of capacitors. Second, an advanced multilevel and partial-power-processing approach is demonstrated, which achieves over 99.7% charging efficiency. This is a significant reduction of electrical charging losses (by multiple 10-times) compared to a resonant circuit approach previously used for electrocaloric prototypes. It is shown how the combination of low-loss electrocaloric materials and highly-efficient power electronics, both existing already today, will enable a high electrocaloric heat pump performance. For example, for available PMN material data, a best-case relative system coefficient of performance COPr (including the external charging losses) over 50% for Carnot-like cycles and over 75% for Ericsson cycles with temperature regeneration is projected, which is close to the material limit of over 80%. The flexibility of the proposed power electronics is demonstrated: The switched-mode approach allows to efficiently charge also very large capacitive loads which are required for future large-scale heat pumps. On the one hand, over 99% efficient charging of 384 commercial capacitors with a very low cycle frequency below 0.02 Hz is demonstrated, which allows heat transfer between thick electrocaloric elements. On the other hand, over 1 kHz cycle frequencies are efficiently realized, which is useful for characterization of the samples' dielectric losses but is beyond the usable thermal time constants of today's prototypes. The trade-off between performance and power density is analyzed. To increase the system efficiency (COPr), but at the expense or reduced power density, it is shown how an offset-field significantly reduces the effective electrocaloric capacitance while the temperature effect is only reduced slightly. The effect of increasing system frequency is discussed. It is discussed how it improves the power density of the system by reduction of electrocaloric material required for the same cooling power. However, it is also shown that it does not reduce the required power rating of the charging circuit and thus does not reduce the size of the electronics. The control system has an inner current-control for adjustable constant-current charging, and an outer voltage-control for waveform generation (arbitrary field variation). A trigger signal allows synchronization of for example servo-control signals, which are useful to realize complete heat pump prototypes. While maintaining a high charging efficiency, the voltage waveform generation is used with an electrocaloric heat-pump prototype to experimentally demonstrate Carnot-like cycles, further verified by temperature and heat flux measurements. Finally, it is shown how the highly-efficient power electronics will be applied to an electrocaloric prototype in the ongoing Fraunhofer lighthouse project "ElKaWe – Electrocaloric heat pumps", which is targeting a high cycle frequency by using a heat-pipe system approach. The discussed multi-disciplinary approach combines ideas from material research, mechanical engineering and electrical engineering. This allows to accelerate the development of electrocaloric heat pumps, and the transition towards emission-free heat pumps for efficient cooling and heating applications.

SESSION EN03.05: Magnetocaloric Materials and Devices II

2:00 PM *EN03.05.02
Room-Temperature Polymer-Assisted Additive Manufacturing of Microchanneled Magnetocaloric Structures Radhika Barua, Vaibhav Sharma, Eddie Goldworthy, Hong Zhao and Ravi Hadimani; Virginia Commonwealth University, United States

Magnetic refrigeration is an energy-efficient, sustainable, environmentally-friendly alternative to conventional vapor-compression cooling technology.[1] There are several magnetic refrigerator device designs in existence today that are predicted to be highly energy-efficient, on condition that suitable working materials can be developed.[1] This challenge in manufacturing magnetocaloric devices is unresolved, mainly due to issues related to shaping the mostly brittle magnetocaloric alloys into thin-walled channeled regenerator structures to facilitate efficient heat transfer between the solid refrigerant and the heat exchange fluid in an active magnetic regenerator (AMR) cooling device.[2]

To address this challenge, we have developed a novel low-temperature extrusion-based additive manufacturing (AM) method to 3D print microchanneled magnetocaloric structures.[3] The printing ink consists of magnetocaloric powders, a polymer binder, and multiple solvents to achieve desirable shear-thinning property, which is critical for a robust printing process. Acting as a sacrificial binding agent for the magnetic powders, the polymer binder holds the 3D printed structures in place and is subsequently removed using a two-step heat-treatment process. Research efforts pertaining to AM process development using three precursor magnetocaloric powders will be presented - **(1)** $La_{0.6}Ca_{0.4}MnO_3$ powders prepared by a patented modified Pechini sol-gel wet chemical method[4] **(2)** $AlFe_2B_2$ powders manufactured by a unique molten salt sintering method[5] and **(3)** $La(Fe_xCo_ySi_{1-x-y})_{13}$ powders produced via gas-atomization. The effect of various process parameters, such as powder-binder ratio, the viscosity of printing ink, powder size, shape and internal porosity etc., on the geometrical and mechanical characteristics of green parts will be discussed. In addition, the effects of sintering and printing parameters on the quality of the densified magnetocaloric structures will be deliberated upon. Last, the feasibility of 3D printing magnetocaloric structures with spatially designed microchannels of minimum dimensions of 150 µm will be demonstrated. Overall, this study provides strategies for realizing low-cost functionally graded magnetic regenerators, thus potentially eliminating one of the main barriers to commercialization of magnetic cooling technology.

Improving Performance of Active Magnetocaloric Regenerators Agata M. Czernuszewicz[1], Lucas Griffith[1], Julie Slaughter[1] and Vitalij K. Pecharsky[1,2]; [1]Ames National Laboratory, United States; [2]Iowa State University, United States

Heat pumping based on the magnetocaloric effect has the potential to become a more environmentally benign and sustainable replacement for vapor-compression technologies commonly used in air conditioning and refrigeration. The cost of producing high magnetic field changes and the necessity of using large amounts of magnetocaloric materials are known limitations that hinder the adoption of this technology. One way to boost performance of Active Magnetic Regenerators (AMRs) without investing in stronger magnetic fields or larger mass of working materials is optimizing the AMR shape; specifically tailoring aspect ratio, which is defined as the ratio of the regenerator length to the square root of its cross-sectional area. This parameter strongly influences viscous dissipation and axial conduction losses inside the regenerator. High aspect ratio AMRs are more susceptible to viscous dissipation losses, however, low aspect ratio AMRs suffer from more significant axial conduction losses [1].

Using CaloriSMART [2] and a moderate maximum magnetic field of 1.13 T, we experimentally demonstrate how a simple change in shape greatly impacts AMR performance. Five different aspect ratios ranging from 1.0 to 3.8 were tested across a wide range of operating conditions. Regenerators were filled in with 16.6 ± 0.3 g of Gd spherical powders. The results show that increasing the aspect ratio positively impacts temperature spans, however, shortening regenerators helps to maximize the cooling power. Maximum exergetic cooling power [3] and maximum exergetic power quotient [2] varied with aspect ratio, respectively, by as much as 37 and 21%, with a clear optimum.

This work was performed with joint funding from the Advanced Manufacturing Office and the Building Technologies Office of the Office of Energy Efficiency and Renewable Energy of the United States Department of Energy. Ames Laboratory is operated for the U.S. Department of Energy by Iowa State University of Science and Technology under Contract No. DE-AC02-07CH11358.

Giant Multicaloric Effects in Charge-Transition Oxides Yuichi Shimakawa, Yoshihisa Kosugi and Masato Goto; Kyoto University, Japan

Some transition-metal oxides containing cations with unusually high valence states show charge transitions to relieve the electronic instabilities. Such compounds often release significant latent heat by the first-order charge transitions. We found that the large latent heat and the corresponding isothermal entropy changes can be utilized through caloric effects by applying pressure (barocaloric effects) and/or magnetic fields (magnetocaloric effects). The A-site-ordered quadruple perovskite $NdCu_3Fe_4O_{12}$ containing the unusual high valence $Fe^{3.75+}$ shows the large entropy change of 84.2 $J\ K^{-1}\ kg^{-1}$ by the intersite charge transfer transition ($NdCu^{2+}{}_3Fe^{3.75+}{}_4O_{12} \leftrightarrow NdCu^{3+}{}_3Fe^{3+}{}_4O_{12}$) near room temperature. This entropy change can be utilized by applying pressure through the barocaloric effect. The analogue quadruple perovskite $BiCu_3Cr_4O_{12}$ containing $Cr^{3.75+}$ also shows the large entropy change by the charge disproportionation transition ($BiCu_3Cr^{3.75+}{}_4O_{12} \leftrightarrow BiCu_3Cr^{3+}Cr^{4+}{}_3O_{12}$) at 190 K. Because the charge disproportionation yields a ferrimagnetic phase below the transition temperature, the observed entropy change can be controlled by applying magnetic fields as well as pressure. The compound is thus demonstrated to show the multicaloric effects. The charge transitions, where the charge, spins, and lattice degrees of freedom are strongly correlated, are crucial to the observed novel giant caloric properties.

Multicaloric Effect Studied in High Magnetic Fields—Dissipation Losses Limiting First-Order Phase Transition Materials for Cryogenic Caloric Cooling Timo Niehoff[1,2], Benedikt Beckmann[3], Tino Gottschall[1], Catalina Salazar-Mejia[1], David Koch[3], Lukas Pfeuffer[3], Andreas Taubel[3], Esmaeil Adabifiroozjaei[3], Olga Miroshkina[4], Stefan Riegg[3], Nagaarjhuna Kani[3,3], Markus Gruner[4], Leopoldo Molina-Luna[3], Konstantin Skokov[3], Oliver Gutfleisch[3] and Joachim Wosnitza[1,2]; [1]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [2]Technische Universität Dresden, Germany; [3]Technische Universität Darmstadt, Germany; [4]Universität Duisburg-Essen, Germany

With the world's increasingly affluent population demanding more comfortable living and working conditions and rising global temperatures, leading to an ever growing demand for cooling [1], which is predicted to exceed the energy consumption for heating in this century [2], it is vital that we address the development of much more efficient cooling technologies as an urgent priority. A promising alternative approach is based on solid-state refrigeration by one of the caloric effects – electrocaloric, magnetocaloric, barocaloric or elastocaloric - where the material's temperature is changing under the application of an electrical, magnetic, or mechanical field [3]. However, there is also the possibility to combine these different effects in a beneficial way, in the so-called multicaloric cooling cycle. Magnetic Ni-Mn-based Heusler alloys are ideally suited for multicaloric applications due to their coupled magnetostructural transformation between martensite and austenite [4].

Ni-Mn-based Heusler alloys, are highly promising materials for solid-state cooling, because large multicaloric effects can be achieved across their magnetostructural martensitic transformation over a broad temperature range, which is possibly also relevant for cryogenic applications such as the liquefaction of hydrogen. In this work, we simultaneously measured the responses of the magnetic structural and electronic subsystems to the temperature-and field-induced martensitic transformation of Ni(-Co)-Mn-Ti at low temperatures, showing an abnormal increase of hysteresis and consequently dissipation energy at cryogenic temperatures [5]. Simultaneous measurements of magnetization and adiabatic temperature change in high pulsed magnetic fields up to 50 T [6] reveal a positive and irreversible adiabatic temperature change as a consequence of increased dissipation losses and decreased heat capacity. This is in contradiction to the expected negative adiabatic temperature change, which was determined indirectly by heat capacity measurements. Most importantly, this irreversible phenomenon was also observed in other material systems and is universal to any first-order material with non-negligible hysteresis, effectively limiting the utilization of their caloric effects for gas liquefaction at cryogenic temperatures.

4:30 PM EN03.06.03
Thermal Switch Capacitor in a Magnetocaloric Device Nada Petelin[1], Katja Vozel[1], Katja Klinar[1], Matej Šadl[2], Hana Uršič[2], Barbara Malic[2], Mitjan Kalin[1] and Andrej Kitanovski[1]; [1]University of Ljubljana, Slovenia; [2]Jozef Stefan Institute, Slovenia

The quest for better performance of magnetocaloric devices has led to the development of thermal management devices such as thermal switches, thermal diodes, and thermal capacitors. These types of devices are capable of controlling the heat in a manner similar to how their electrical counterparts control electrical current. Most existing caloric devices use active caloric regeneration, in which the working fluid oscillates through the caloric regenerator compose of caloric material. The unavoidable, irreversible viscous and heat-transfer losses, associated with the active caloric regeneration principle limit the operating frequency (number of thermodynamic cycles per unit of time), which is directly related to the power density of a caloric device. Thermal management devices offer a new way to control the intensity and direction of heat flow between the magnetocaloric material and the heat source or heat sink, and therefore could improve the performance of caloric devices during high-frequency operation, which is crucial for increasing in the power density (compactness) and energy efficiency.

A thermal switch relies on a control parameter such as an electric field, magnetic field, or pressure to change the thermal conductance of the device. The switching ratio between the highest thermal conductance achieved (the on state) and the lowest thermal conductance achievable (the off state) represents a figure of merit for a thermal switch. Thermal switches can be either static or motional. Motional thermal switches change their thermal conductance by changing their position and making and breaking thermal contacts. Static thermal switches are always in physical contact with adjacent interfaces. The thermal capacitor, on the other hand, is a single-pole element because the other side of this element is always “grounded,” i.e., connected to a heat reservoir. It acts as a temporary heat-storage device, similar to the “self-capacitance” of an insulated electrical conductor in the electrical analogy. The operation of a thermal switch (TS) and a thermal capacitor (TC) can also be combined in a so-called thermal switch capacitor (TSC).

In this work, we have analyzed a novel thermal switch capacitor made of silicon operating as a solid heat transporting device. The thermal switch capacitor first stores energy and then releases it by means of the transport of heat caused by the motion of the material. We studied the impact of different design parameters and operating conditions on performance of magnetocaloric device, and based on this, established guidelines for an optimal design for further experimental studies. The proposed design provides a compact cooling solution that can be attached directly to the heat reservoir, making it attractive for a variety of applications.

4:45 PM EN03.06.04
Digital Microfluidic Thermal Switch in Magnetocaloric Cooling Urban Tomc[1], Hana Uršič Nemevšek[2], Victor Regis[2], Blaz Velkavrh[1,2], Lluis Mañosa[3], Jens Freudenberger[4], Bruno Weise[4] and Andrej Kitanovski[1]; [1]University of Ljubljana, Slovenia; [2]Jozef Stefan Institute, Slovenia; [3]University of Barcelona, Spain; [4]Leibniz Institute for Solid State and Materials Research Dresden, Germany

Among the related technologies, magnetocaloric energy conversion represents one of the most promising alternatives to vapour compression. Despite the fact that this technology has made substantial progress over the last two decades, there are unfortunately still unsolved and strongly relevant challenges regarding the use of rare-earth materials, energy efficiency, and the competitive cost of potential future devices.

Namely, today’s state-of-the-art devices are based on the so-called Active Magnetic Regeneration, which is moderately efficient at low operating frequencies (up to 5 Hz). To achieve considerable cooling power and magnetic fields at such low frequencies, a significant amount of magnetocaloric and permanent magnet material is required, which also affects the cost. Therefore, a new research direction has emerged in recent years in which researchers are trying to develop devices that operate efficiently at much higher frequencies (up to 20 Hz or more). This would increase the power density, which in turn would allow miniaturization of the devices and the use of drastically less magnetocaloric and magnetic material. There are two major challenges to be solved. One concerns the application of new magnetic field sources that can generate a fast and efficient alternating magnetic field at high frequencies. The other one deals with the application of new thermal management principles in a form of thermal control devices. One particular sub-domain of thermal control devices are thermal switches.

An interesting field, to look for thermal switch mechanisms, is microfluidics, which has enabled the development of integrated lab-on-chip devices. Although most microfluidic devices are based on a continuous flow of liquids in microchanells, there has been an increasing interest for the past couple of years in devices that rely on manipulation of discrete droplets using surface tension effects. One such technique is ElectroWetting On Dielectric (EWOD), which is based on wettability of liquids on a dielectric solid surface by varying the electrical potential. EWOD system’s similarity to the digital microelectronic systems has led to the term digital microfluidics.

In this contribution we will present a new concept of magnetocaloric device which couples magnetocaloric effect and EWOD droplet actuation as thermal switch mechanism. We will show different potential designs of such a devices and their operation. Furthermore, the materials and its properties, which constitute the whole device will be discussed.

SESSION EN03.07: Barocaloric Materials and Devices

Barocaloric Effects from Hydrocarbon Order–Disorder Transitions Jarad A. Mason, Jinyoung Seo, Adam Slavney, Selena Zhang, Faith Chen, Vidhya Dev, Ryan McGillicuddy, Rahil Ukani and Jason Braun; Harvard University, United States

Efficient barocaloric cooling requires materials that undergo reversible phase transitions with large entropy changes, high sensitivity to hydrostatic pressure, and minimal hysteresis—the combination of which has been challenging to achieve in existing barocaloric materials. Here, I will describe how hydrocarbon order-disorder phase transitions in organic and metal–organic materials can be manipulated to induce large, reversible barocaloric effects at moderate pressures. In particular, I will discuss the structural and chemical factors that contribute to entropy changes, sensitivity to hydrostatic pressure, and hysteresis for two classes of layered materials that undergo structural transitions associated with the disordering of hydrocarbon bilayers. Additionally, I will highlight the important role the pressure-transmitting medium plays in directing these barocaloric effects.

9:00 AM *EN03.07.02
Reversible Colossal Barocaloric Effects at Low Pressures in Disordered Materials Pol Lloveras[1], Junning Li[2], Maria Barrio[1], David J. Dunstan[3], Richard J. C. Dixey[3], Xiaojie Lou[4], Anthony E. Phillips[3], Kartik Sau[5,5], Sangryun Kim[6], Shigeyuki Takagi[5], Tamio Ikeshoji[5], Shin-ichi Orimo[5,5], Claudio Cazorla[1] and Josep-Lluís Tamarit[1]; [1]Universitat Politècnica de Catalunya, Spain; [2]Luxembourg Institute of Science and Technology, Luxembourg; [3]Queen Mary University London, United Kingdom; [4]Xi'an Jiaotong University, China; [5]Tohoku University, Japan; [6]Gwangju Institute of Science and Technology, Korea (the Democratic People's Republic of)

Materials undergoing order-disorder first-order phase transitions are attracting interest for thermal management because they can act as heat sinks or sources due to the energy stored in the disordered phases. Moreover, the application of pressure on these materials may allow an active control of the heat exchange, which leads to conceive barocaloric methods for solid-state cooling and heat pumping [1]. Interestingly, they promise a more environmentally friendly and efficient alternative to harmful vapor compression. Fast progress on materials research has allowed the identification of some organic plastic crystals as outstanding barocaloric agents, with colossal barocaloric effects much above 100 J K^{-1} kg^{-1}. However, typical moderate or large hysteresis and a moderate sensitivity of the transition to pressure make these colossal barocaloric effects be obtained reversibly upon pressure changes above 100 MPa, which limits their potential applicability. Here we present two recently investigated materials that exhibit relatively little-hysteretic phase transitions releasing strong disorder in the high temperature phase and accompanied by large volume changes. These features allow to obtain reversible colossal barocaloric effects below 100 MPa in both compounds, with simultaneously large values for isothermal entropy changes ΔS and adiabatic temperature changes ΔT. One material is a layered hybrid organic-inorganic pseudoperovskite [2] whose disorder is associated with the melting-like process and rotation of the organic chain linked to the inoganic octahedra. It displays reversible $\Delta S \sim 230$ J K^{-1} kg^{-1} under low pressure changes of 50 MPa, and reversible $\Delta T \sim 10$ K under pressure changes of 80 MPa. The other material is a fast-ionic conductor [3] displaying strong molecular orientational disorder of anions coupled to diffusion of cations. In that case, the material undergoes reversible $\Delta S \sim 170$ J K^{-1} kg^{-1} and $\Delta T \sim 10$ K under pressure changes of 84 MPa. Here, the high transition temperature suggests that it could be also used for solid-state barocaloric waste heat recovery [4].

Microstructural Observations of Reversible Phase Transformations in Barocaloric Plastic Crystal Systems Chase Somodi, Denali Ibbotson, Alex Foncerrada and Patrick Shamberger; Texas A&M University, United States

Plastic crystals exhibit a degree of structural order between an ordered crystal, in which molecules have fixed position and orientation, and liquid, in which molecules can rotate and translate in every direction. Small molecules within plastic crystals are fixed on a rigid lattice, but still maintain rotational degrees of freedom. Such plastic crystals typically crystallize in cubic systems (FCC or BCC) at high temperature, and undergo a first order phase transition associated with a large entropy change to lower symmetry phases upon cooling. The transition between ordered crystals and plastic crystals are associated with introduction of rotational degrees of freedom and thus, large changes in entropy, with a pressure-dependent T_{cr} due to the Clausius-Clapeyron coupling between pressure and volume change at the transition. This pressure and volume change dependence forms the basis for giant barocaloric effects, which can be used in heat pump or refrigeration cycles, and can also be considered to represent a tunable thermal energy storage media, where pressure is used as an independent variable to control the temperature at which heat is stored or discharged. In both cases, the overall efficiency of the refrigeration cycle or the energy storage scheme is dominated in large part by the reversibility of the plastic crystal transition. Thus, understanding the origin of the undercooling in plastic crystal transformations and developing strategies to reduce undercooling is a critical element of advancing these systems towards practical use.

Here, we use calorimetry and optical microscopy to investigate the reversibility of the plastic crystal transformation, and its microstructural evolution through the heating and cooling transformations. We demonstrate that the transformation on heating (low to high symmetry) exhibits a dense concentration of nucleation points and significant phase coexistence, which remains stable when held under isothermal conditions. In contrast, the transformation on cooling is nucleation-limited, resulting in abrupt propagation of a phase boundary throughout the sample volume after nucleation of an under-cooled volume. This cooling transformation does not appear to conserve the original microstructure of the rotationally ordered plastic crystal phase. We report specifically on the role of plastic crystal chemical structure and the impact of introducing small concentrations of other plastic crystal molecules below the solubility limit (<5 wt%) on the degree of undercooling and microstructure of the system. These results reveal the fundamental mechanisms occurring during the transition, including its asymmetric nature, and demonstrate a pathway towards dramatically decreasing undercooling and thereby increasing efficiency in plastic crystal systems.

9:45 AM EN03.07.04
Overcoming Hysteresis in Barocaloric Materials Jinyoung Seo, Adam Slavney and Jarad A. Mason; Harvard University, United States

From air conditioning to refrigerators to heat humps, cooling technologies have played critical roles in enabling access to improved living conditions. Yet, ironically, the very technologies that helped us beat the heat are now making the planet warmer. Current cooling systems rely on volatile hydrofluorocarbon refrigerants, the majority of which are potent greenhouse gases. As demand for cooling continues to increase, the direct emission of volatile refrigerants is predicted to dramatically increase—well above 10% of greenhouse gas emissions by 2050. In the face of an increasingly warming world, new technologies are urgently needed to provide sustainable cooling. Solid-state cooling through barocaloric effects—pressure-induced thermal changes in a material—offers an environmentally-friendly alternative to conventional cooling technologies. Unlike gaseous refrigerants, solid refrigerants have zero global warming potential as well as a variety of potential advantages, including increased efficiency, reduced system size, and greater recyclability. Importantly, barocaloric materials are particularly well suited to providing cooling at scale. This is, in part, because pressure is easy to generate, can be applied to materials regardless of their form factor, and, due to the dominance of vapor-compression technology, extremely amenable to scaling.

To produce useful barocaloric effects at low pressures, phase transitions that feature large entropy changes, high sensitivity to pressure, and minimal hysteresis are needed. In particular, hysteresis—which represents the dissipated energy during a pressure-driven phase change—plays a central role in determining the cooling performance. In addition to increasing the operating pressure, large hysteresis compromises efficiency, cooling power, and cyclability. Despite the range of barocaloric materials that have been studied to date, it has proven challenging to manipulate—and understand—hysteresis in barocaloric materials. Because existing classes of barocaloric materials are often difficult to manipulate synthetically in a systematic fashion, it is challenging to establish structure–property relationships needed to inform efforts to overcome hysteresis. As such, strategies to reduce—and, ideally, eliminate—hysteresis in barocaloric materials have yet to be developed.

Here, we present systematic studies on hysteresis in barocaloric materials. We leverage the new classes of tunable barocaloric materials recently discovered in our laboratory—including two-dimensional hybrid perovskites [1] and molecular spin-crossover complexes [2]—to elucidate key molecular factors that govern the hysteresis of pressure-driven transitions. In particular, we characterize the compositionally diverse library of barocaloric materials using advanced calorimetry and operando X-ray diffraction techniques, as well as direct temperature measurements under variable-pressure conditions. These efforts are complemented by molecular modeling and microstructural analyses. Finally, we describe our efforts to understand the impact of hysteresis at the device level. By evaluating the performance of select barocaloric materials in our recently developed cooling prototype, we directly probe materials losses—especially those that originate from hysteresis—in a wide range of driving conditions. Bridging the gap between materials discovery and prototype development, this work represents a crucial step toward the development of barocaloric materials for practical solid-state cooling. We envision that our approach to understand barocaloric effects across length scales—ranging from molecular to device levels—will provide new insights and opportunities for studying phase transitions and thermal behaviors in materials.

10:00 AM BREAK

10:30 AM *EN03.07.05
Exploring Atomic Structure and Dynamics in Barocalorics for Solid-State Cooling with Neutron Scattering Helen C. Walker; Rutherford Appleton Laboratory, United Kingdom

Conventional vapour-compression refrigeration relies on refrigerants that contribute both to global warming and ozone depletion. Barocaloric materials, in which a large isothermal entropy change is associated with a pressure-induced phase transition, offer an eco-friendly solid-state alternative. While an increasing number of materials are being identified as barocalorics, a microscopic understanding of what drives the entropy change is often lacking, negatively impacting the opportunity to create a roadmap for developing new optimised barocaloric materials.
We have used a range of neutron scattering methods: total scattering, quasielastic neutron scattering and inelastic neutron scattering to investigate both the structure and dynamics in two barocaloric systems: ammonium sulfate [1,2] and adamantane [3]. Combining our data with density functional theory and molecular dynamics simulations we have obtained an insight into the significance of configurational and dynamic entropy, providing ideas for crystal engineering better barocalorics for applications in both cooling and heat pumps.

Key Parameters for Barocaloric Cooling and Heating Enric Stern Taulats[1,2], Pol Lloveras[3] and Xavier Moya[2]; [1]Universitat de Barcelona, Spain; [2]University of Cambridge, United Kingdom; [3]Universitat Politècnica de Catalunya, Spain

Heating and cooling markets sum up a 70% share of energy consumption worldwide and urge the shift towards more efficient and low-carbon solutions [1, 2]. Heating market heavily relies on fossil fuel-dominated technologies. Cooling market relies on the use of refrigerant gases that have been severely in the spotlight of environmental protocols and EU regulations in view of their high Global Warming Potential and ozone-depletion properties.

In the last decades, substantial research effort has been concentrated on the development of alternative, more sustainable technologies based on caloric materials [3], which can exhibit a giant thermal response in the vicinity of a phase transition under the influence of a magnetic field, an electric field, or mechanical stress. Particularly, barocaloric materials are blossoming into calorics with the outbreak of new classes of materials displaying colossal thermal effects that compare to those of refrigerant gases [4, 5].

However, implementing these promising materials still remains preliminary, which poses a challenge from both the materials science and engineering viewpoints. In this regard, I will review the state-of-the-art caloric materials and the conditions yielding enhanced thermal responses. I will discuss the key parameters related to materials cyclability and heat transfer phenomena to be addressed to match applications' demands and design constraints.

11:30 AM EN03.07.07
Device-Level Thermodynamic and Heat Transfer Model for a Barocaloric Solid State Refrigerator Naveen D. Weerasekera, Kameswara Pavan Kumar Ajjarapu, Kavish Sudan, Gamini Sumanasekera, Kunal Kate and Bikram Bhatia; University of Louisville, United States

Solid state refrigeration based on caloric materials has demonstrated the ability to replace existing vapor compression cooling systems that are inefficient, difficult to scale and have a high global warming potential. Unlike solid state cooling based on electrocaloric, magnetocaloric and elastocaloric effects, barocaloric refrigeration – based on the entropy change due to applied hydrostatic pressure – have received comparatively less attention but have recently demonstrated significant potential in material-level studies. However, device-level numerical and experimental studies are still missing in the literature. This work presents a thermodynamic and heat transfer model for a barocaloric refrigerator comprising commercially-available nitrile butadiene rubber (NBR) and operating between a hot and a cold thermal reservoir. We combine experimentally-validated barocaloric properties of NBR with transient heat conduction modeling to evaluate the performance of a reverse Brayton refrigeration cycle. Specifically, we evaluate the coefficient of performance (COP), energy density and power density of the device, and quantify the contributions of device geometry, operating frequency, heat transfer coefficient, and applied pressure. We show that a barocaloric refrigerator operating with a 2.3 K temperature span, 10 mHz cycle frequency and 0.1 GPa applied pressure change can achieve a COP as high as 8 – exceeding that of traditional vapor compression-based refrigerators. Additionally, we show that increasing the thermal conductivity of the elastomeric solid-state refrigerant can substantially improve performance – increasing the COP by 67% when the refrigerant's thermal conductivity was raised from 0.2 W m^{-1} K^{-1} to 1 W m^{-1} K^{-1}. This work demonstrates the promise of solid state cooling devices based on soft barocaloric materials and provides a framework to quantify its performance at the device-level.

11:45 AM EN03.07.08
TCCbuilder: an Open-Source Tool for the Design and Evaluation of Thermal Circuits in Calorics and Other Applications Katja Klinar, Katja Vozel and Andrej Kitanovski; University of Ljubljana, Slovenia

Thermal management as control of the temperature, as well as the intensity and the direction of heat flow between components of a system, is crucial for high energy efficiency, optimized performance, high reliability, and safety. Thermal management is also the key challenge of modern technology in the whole energy chain: energy production, conversion, transport, and utilization.

It is becoming more and more evident that thermal management methods like conventional thermal resistors (i.e. thermal insulation) and capacitors (i.e. thermal storage) cannot meet thermal control requirements of advanced, especially small-scale systems with higher power densities or potentially transient, fluctuating, or migrating hot or cold spots, as well as for temperature-sensitive equipment. The newly emerging thermal control devices (TCDs), including thermal conduits, thermal resistors, thermal switches, thermal regulators, thermal diodes, and thermal capacitors, allow nonlinear, switchable, and active control of the heat, just as their electrical counterparts control the electrical current.

We wanted to take a step forward in the development of these novel thermal management techniques, which led us to this project, whose main goal is to provide researchers and broader society with the world's first open-source numerical tool for simulating thermal control circuits (TCCs). Therefore, we present here the TCCbuilder tool and its associated library – a large database of appropriate materials and TCDs already published in the literature. The tool will also serve as a solid foundation for sharing knowledge in the field of thermal management.

The implementation of nonlinear and switchable TCDs, together with a heat source and a heat sink, forms TCCs and leads to qualitatively better thermal capabilities, including better regulation or stabilization of temperature, rectification, heterodyning, amplification, regulation, redirection, and stabilization of heat flux density, temporary storage of excess heat, heat scavenging, thermal computation, etc. The output of the TCCbuilder will be demonstrated with several examples, where TCDs have been implemented and have improved the operation of conventional devices, e.g. temperature doubler, peak detector, and load shifter.

One of the most important areas of investigation in thermal management are caloric devices. It has already been demonstrated that thermal switches and/or thermal diodes can enable the operation of magnetocaloric, electrocaloric, and elastocaloric devices at higher frequencies. To increase the cooling power density of caloric devices, breakthrough ideas are needed, which can be tested, accepted, or disproved with the TCCbuilder.

Multi-Mode Elastocaloric Cooling Systems Based on Superelastic Shape Memory Alloys Ichiro Takeuchi; University of Maryland, United States

Elastocaloric/thermoelastic cooling based on superelastic shape memory alloys uses the large latent heat associated with the martensitic transformation to pump heat. Elastocaloric cooling has been recognized by DOE as one of the most promising alternative cooling technologies. We have been developing prototypes of elastocaloric cooling systems using superelastic NiTi. Our effort started with tension-based coolers using NiTi wires. Because of the fatigue issue associated with wires, we have since been focusing on compression-based devices. Key features of our cooling devices include tube-bundle-based heat exchangers and a work-recovery system which is necessary for high-efficiency operation of the systems. We have developed a multi-mode elastocaloric system, where operational modes can be switched between the high-utilization mode and the active regenerator mode. The high-utilization mode allows delivery of maximum cooling power, while the active regeneration mode can build a large temperature lift across the regenerator. In the current 4-bundle system, our system can deliver over 100 W of cooling power in the high-utilization mode, while the active regenerator mode can generate larger than 20 K in the temperature lift. I will also discuss our effort in development of new materials for elastocaloric cooling. Comparison of recent advances in elastocaloric cooling with other caloric cooling technologies will be discussed. This work is carried out in collaboration with Suxin Qian, David Catalini, Nehemiah Emaikwu, Jan Muehlbauer, Yunho Hwang, Huilong Hou, Jun Cui, Kenjiro Fujimoto, and Reinhard Radermacher. Our work is funded by the DOE EERE BTO BENEFIT project.

Miniature-Scale Elastocaloric Cooling by Rubber-Based Films Manfred Kohl; Karlsruhe Institute of Technology, Germany

The elastocaloric effect associated with the strain-induced crystallization and entropy elasticity in elastomers is of special interest for environmentally friendly and low-cost solid-state cooling applications and may provide an alternative for vapour compression technology. One material candidate is natural rubber, which has the potential to meet the various challenges associated with elastocaloric cooling, including large adiabatic temperature change and

extraordinary fatigue resistance under dynamic load. For miniature-scale cooling applications addressed in this work, the focus is on rubber-based films having a large surface-to-volume ratio to enable rapid heat transfer. Target applications are on a small scale including microelectronics, micro-electro-mechanical systems (MEMS) and lab-on-chip systems. Yet, larger scales are accessible by massive parallelization.
Elastocaloric materials should fulfil a number of key properties including (i) a large adiabatic temperature change ΔT, (ii) minimum fatigue, (iii) high materials efficiency and (iv) sufficient thermal conductivity for efficient heat transfer. Though the thermo-mechanical properties of natural rubber are well investigated, the key properties (i)-(iv) required for elastocaloric cooling are not examined systematically. A series of laser-cut and cast samples based on cured natural rubber foils and prevulcanized natural rubber latex concentrate is presented for various thicknesses in the range (50 – 900) µm. The samples are characterized by uniaxial tensile tests in combination with infrared thermography to determine suitable elastocaloric materials. Among the investigated materials, laser-cut cured natural rubber foils exhibit the highest elastocaloric temperature changes of +7.4/-10 K and a material's coefficient of performance of 3.6.
Elastocaloric cooling devices require an appropriate actuation mechanism to meet required strain levels up to 700 % and rates up to 5 s^{-1}. Separation of heat and cold can be achieved via directional heat transfer by alternating mechanical contact of the film sample to heat sink and source elements. Engineering issues comprise sample fixations and the designs of thermal and mechanical interfaces for efficient heat transfer as well as force recovery to enhance the COP on the system level. First demonstrators will be presented that address the various design issues. The design studies are complemented by lumped-element modelling to understand the dynamics of heat transfer and resulting cooling capacity.

Experimental Regenerative Elastocaloric Heat Pump Using Natural Rubber Gael Sebald[1], Giulia Lombardi[2,1], Gildas Coativy[3], Jacques Jay[4], Laurent Lebrun[3] and Atsuki Komiya[2,1]; [1]ELyTMaX IRL3757, CNRS, INSA Lyon, Centrale Lyon, Université Claude Bernard Lyon 1, Tohoku University, Japan; [2]Institute of Fluid Science, Tohoku University, Japan; [3]Univ. Lyon, INSA Lyon, LGEF EA682, France; [4]Univ. Lyon, CNRS, INSA-Lyon, CETHIL, UMR5008, France

In the search of refrigeration alternatives for performance optimization and environmental sustainability/friendly issues, caloric materials may offer several advantages, such as a high coefficient for performance (COP) and low global warming potential. Refrigeration prototypes using magnetocaloric, electrocaloric and metallic elastocaloric materials were proposed in recent years with particularly promising performances. Elastocaloric polymers may offer additional specific advantages, such as their low CO_2 footprint, their abundancy and their low cost, as well as low actuation stress. However, such materials require large deformations to obtain significant adiabatic temperature change DT_{ad} (i.e. elongation >400% for DT_{ad}>3 K), and exhibit a low thermal conductivity (~0.2W/(m K)), one or two decades lower than ceramics and metals.
In this work, taking into account the above-mentioned limits, we developed an experimental proof of concept of a refrigeration device using natural rubber tubes. An active regenerative configuration was used, which consists basically of activating the caloric material cyclically, and circulating a fluid at the same frequency with a phase shift of 90°. Such technique is known to provide large temperature span and cooling power for other caloric materials. The thickness of the rubber walls was ensured to be lower than that of the harmonic thermal boundary layer in the rubber for typical operating conditions, thus solving the low thermal conductivity issue. The large required deformation issue was solved by working from a pre-elongation of 400% and by imposing cyclic deformations between 400% and 600%. Finally, a technique for the grip of the natural rubber materials was proposed. Two geometries were tested using natural rubber tubes-based regenerators.
The natural rubber tubes were first stretched cyclically without fluid, an adiabatic temperature variation of ~3.5 K was measured for an elongation varying between 3.5 and 5.5. Heat exchangers were then added on both sides of the regenerators, the fluid circulation in the natural rubber tubes was provided by a piston pump, and the hot heat exchanger was maintained at room temperature by a dedicated fluid circulation. The cold heat exchanger comprised a heating source for determining the cooling power for a given temperature span.
Different operating conditions were tested and the maximal temperature span, cooling power, and COP was determined for each condition. It was obtained temperature span as high as 10 K, a cooling power in the Watt range and COP above 5. The corresponding specific cooling power ranged 100~200W/kg. For regenerative systems, from the literature, the displacement of the fluid strongly influences the temperature span and the cooling power, where an optimum displacement is observed. In the devices using natural rubber, it was found that the temperature span and cooling power were monotonic functions of the displaced volume. It was interpreted in the light of the low thermal conductively of natural rubber, which contributed to maintain a large temperature span even for low cooling power.
Finally, the proposed design is fully scalable: it is straightforward to increase the number of natural rubber tubes to meet a given targeted cooling power.

3:45 PM EN03.08.04
Fatigue Resistant Elastocaloric Regenerative Cooler / Heat Pump Showing High Performance Stefano Dall'Olio, Ziga Ahčin, Andrej Zerovnik, Parham Kabirifar, Luka Porenta, Jan Cerar and Jaka Tusek; University of Ljubljana, Faculty Of Mechanical Engineering, Slovenia

Due to the high global warming potential of refrigerants in the short and long term, the refrigeration community is looking for a reliable alternative technology that could replace the current dependency on vapor compression systems. A valuable alternative technology should be highly efficient and environmentally friendly. Recently, devices based on the elastocaloric effect (eCE) proved to be one of the most promising candidates to replace vapor compression cooling and heating systems in the following years. The elastocaloric cooling is based on the elastocaloric effect (eCE), which is closely related to the superelasticity of shape memory materials. In the specific case of shape memory alloys, which are the most studied elastocaloric materials (eCM), the eCE occurs due to a stress-induced martensitic transformation. When an external force is applied to an eCM, the transformation from an austenitic to a martensitic phase occurs. This is an exothermic transformation that leads to the release of latent heat and thus to the heating of the eCM under adiabatic conditions. During unloading, the endothermic reverse martensitic-austenitic transformation occurs, leading to the absorption of the latent heat, causing the material to cool below its initial temperature, under adiabatic conditions.
In our recent work [1] we developed an elastocaloric cooling and heat-pumping device that showed outstanding specific performance compared to the existing caloric devices. It is based on the concept of an active elastocaloric regenerator made of Ni-Ti tubes loaded in compression. It has the shape of a shell-and-tube heat exchanger and consists of eighteen 56 mm long tubes, equivalent to only 13.7 g of eCM. The regenerator can operate in both cooling and heat-pumping modes and shows durable operation and record performance with a maximum temperature span of more than 31 K at zero thermal load and a heating power of more than 60 W, equivalent to 4,400 W per kg of eCM at a temperature span of 10 K. The best performance was obtained at a frequency of 2 Hz and a stress level of 825 MPa.
In this talk we will present the performance of our elastocaloric regenerator, its main characteristics and the research behind the development of the device. In particular, we will focus on the optimization process of the critical areas of the regenerator: the flow distribution inside the regenerator, the displaced fluid volume ratio, the dead volume and the heat transfer losses to the ambient. Moreover, motivated by the excellent results we have obtained with a single elastocaloric regenerator, we are designing a more complex and compact prototype device with four phase-shifted regenerators including a force recovery mechanism, to increase the total cooling/heating power with respect to a single regenerator and to reach a performance comparable to that of a small conventional cooling/heat-pumping unit.

Richness of Ferroelectrics for Caloric Cooling Brahim Dkhil; Univ. Paris-Saclay, CentraleSupélec, France

The search for alternative solid-state refrigeration materials to hazardous gases in conventional and cryogenic cooling devices is a very active field of condensed matter. The use of phase transitions is a powerful tool to achieve giant caloric effects in ferroic materials in which magnetization, polarization, strain and/or volume can be strongly tuned under a moderate external stimulus. Here, we explore various features of ferroelectric materials to reveal their potentialities as solid state coolers. This includes their phase transitions, the multiphase and critical points, their stress-sensitivity, their inverse electrocaloric effect, the asymmetry in non-ergodic states, the use of dual-stimuli multiferroics or intentionnally introduced defects. These aspects will be put in perspective of the recent works in the literature.

4:30 PM *EN03.09.02
Electrocaloric Materials for Practical EC Heat Pumps Qiming Zhang; The Pennsylvania State University, United States

More than a decade of active electrocaloric (EC) material research has produced several EC materials that exhibit a giant electrocaloric effect (ECE) at high electric fields which is assured by direct measurement. These EC materials have enabled the demonstration of EC cooling devices, which exhibit temperature lifts of more than 10 K at thermal non-loading. These research and development efforts have revealed the critical importance of electrical breakdown, which is common in all electric and dielectric materials and devices under high voltages and electric fields, in developing EC materials and their use in EC devices. This talk will present general considerations in developing EC materials for EC coolers that generate large temperature span with significant cooling powers. Recently reported large ECE at low electric fields (fields much below the electric breakdown) in the P(VDF-TrFE-CFE-FA) tetrapolymers creates opportunities for practical EC coolers. We will present materials studies related to the phase transition behavior in this new class of relaxor polymers. We will also present the associated electromechanical actuations of the materials which may be utilized for heating pumping from the cold load to heat sink.

Magnetic Shape Memory Heuslers for Caloric Applications—The Crucial Role of Microstructure in the Martensitic Transformation Franca Albertini[1], Milad Takhsha Ghahfarokhi[1], Simone Fabbrici[1], Francesca Casoli[1], Lucia Nasi[1], Giovanna Trevisi[1], Greta Cavazzini[1,2], Lorenzo Gallo[1,2], Francesco Cugini[1,2] and Massimo Solzi[1,2]; [1]Consiglio Nazionale delle Ricerche IMEM-CNR, Italy; [2]Università degli Studi di Parma, Italy

The vast family of Ni-Mn based Heusler alloys provides an extended playground of physical properties. The interplay between a martensitic transformation and magnetically ordered states gives rise to a series of functional properties that can be exploited in different technological sectors, among which remote actuation, solid state refrigeration and thermomagnetic generation. Their excellent responsiveness to external fields, i.e. magnetic field, pressure and stress and their combined application, makes them promising for multifunctional exploitation. On the other hand the hysteretic character of the martensitic transformation cripple the performance of these materials in cyclic operations.

In my talk I will present some recent results on NiMn-based Heuslers, including nano/microscale materials obtained by different fabrication methods, i.e. epitaxial thin films [1], patterned micro/nanostructures [2], mechanically-milled particles [3]. Thin films and micro/nanostructures are of particular interest not only for the realization of miniaturized new-concept devices, but also for providing insights into the magneto-structural coupling at the different length scales, suggesting possible strategies for the optimization of material performances.
The talk will focus on microstructure tuning and microstructure-related effects on the martensitic transformation, in view of the possible exploitation of this class of materials in smart and caloric applications.

Large Electrocaloric Effects in Lead-free $BaTiO_3$ Multilayer Capacitors Junning Li[1], Alvar Torelló[1], Veronika Kovacova[1], Sakyo Hirose[2] and Emmanuel Defay[1]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]Murata Manufacturing Co., Ltd., Japan

Electrocaloric (EC) materials, presenting large adiabatic temperature change or isothermal entropy change under the application (or removal) of electric fields, hold the potential to offer more efficient alternatives to caloric heat pumps for replacing hazardous gases used in traditional vapour-compression systems. Recently, large EC effects with 5.5 K have been reported in $Pb(Sc_{0.5}Ta_{0.5})O_3$ multilayer capacitors (MLC) [1] thanks to its strong first-order phase transition, and then a 13 K of temperature span is reported in a prototype based on these MLC [2]. However, the toxicity of lead forces researchers to find eco-friendly materials exhibiting EC performances competitive with lead-based. Here, we study the EC effects in lead-free $BaTiO_3$ (BTO) MLC using an infrared camera. Unlike the commercial BTO MLC, we prepared our sample without scarifying the feature of first-order transition in BTO. The adiabatic temperature variation versus temperature profile shows two peaks, which matches with two first-order phase transitions of BTO in the same temperature range, as observed by Differential Scanning Calorimetry. We measured a temperature drop of ~ 0.9 K with a temperature span of 70 K under 170 $kV\ cm^{-1}$, starting at 30 °C near the tetragonal-to-orthorhombic transition. Under the same electric field, a larger temperature change of ~ 2.4 K was recorded above 126 °C, the Curie temperature of BTO. Our findings suggest that further optimized BTO MLC can offer a path for designing lead-free caloric cooling prototypes with promising results.

8:30 AM *EN03.10.01
Giant and Durable Electrocaloric Effect in Polar High-Entropy Polymers Xiaoshi Qian and Donglin Han; Shanghai Jiao Tong University, China

For a practical electrocaloric (EC) device, a $\Delta T > 5$ K is required for its solid-state working body. Although giant ECEs have been observed for more than 15 years, the large temperature change ($\Delta T > 5$ K) still requires large electric fields, *e.g.*, 5.5 K under 29 MV/m for PST ceramic MLC (Nature 575, 468, 2019) and 5.1 K under 83.3 MV/m for P(VDF-TrFE-CFE) polymeric MLC (Science 357, 1130, 2017). These two materials represent the best EC material in inorganics and organics, but the fields applied were too close to the breakdown field (E_b) of respective materials, raising issues in reliability and practical deployment of the technology. In this work, we developed a high-entropy EC polymer by incorporating C=C double bonds in the polymeric main chain to induce localized nano-scale structural modification. Compared to state-of-the-art polymers, this new polymer tripled the cooling effect under ultra-low electric field of polymer, *i.e.*, the ΔT was enhanced from below 2 K to over 7.5 K (3.75-fold) under ultra-low field of 50 MV/m, which is merely 14% of its breakdown field. For the first time, we show that the large ECE ($\Delta T > 5$ K) can operate with fatigue resistance for more than one million cycles.

9:00 AM *EN03.10.02
High-Performance Elastocaloric Materials via Novel Design and Advanced Fabrication Daoyong Cong; University of Science and Technology Beijing, China

Elastocaloric refrigeration, which employs the large latent heat associated with stress-induced martensitic transformation, has been considered as one of the most promising non-vapor-compression cooling technologies. Development of high-performance elastocaloric materials is central for the implementation of elastocaloric refrigeration. After a short review of the elastocaloric research field, this talk will introduce our recent endeavour on developing high-performance elastocaloric materials via novel design and advanced fabrication. The concept "the larger the unit cell volume change across phase transition, the larger the transition entropy change" was used to design a novel alloy with a colossal elastocaloric effect. The "high-entropy alloy" concept was employed to design elastocaloric alloys with a wide operating temperature window. Advanced fabrication techniques, including directional solidification and additive manufacturing, were applied for microstructure control to increase the magnitude of elastocaloric effect and enhance its long-term cyclic stability. Perspectives on future directions for advanced elastocaloric materials development will be given.

9:30 AM *EN03.10.03
Multicaloric Effects and Additively Manufactured Elastocaloric Materials with Tailored Transformations Huilong Hou[1], Bin Wang[1], Kai Wang[1], Yongzhong Lai[1], Suxin Qian[2], Xinqing Zhao[1] and Ichiro Takeuchi[3]; [1]Beihang University, China; [2]Xi'an Jiaotong University, China; [3]University of Maryland, College Park, United States

The field of caloric cooling has undergone a series of transformations in the past decade bolstered by the advent of new materials and devices, and yet there remain challenges that need to be overcome before they can enjoy widespread commercialization. An exciting new direction in the field is multicaloric materials systems, which inherently display several first-order transitions and thus can be cooled using multiple fields. In this talk, we survey the emerging field of multicaloric cooling and explore state-of-the-art caloric materials systems responsive to multiple fields. We show that all caloric cooling processes fall into one of the four schemes of multicaloric cooling modes depending on whether a material is a single-phase or a composite and whether a single field or multiple fields are required for pumping heat. We examine the physics of multicaloric cooling concerning intrinsically coupled ferroic order parameters in multiferroic materials. We will also discuss the key factors governing the overall system efficiency of multicaloric cooling devices.

Because the mechanocaloric effect plays an important role in multicaloric cooling configurations, we revisit the definition of the mechanocaloric effect and expand its scope beyond the limited two members of elastocaloric and barocaloric effects. Further, we employ additive manufacturing to design highly-reversible superelastic transition pathways at a microscopic level in elastocaloric Ni–Ti-based alloys. Through rapid cooling and high-precision compositional tuning, we have fabricated Ni–Ti binary nanocomposites with unique curved nano-interfaces, which give rise to quasi-linear stress-strain behaviors with unusually narrow hysteresis, resulting in an enhancement in the materials coefficient of performance by a factor of four to seven. Our nanocomposite NiTi is stable over 1 million cycles of superelastic transitions. In addition, we have fabricated Ni–Ti-based ternary alloys whose transformation temperature and latent heat can be tailored in a large range.

Lock-In Thermography as a Tool for Investigating Caloric Effects Ken-ichi Uchida; National Institute for Materials Science, Japan

Thermal measurement techniques play an important role in pioneering new thermal management principles. We have investigated various physical phenomena and heat control functionalities through active thermal measurement techniques based on the combination of non-contact temperature measurements and lock-in detection. Specifically, we have mainly used the lock-in thermography (LIT) method, in which thermal images are acquired by an infrared camera while periodically applying thermal excitation to a sample. In the LIT method, only the temperature change components that follow the periodic excitation are selectively extracted by Fourier analysis, which makes it easy to achieve highly sensitive temperature measurements with sub-mK-order resolution. There are various choices of excitation sources, such as a charge current, heat current, magnetic field, and light, and a variety of heat generation phenomena responding to the excitation sources can be precisely measured. The main application of the LIT technique has been nondestructive failure analysis of semiconductor devices, since the path of a charge current can be visualized by measuring Joule heating distribution associated with periodic current application. Recently, it has been used for fundamental studies on spin caloritronics and thermoelectrics [1-4].
In this talk, we will summarize the measurement principles and features of the LIT method and present recent experimental results on magnetocaloric [5,6], electrocaloric [7], and elastocaloric [8] effects obtained by this technique. The LIT method not only enables non-contact, simultaneous measurements of adiabatic temperature changes induced by the caloric effects for a large number of samples, but also leads to the demonstration of their new functionalities. This technique will thus be useful for material exploration and application research of the caloric effects.

Top-Down Production of Macroscopic Monolayers For Study of Static and Dynamical Properties Fang Liu; Stanford University, United States

Two dimensional (2D) materials and their artificial structures hold great promises for electronic, optoelectronic, and electrochemical applications. The best quality monolayers for exploring the exotic quantum properties so far are mostly produced by scotch tape exfoliation, which is stochastic and often yields microscopic sized monolayers. On the other hand, bottom-up growth techniques such as chemical vapor deposition often produces monolayers with higher defect densities. Beyond the Scotch tape exfoliation, a few new scalable and controllable top-down processes have been developed to exfoliate a variety of van der Waals (vdW) single crystals into monolayers and monolayer nanoribbons with high yield, high quality, and macroscopic dimensions. High-quality and large-area crystals will allow us to further assemble them into artificial heterostructures. The monolayers and other 2D structures have been demonstrated to achieve enhanced nonlinear optical responses, and integrate into multiple pump probe techniques as electron diffractions to explore the key static and dynamic properties in these low dimensional systems. Obtaining high quality materials with enhanced yield will not only facilitate the basic research, but also take us one step closer to mass production and commercialization of the 2D devices in the future.

11:00 AM EN04.01.02
Energy Level Alignment at 2D Semiconductor/Electrolyte Interfaces for Photoelectrochemical Energy Conversion Justin Sambur; Colorado State University, United States

The fundamental problem that limits the solar energy conversion efficiency of conventional semiconductors such as Si is that all absorbed photon energy above the band gap is lost as heat. The critical question that our research addresses is: *Can we avoid energy losses in semiconductors*? Hot-carrier systems that avoid such losses have tremendous potential in photovoltaics and solar fuels production, with theoretical efficiencies of 66% (well above the detailed-balance limit of 33%). Ultrathin 2D semiconductors such as monolayer (ML) MoS_2 and WSe_2 have unique physical and photophysical properties that could make hot-carrier energy conversion possible. The specific knowledge gap in the field is how the energy levels of 2D semiconductors move with applied potential and/or illumination, making the driving force for charge transfer ($\Delta G^{0'}$) unclear. Since $\Delta G^{0'}$ governs the hot-carrier extraction rate (k_{ET}), understanding how and why $\Delta G^{0'}$ changes under solar fuel generation conditions is critical to controlling k_{ET} relative to the cooling rate. Absence of this critical information is limiting our ability to perform hot-carrier photochemistry. Our research team has employed photocurrent spectroscopy, steady-state absorption spectroscopy, and in situ femtosecond transient absorption spectroscopy as a function of applied potential to characterize underlying steps in a ML MoS_2 photoelectrochemical cell. The rich data set informs us on the timescales for hot-carrier generation/cooling and exciton formation/recombination, as well as the magnitudes of changes in exciton energy levels, exciton binding energies, and the electronic band gap. These findings open the possibility of tuning the hot-carrier extraction rate relative to the cooling rate to ultimately utilize hot-carriers for solar energy conversion applications.

11:15 AM EN04.01.04
Large-Area Triazine-Based Covalent Organic Framework Nanofilm on Cu for Electrochemical CO_2 Reduction Yusik Oh and Hye Ryung Byon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Carbon dioxide (CO_2) emission from the combustion of fossil fuels causes global warming and climate change. Much attention has been paid to converting CO_2 gas to high-value fuels, and electrochemical CO_2 reduction reaction (*e*-CO_2RR) is one of the promising methods operated at ambient pressure and room temperature. Indeed, the *e*-CO_2RR successfully generated carbon monoxide (CO) with >90% Faradaic efficiency (FE) using Ag and Au catalysts.[1] In comparison, ethylene (C_2H_4), ethanol (C_2H_5OH), and propanol (C_3H_7OH) production, called C_{2+} species, remained challenging due to complicated reaction pathways and low selectivity. Copper (Cu) is the sole catalyst facilitating these multicarbon formations but also allowing H_2 and CO evolution.[2] Thus, it is necessary to suppress these undesired reactions while enhancing CO coverage for the C-C dimerization.
Here, we developed a large-area covalent organic framework (COF) nanofilm on the Cu substrate to enhance the C_{2+} selectivity. Triazine, as a well-known CO_2-capturing moiety, was used as the main motif in the COF. A photo-assisted Schiff-base reaction assembled triazine and linkage building blocks and formed ~3.3 nm diameter of hexagonal pores and well-ordered eclipse structure by the reaction at solution/air interface. Then, a floating COF film was transferred to the Cu substrate. The resulting seamless COF nanofilm can provide a consistent local condition for triazine moieties, thus being distinguished from previously studied powdery and polymeric organic layers.[3] For the *e*-CO_2RR, the COF/Cu provided 52.2% FE of C_{2+} at -1.1 V vs. RHE, which was twice higher than the bare Cu (23% for C_{2+}). In particular, C_2H_4 was predominant and occupied ~25% of FE. The hydrophobic COF film was significantly suppressed in H_2 evolution (17.8% vs. 35.1% FE for triazine-COF and Cu, respectively). In addition, the porous nanochannels provided high local pH in the confined COF/Cu interface, causing further mitigation of H_2 evolution. The COF film also helped perform stable *e*-CO_2RR and was preserved on the Cu substrate after 2 hours, although some torn holes appeared. This result was in contrast with the rapid deactivation of the bare Cu (<1 h). We also separately prepared triazine-free COF by replacing triazine with benzene and detected 30.5% of FE_{C2+} and 18.7% of FE_{C2H4}. It suggested better CO_2 and CO interaction at triazine and promoted the C-C dimerization at the COF/Cu interfaces. Compared to the ~4 nm thickness of triazine-COF films, a thick one (~27 nm) showed significant CH_4 conversion efficiency at the expense of C_{2+} production. It revealed the competitive CO conversion reaction to hydrogenation and the C-C coupling at a thicker organic film. In the presentation, I will discuss the detailed role of triazine-COF and highlight the pivotal material design to understanding electrochemical reactions and optimizations in the presentation.

Effects of Nitrogen Functionalities and Metal Ions in Defect Engineered Low Dimensional Carbon Catalysts on Carbon Dioxide Electroreduction
Soumyabrata Roy[1], Ram Manohar Yadav[2,1], Zhengyuan Li[3], Jingjie Wu[3] and Pulickel Ajayan[1]; [1]Rice University, United States; [2]VSSD College, CSJM University, India; [3]University of Cincinnati, United States

Renewable electricity powered reduction of carbon dioxide (CO_2) to fuels and chemicals has extensive potential to close the anthropogenic carbon cycle. The large spectrum of CO_2 electroreduction (eCO_2R) products offers great opportunity from an electro-synthetic standpoint, although its potential is still limited by low catalytic selectivity for specific key products. Metal catalysts majorly dominate the state-of-the-art scenario in eCO2R. Copper (Cu) leads the way with its ability to produce hydrocarbons and oxygenates beyond the 2e-reduction process, but unfortunately with a wide product distribution. On the other hand, Ag/Au and Sn/Bi produce C1 products like carbon monoxide (CO) and formate ($HCOO^-$) respectively, with >90% Faradaic efficiency (F.E.). Methane (CH_4), which is a kinetically hindered 8e- electron eCO_2R product, can be used both as a fuel and hydrogen carrier. Thus, the challenging CO_2-to-CH_4 conversion pathway has received considerable attention in the past few years as an important step in the carbon capture and utilization roadmap.[1,2] Interestingly, low dimensional carbon matrices provide a reasonable alternative to metal-systems as tunable catalysts for eCO_2R. Over the years our group has systematically investigated several avenues of defect engineering, nitrogen (N) doping, amine functionalization etc. to develop important structure-activity correlations in carbon nanocatalyst (quantum dots, carbon nanotubes, graphene etc.) for eCO_2R.[3-7] In our current study, we present a general molecular tuning strategy- in-situ amine functionalization of nitrogen-doped graphene quantum dots (N-GQDs) for CO_2-to-CH_4 conversion at high efficiencies.[8] N-GQDs achieve a CH_4 Faradic efficiency (FE) of 63% and 46%, respectively, at CH4 partial current densities of 170 and 258 mA cm^{-2}, matching to or even surpassing the performance of the state-of-the-art Cu-based catalysts.[9,10] The N-GQDs also produce C_2 products comprising primarily ethylene (C_2H_4) and ethanol (C_2H_5OH) with a maximum FE of ~10%. Detailed structure-activity relationship studies reveal that the

CH_4 yield varies linearly with amine group content, whereas the C_2 production rate shows a positive dependence on the pyridinic N dopant content. A holistic analysis of our collective studies on carbon nanocatalysts provides meaningful insights into the routes and effects of controlled N-defect doping strategy (defect nature and density) with specific N configurations, variable local chemical environments, and functionalization on eCO_2R outcomes. These works can guide the rational design of defect-engineered carbon nano-catalysts with CO_2-to-C1 product conversion efficiency at the industrially relevant level.

A Platform of 3D Printed Devices to Power Wearable Sensors Cecilia Mattevi; Imperial College London, United Kingdom

3D-printing is regarded as a sustainable manufacturing technique with applications in different industries, from automotive to aerospace, medicine, and energy.
At small scale, 3D printing can enable the fabrication of miniaturized electrodes with free form factors and high mass loading over small footprint areas. 2D materials with outstanding electrochemical properties are particularly suitable to serve as functional materials in energy harvesting, conversion and storage devices.
In this talk, I will present our work on 3D printed miniaturized electrodes in the form of supercapacitors, rechargeable batteries beyond lithium, and energy harvesting systems. We use earth-abundant electrode materials and water-based electrolytes or gel electrolytes to manufacture energy storage and harvesting devices to meet the growing energy demand to power wearable and portable electronic devices.
I will discuss the materials challenges in formulating inks of nanomaterials and different architectural design to optimize the electrochemical performance. I will then show how these devices can power wearable sensors.

2:00 PM EN04.02.03
Intermediate Temperature Alkaline Fuel Cells Enabled by Using Inorganic Layered Double Hydroxides as Solid Electrolyte Leanna Schulte, Jarrett Dillenburger, Zahra Fakhraai and Thomas Mallouk; University of Pennsylvania, United States

Layered double hydroxides (LDHs) are a class of two-dimensional material whose nanosheets are comprised of metal cations octahedrally coordinated to hydroxides. LDHs typically exist as micron wide hexagonal crystallites, and within each crystal, tens of nanosheets are vertically stacked together, forming inter-sheet regions that contain water, hydroxides, and other anions to balance charge. Unique among inorganic layered materials, LDH nanosheets have a positive charge which facilitates impressive hydroxide conductivity on the order of 10^{-2} – 10^{-1} S/cm, competitive with state-of-the-art polymer ion-exchange membranes that are employed as solid electrolytes in alkaline fuel cells and electrolyzers. LDHs also excitingly preserve water content in their inter-sheet galleries well beyond the boiling point of water, up to 200 °C in some cases, a temperature range in which polymer electrolytes experience critical loss of humidity and thermal degradation. Therefore, LDHs are a promising candidate for solid electrolyte in alkaline fuel cells and electrolyzers as they could enable higher operating temperatures (100-200 °C) leading to faster kinetics of desired redox reactions and higher energy conversion efficiency.

In my presentation, I will describe my work in implementing LDHs as inorganic solid electrolyte in alkaline fuel cells to access to an elevated range of operating temperatures at and above 100 °C. First, I will discuss the fundamental relationship between hydroxide conductivity and LDH interlayer anion identity under ambient pressure conditions and over a temperature range up to 140 °C that has not yet been explored for this two-dimensional material. I will then share fabrication strategies to transform crystalline LDH powders into gas impermeable, mechanically robust, and chemically stable membrane architectures. Lastly, fuel cell polarization behavior of LDH alkaline fuel cells will be presented, and *in operando* three electrode characterization of the anode and cathode will be used to understand kinetics of the hydrogen oxidation and oxygen reduction reactions in this new class of inorganic fuel cell.

2:15 PM EN04.02.04
Defect-Modified Two-Dimensional Carbon Nitride for Solar Energy Storage and Hydrogen Production Li-Che Chueh and Jih-Jen Wu; National Cheng Kung Univ, Taiwan

Cyanamide-functionalized potassium poly(heptazine imide) (CFKPHI) which exhibits the abilities of light harvesting and photoelectron storage for solar energy conversion is a new class of two-dimensional (2D) carbon nitrides. In this work, CFKPHIs were synthesized by ionothermal treatment of supramolecular complexes of various nitrogen-rich organic compounds. Solid-state nuclear magnetic resonance characterizations reveal that in addition to the cyano defect in CFKPHI, intrinsic defect modified CFKPHIs, including C-H group-functionalized and carbon vacancy-modified CFKHPIs, can be tailored by the compositions of the supramolecular complexes. The C-H group-functionalized and carbon vacancy-modified CFKHPIs demonstrate comparable photocatalytic activities for hydrogen evolution under AM 1.5G (100 $mWcm^{-2}$) illumination in the presences of the Pt nanoparticle cocatalyst and the hole scavenger of triethanolamine (TEOA), which are 3-fold enhanced compared to the photocatalytic activity of CFKPHI. The dark photocatalytic performances of the two defect-modified CFKPHIs were also examined in this work. The CFKPHI photocatalysts in TEOA aqueous solution were irradiated using AM 1.5G (100 $mWcm^{-2}$) for 2 h, the Pt precursor was injected into the solution as soon as the irradiation was turned off. The delayed H_2 productions over the C-H group-functionalized and carbon vacancy-modified CFKPHIs are 14-fold and 194-fold higher than that over CFKPHIs. The photophysical properties of light-storing carbon nitrides are variable by modifying the microstructure of CFKPHIs towards efficient solar energy storage and conversion. The influences of chemical and electronic structures on the solar energy storage and photocatalytic activity of KPHIs will be discussed in this presentation.

2:30 PM BREAK

3:00 PM EN04.02.06
Electrodeposited Single-atom Coupled with CoFe Layered Double Hydroxides for Enhanced Oxygen Evolution Jaehyun Kim[1] and Ho Won Jang[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Advanced Institute of Convergence Technology, Korea (the Republic of)

To address the global energy crisis, hydrogen production from electrochemical water electrolysis is one of the most promising strategy for obtaining a sustainable and eco-friendly energy source without emitting carbon dioxide. For industrial large-scale hydrogen production from water electrolysis, current densities larger than 1 A cm-2 at low overpotentials less than 300 mV should be acquired to reduce the price of hydrogen and substitute the fossil fuels. However, the oxygen evolution reaction (OER) in water electrolysis requires a four-electron transfer process, which leads to the sluggish kinetics with high activation barriers and overpotentials. Ir or Ru-based electrocatalysts has excelled at decreasing the overpotential of OER but these scarce elements are expensive and also suffer from the poor stability. Therefore, developing active and durable electrocatalysts with abundant elements or ultralow noble metal usage is urgent for industrial hydrogen production. In this research, we atomically dispersed Ir and Ru metal atom on the iron–cobalt layered double hydroxide (FeCo-LDH) with unsaturated coordination sites using facile two-step electrodeposition. Ir and Ru single-atoms facilitate the electron transfer of FeCo-LDH by balancing the adsorption and desorption behavior of the intermediates for the four-electron transfer process of OER. First-principle calculations revealed that the energy barrier of deprotonation intermediate step from *OH to *O was dramatically lowered in FeCo-LDH with Ir and Ru single-atom compared to pristine FeCo-LDH and metal oxides. By using X-ray absorption spectroscopy, it was confirmed that Ir and Ru single atoms coupled with unsaturated surface oxygen atoms of FeCo-LDH exist at a low valence state, which hinders the oxidation of Ir and Ru single-atom and prevent the metal dissolution into the electrolyte during OER. With less than 1 wt.% loading of Ir and Ru, FeCo-LDH with Ir and Ru single-atom achieved the current density of 10 mA cm-2, 100 mA cm-2, and 1000 mA cm-2 at the overpotential of 187 mV, 210 mV, and 270 mV, respectively, with a small Tafel slope of 31 mV dec-1. We further investigated other transition metal elements as atomically dispersed on FeCo-LDH by density functional theory (DFT) based graph neural network (GNN) model and predicted that non-noble element as Cr, W, and Ce single-atom on FeCo-LDH might show ideal adsorption and desorption behaviors of the intermediates for OER. We believe that synergetic coupling between metal single-atom and FeCo-LDH supports is the key for developing a superior OER electrocatalysts and the practical large-scale hydrogen production from water electrolysis to substitute fossil fuels and facilitate a green global energy ecosystem.

3:15 PM EN04.02.07
Ultrathin 2D-Pt/NiFe-LDH/2D-Pt Sandwiched Catalyst toward Synergistically Enhanced Electrocatalytic Hydrogen Evolution Reaction SunWoo Jang; Pohang University of Science and Technology, Korea (the Republic of)

The search for efficient Pt electrocatalysts in hydrogen evolution reaction (HER) from alkaline water is noteworthy, but the obtained HER activity is hugely relies on synergistic catalysis with its accompanying oxophilic component responsible for water dissociation. In addition, the exfoliation of Pt into atomic level and their precise electronic modification could play pivotal role for achieving superb HER performance. Herein, a surfactant-free, facile, wet-chemical protocol is established to develop nanometre-thin, two-dimensional Pt nanosheets (2D-Pt) through 'surface-surface confined growth' on 2D-nickel iron layered double hydroxides (LDHs) template. Under an optimized reaction condition, a 2D-Pt/LDH/2D-Pt sandwich structure were realized, where the close proximity of the two 2D-catalytic entities i.e., Pt and oxophilic LDH are recognised to maximize their electronic interaction in the strongly bound nanohybrid. Thus, through judicious installation of layered LDH/2D-Pt interface for the water dissociation and combining with the fast and efficient hydrogen evolution from the on-bound thin and porous 2D-Pt layers, an well-organized interfacial synergy endows the HER performance to reach 6.1 times superior Pt mass utilization than commercial 20% Pt/C at -0.07 V vs RHE, whereas their sandwiched nature of the catalytic entities promote a record-high HER stability over 50 h long electrochemical study. This work highlights the opportunity for merging the exfoliated Pt into atomic level and their strong integration with catalytic in-house LDH surface to challenge remarkable electrochemical HER activity and excellent durability.

3:30 PM EN04.02.08
Electrode Material based on 2D MoS$_2$ and rGO Aerogels for Supercapacitor Applications Glaura G. Silva, Daniel E. Lippross, Felipe Medeiros and Rodrigo L. Lavall; Universidade Federal de Minas Gerais, Brazil

Supercapacitors are of great interest as they bridge the gap of energy density versus power density between conventional capacitors and batteries. The development of new materials for electrodes of supercapacitors is the challenge addressed in this work. The semiconductor phase of MoS$_2$ (H-MoS$_2$) is the stable phase while the metallic conducting phase (T-MoS$_2$) is metastable and will transition to H-MoS$_2$ with heating and ageing. However, when layers of MoS$_2$ contact rGO they may transition and remain in the T-MoS$_2$. In this work, a composite of 2D MoS2 and an rGO aerogel was investigated to produce an effective supercapacitor electrode. Aerogels have potential in this application as their porous morphology give the material a high surface area in which electrolyte can diffuse and electric double layers can form. MoS2 monolayers were prepared by intercalating MoS2 with lithium and exfoliating with sonication, this produced a suspension of monolayer MoS2 with a mean diameter of 500 nm. The rGO aerogel was produced in a self-assembly reduction reaction of GO with ascorbic acid. The MoS2 suspension could be dripped onto the aerogel's sponge-like structure that effectively soak up the suspension, depositing the MoS2 on the rGO surface. The obtained materials were examined by scanning electron microscopy with element mapping, transmission electron microscopy, atomic force microscopy in contact mode, X-ray diffraction and Raman spectroscopy. Cyclic voltammetry was used to determine the electrochemical window of the electrode, galvanostatic charge-discharge to determine the specific capacitance and electrochemical impedance to analyze the charge transfer kinetics, all experiments were conducted using a three-electrode flooded cell in a 1M solution of Li$_2$SO$_4$. The tested devices showed capacitance of 140.4 F g^{-1} at 0.5 A g^{-1} for the supercapacitor with rGO-MoS$_2$, which is 60% higher than the device using only rGO in the electrode. Moreover, the rGO-MoS$_2$ electrode based supercapacitor evidenced great cyclability maintaining 85% efficiency after 5000 cycles. Its superior performance over a pure rGO aerogel electrode can be attributed to the increase in surface area of the porous electrode and the increase of interaction with the electrolyte.

3:45 PM EN04.02.09
Trimetallic Oxides/GO Composites Optimized with Carbon Ions Radiations for Supercapacitive Electrodes Adil Alshoaibi; King Faisal University, Saudi Arabia

Hydrothermally synthesized electrodes of Co3O4@MnO2@NiO/GO were produced for use in supercapacitors. Graphene oxide (GO) was incorporated into the nanocomposites used for electrode synthesis due to its great surface area and electrical conductivity. The synergistic alliance among these composites and GO enhances electrode performance, life span, and stability. The structural properties obtained from the X-ray diffraction (XRD) results suggest that nanocomposites are crystalline in nature. The synergistic alliance among these composites and GO enhances electrode performance, life span, and stability. Performance assessment of these electrodes indicates that their characteristic performance was enhanced by C2+ radiation, with the uttermost performance witnessed for electrodes radiated with 5.0 1015 ions/cm2.

4:00 PM EN04.02.10
Crumpled Graphene-MoS_2-Graphene Heterostructure for Flexoelectric Energy Harvester Yeageun Lee[1], Hyungjong Bae[1], Farhadul M. Haque[1] and SungWoo Nam[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of California, Irvine, United States

Flexoelectric effect induces an electric polarization from strain gradient. Theoretically, since the size of the strain gradient grows quadratically as the material's length scale decreases, the flexoelectricity-induced polarization grows quadratically as the material's length scale decreases as well. Consequently, the flexoelectric-induced electric polarization can be maximized in atomically thin two-dimensional (2D) materials. In this study, we demonstrate flexoelectric energy harvesters by utilizing crumpled 2D molybdenum disulfide (MoS_2) as an active material to generate power output from strain gradient. We assembled graphene-MoS_2-graphene vertical stack on a pre-stretched very high bond (VHB) substrate followed by a release of the stretch to create a crumpled heterostructure. The fabricated flexoelectric energy devices showed 1 V of open circuit voltage (OCV) and 10 nA of short circuit current (SCC) under repetitive bending motions. However, the devices showed limited capability on harvesting energy from the translational motion. To overcome this challenge, we employed an asymmetric device configuration. The asymmetric device configuration was achieved by two-step stamping-crumpling methods and resulted in a periodic contact between one graphene electrode and the MoS_2 active layer while maintaining a full contact between the other graphene electrode and the MoS_2 active layer. As a result, the device with asymmetric device configuration showed 3 mV of OCV and 0.01 nA of SCC under repetitive translational motions. Furthermore, the crumpled structure allowed high deformation endurance, and the devices demonstrated robust energy harvesting ability up to 100 % and 50 % stretching strain for symmetric and asymmetric configurations, respectively.

SESSION EN04.03: Poster Session I: Catalysis
Session Chairs: Hong Li and Xiaolin Zheng

Moscone West, Level 1, Exhibit Hall

5:00 PM EN04.03.01
Universal Platform for Robust 2D Dual Atom Catalysts with Superior Hydrogen Evolution in Wide pH Media Laud Anim Adofo[1,2], Seon Je Kim[1,2], Soo Ho Choi[2], Young-Min Kim[1,2], Soo Min Kim[3] and Ki Kang Kim[1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Institute for Basic Science (IBS), Korea (the Republic of); [3]Sookmyung Womens' University, Korea (the Republic of)

Layered two-dimensional (2D) transition metal dichalcogenides (TMDs) have been suggested as efficient substitutes for Pt-group metal electrocatalysts in hydrogen evolution reaction (HER) during water electrolysis. While scalable synthesis of TMDs is available by chemical vapor deposition (CVD), it is often required to transfer on the electrode, degrading the long-term durability due to the weak adhesion. Furthermore, poor catalytic activities in neutral and basic medium retard the practical applications. Here, we report the universal platform for direct synthesis of superior 2D TMD electrocatalysts (MoS_2, WS_2, ReS_2) for HER in a wide pH. Catalytic activity was further boosted by the incorporation of V-Co dual atoms in ReS_2 for highly efficient wide pH water electrolysis. It shows the ultralow overpotentials of 31 mV, 83 mV, and 35 mV at a current density of 10 mA/cm^2 in acidic, neutral, and alkaline medium, respectively, with high unperturbed durability of more than 70 hours in all media at 200 mAcm^{-2}. These recorded values are the best milestone among TMD catalysts without Pt group metals. The high intrinsic HER performance is explained by the robust catalyst-support synergy, lower energy barrier for water adsorption/dissociation, and the thermoneutral Gibbs free energy after V-Co dual doping. This study holds great promise for scaling up TMDs for industrial water splitting.

5:00 PM EN04.03.02
Surface Active Self-Reconstruction of Ni-Fe Thiophosphate to Core-Shell Oxyhydroxide Nanosheets for Efficient Oxygen Evolution Reaction Ki Kang Kim[1], Balakrishnan Kirubasankar[1,2], Yoseob Won[1], Soo Min Kim[2], Soo Ho Choi[1] and Jae Woo Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sookmyung Women's University, Korea (the Republic of)

Designing a high efficient, robust oxygen evolution electrocatalyst is an essentially important process in water splitting. Two-dimensional (2D) layered transition metal thiophosphate (MTPs or MPX_3) are evolving as potential candidates for wide-range of applications. In this work, we chose a dual cationic and anionic 2D layered van der Waals Ni-Fe thiophosphate ($NiFePS_3$) ultrathin nanosheets as an OER electrocatalyst rather than conventional Ni-Fe oxides, layered hydroxide and oxyhydroxide. During the electrochemical activation process the abundant dual anionic edge P/S sites react with OH^- ion to form an oxyhydroxide (OOH^*) layer over the surface of $NiFePS_3$. The surface reconstructed NiFe oxyhydroxide (OOH^*)/$NiFePS_3$ can efficiently acts as ultimate catalytic center for oxygen evolution reaction (OER) and trigger dual cationic sites OER mechanism rather than conventional adsorbate evolution mechanism (AEM). As a result, the surface reconstructed NiFe(OOH)/$NiFePS_3$ delivers overpotential of 278 mV at a current density of 20 mA cm^{-2} and better stability over 50 h in alkaline electrolyte. The assembled NiFe(OOH)/$NiFePS_3$||Pt/C full cell water splitting delivers 10 mA cm^{-2} at 1.53 V with excellent stability in alkaline medium and outperformed most NiFe based electrocatalysts. This work provides a valuable fundamental insight toward surface reconstruction of $NiFePS_3$ and the role of dual species involved in dual-site OER mechanisms for constructing efficient OER electrocatalysts.

5:00 PM EN04.03.04
The Atom-level Understanding on the Role of a Transition Metal Heteroatom in the Hydrogen Evolution Reactions on Transition Metal Dichalcogenides Sangjin Lee, Sujin Lee and Young-Kyu Han; Dongguk University, Korea (the Republic of)

Hydrogen has attracted tremendous attention as a sustainable and renewable energy source, and for the last decade, a clean generation of hydrogen has been extensively studied. Since the expected demands for hydrogen will keep increasing up to about 12% of the total energy sources until 2050, establishing clean and feasible hydrogen generation methods from water-splitting is essential because the hydrogen generation still depends largely on fossil fuels, producing massive amounts of greenhouse gases. To effectively generate hydrogen from water, the use of catalysts is considered crucial, boosting the hydrogen evolution reaction (HER) with reduced energy consumption. For effective HER catalysts, the hydrogen adsorption free energy, ΔG_{H^*}, has been considered one of the most significant descriptors to predict the hydrogen generation performance.
Two-dimensional transition metal dichalcogenides (TMDs) are among the most noteworthy catalyst materials for HER because of their earth abundance, high stability and controllable electronic structures. Since Pt catalysts have shown the most superior HER catalytic performances with the near-zero ΔG_{H^*}, intensive research efforts have been carried out to realize new catalyst materials with zero ΔG_{H^*}. Doping of TMD with TM heteroatoms have been

considered promising strategies to optimize the ΔG_{H^*} because doped heteroatoms may provide optimal hydrogen adsorption process and H_2 generation expediting the HER catalytic activity. For examples, Co, Zn, Pd, and Pt were used to reduce the ΔG_{H^*} of MoS_2 by activating its inert basal plane, and doping of Co, Ni, Cu, and Zn into $MoSe_2$ dragged the high ΔG_{H^*} of non-doped structure into the near-zero values. However, although lots of doped TMDs have been suggested for enhanced HERs with optimal ΔG_{H^*}, the atomic-scale process and appropriate general rules explaining the overall relation between the dopant TM and the ΔG_{H^*} have not yet been fully understood.
In this presentation, the universal trends and underlying mechanisms observed in the ΔG_{H^*} on the TM heteroatom doped TMDs are provided. Using first-principles calculations, the electronic and structural analyses were carried out on the 3*d*, 4*d* and 5*d* TM doped MoS_2 catalysts, and we found a distinctive difference between the early and the late TM dopants with respect to the position of Fermi levels on their *d* bands. While the group 9-12 dopants were expected to show an optimal HER performance with the near-zero ΔG_{H^*}, we revealed that the hydrogen adsorption process in those late TM doped MoS_2 is mainly regulated by the strain relaxation from the dopant heteroatom. On the other hand, a structural deformation is barely observed in the early TM doped MoS_2 but the charge in the charge of the chalcogen atom plays a key role to govern the hydrogen adsorption. In addition, we validated that other TMD systems such as $MoSe_2$, $MoTe_2$, CrS_2, and WS_2 had also the similar trends on TM heteroatom doping as found in MoS_2 system.

SESSION EN04.04: MXene and Other Applications
Session Chairs: Damien Voiry and Zongyou Yin
Wednesday Morning, April 12, 2023
Moscone West, Level 2, Room 2004

8:30 AM *EN04.04.01
MXenes for Electrochemistry and Electrocatalysis Yury Gogotsi; Drexel University, United States

The ability of transition metal atoms to reversibly change the oxidation state enables redox energy storage. Catalytic properties of some of the transition metals lead to use of their oxides in catalysis and electrocatalysis. A few oxides that are conductive find applications in transparent conductive layers in solar cells, thus contributing to energy harvesting. However, the majority of oxides have a low conductivity, limiting their applications in electrocatalysis, electrochemical energy storage, harvesting, and conversion. Two-dimensional (2D) carbides and nitrides of transition metals known as MXenes, with a thickness of a nanometer or less, have their surfaces terminated by oxygen or OH, forming compounds like Mo_2CO_2, $Ti_3C_2(O,OH)_x$, or $Nb_4C_3O_2$ with the surfaces resembling that of oxides or hydroxides. They are hydrophilic, form stable colloidal solutions in water, and work well with aqueous, ionic liquid or polar organic electrolytes. They chemically behave very much like the corresponding oxides/hydroxides; however, the fundamental difference is that electrons of the transition metal give them metallic conductivity, thus compensating for the key limitation of oxides and eliminating the need for conductive carbon additives. Moreover, the conductivity of titanium carbide MXene with O, OH, and/or F terminated surface is outstanding and can exceed 20,000 S/cm. A combination of high electronic conductivity with hydrophilicity and 2D structure facilitates electronic and ionic transport, allowing extremely fast charge/discharge with the electron transfer. Naturally, this opens new opportunities in energy storage, electrocatalysis, and other fields where a combination or surface redox with electrical conductivity is required. The family of 2D transition metal carbides and nitrides (MXenes) has been expanding rapidly since the discovery of $Ti_3C_2T_x$ (T stands for surface terminations) in 2011. Close to 50 different MXenes have been synthesized, and the structures and properties of numerous other MXenes have been predicted using density functional theory (DFT) calculations. Furthermore, the availability of solid solutions on M and X sites, control of surface terminations, and the discovery of in-plane and out-of-plane ordered double-M MXenes (e.g., $Mo_2TiC_2T_x$) offer a potential for synthesis of dozens if not hundreds of new materials. The versatile chemistry of the MXene family renders their properties (conductivity, work function, surface charge, etc.) tunable for a large variety of catalytic and energy-related applications.

9:30 AM *EN04.04.03
Architected 2D Materials for Energy Conversion and Transfer Juyoung Leem; Stanford University, United States

Introducing three-dimensionality to two-dimensional (2D) materials opened new possibilities and novel applications in material system design. Extraordinary intrinsic properties of 2D materials have attracted scientific research communities, and various 2D material-based structures and devices have been proposed and demonstrated for photonics applications, energy conversion, and heat and energy transfer. Given the fascinating electrical, optical, and thermal properties of 2D materials, constructing three-dimensional (3D) structures out of 2D materials makes 2D systems even more interesting by providing means of extrinsic modulation of material properties and morphology controls. In this talk, I will focus on architecting 2D materials for nanoplasmonic applications, which allow for confining light, enhancing absorption, and manipulating light-matter interactions. 2D-0D hybrid materials were mechanically deformed to enhance the plasmonic effect of the hybrid materials, and the enhanced plasmonic effects were demonstrated with optical measurements and enhanced sensing efficiency. Lastly, the implications and future directions toward energy conversion and transfer using architected 2D hybrid materials will be briefly discussed.

Interfacial Surface Engineering of Nickel-Iron Sulfide Nanosheets on Layer Ti_3C_2 MXenes/Nickel Foam Electrode for Alkaline Water Electrolysis
Debabrata Chanda[1,2], Karthik Kannan[1,2], Jagadis Gautam[1,2], Mikiyas Mekete Meshesha[1], Jang S. Gwon[1], Gee Seong Lee[3], Dae Won Hong[3], Myungsik Choi[4] and Bee Lyong Yang[1,2]; [1]Kumoh National Institute of Technology, Korea (the Republic of); [2]GHS Co ltd, Korea (the Republic of); [3]National Nanofab Center, Korea (the Republic of); [4]SJ Tech Co, Korea (the Republic of)

The growing environmental issues arising from the unchecked use of fossil fuels and energy shortages arising from the growing population mean that there is a need for the development of clean renewable energy technologies. Renewable-energy-driven electrochemical water splitting is a promising route for the sustainable production of hydrogen as an energy carrier, as well as the production of future green energy fuels. The electrochemical water splitting process includes the hydrogen evolution reaction (HER) and the oxygen evolution reaction (OER); however, both the HER and OER are conventionally carried out using state-of-the-art Pt and Ir catalysts, respectively. Although highly efficient, economical and environment friendly electrocatalysts for hydrogen and oxygen evolution reactions (HER and OER) need to be explored for sustainable hydrogen production. A novel nickel iron sulfides (NiFeS) nanosheets were immobilized on the electrochemically decorated Ti_3C_2 MXene/nickel foam (Ti_3C_2 Mxene/NF) surface via a simple facial hydrothermal pathway (NiFeS@Ti_3C_2 Mxene/NF). Surface morphology and structural engineering of NiFeS with surface effect of Ti_3C_2 MXene creates electronic coupling that can optimize the adsorption energies of water, hydrogen and oxygen, resulting in more accessible a for HER (20 mA cm^{-2}@180 mV) and OER (20 mA cm^{-2}@290mV) combine to provide excellent structural stability over long-term operation. In addition, the synthesized NiFeS@Ti_3C_2 MXene/NF exhibits remarkable overall water splitting performance in a zero-gap anion exchange membrane water electrolyzer (AEMWE) with the current density of 401 mA cm^{-2} at 1.85 V. It provides performance comparable to the state-of-the-art Pt/C||RuO$_2$ and meets the commercial electrolyzer requirements. From a commercial point of view, our electrolyzers are the best because of their low catalyst loading (ca. 1.25 mg cm^{-2}) and low operating temperatures (50 °C), resulting in low capital and operating costs.This result opens new windows for solar hydrogen production for commercial applications and offers the opportunity to replace the polymer electrolyte membrane water electrolyzer (PEMWE).

Vacancy-Rich MXene-Immobilized Ni Single Atoms Enable Remarkable Electrocatalytic Oxidation Reaction Shiqi Zhou and Jiayin Yuan; Stockholm University, Sweden

Single-atom catalysts (SACs) have recently attracted tremendous attention because of their outstanding catalytic performance in the field of heterogeneous catalysis. Building a strong interaction between the single atom and its supporting matrix is pivotal in stabilizing the single atoms. Herein, we reported the successful synthesis of Ni SACs supported by an emerging $Ti_3C_2T_x$ MXene by using a 'self-reduction' strategy *via* the assistance of rich Ti vacancies on $Ti_3C_2T_x$ MXene surface, which act as the trap and anchor sites for individual Ni atoms. The constructed Ni SACs supported by the $Ti_3C_2T_x$ MXene show excellent activity and exceptional operational stability toward the hydrazine oxidation reaction. Density functional theory calculations suggested that this remarkable catalytic performance was attributed to the strong coupling of the Ni single atom and its surrounding C atoms, which optimized the electronic density of states that increased adsorption energy and decreased reaction activation energy, thus boosting the electrochemical activity. Results presented here will encourage a broader pursuit of 2D materials-supported SACs designed by a vacancy-trapped strategy combined with the theoretical calculation.

2D Shuttle $Ti_3C_2T_x$ MXene Systems for Enhancing the Performance of Composite Cu_2O/TiO_2 Photocatalysts – Comparison with Graphene Oxide
Gilles D. Berhault, Ziba Roostaei, Frédéric Dappozze and Chantal Guillard; Research Institute on Catalysis and Environment, France

Introduction

The most common semiconductor used in photocatalysis is titanium dioxide due to its high photocatalytic response under UV irradiation. However, the use of TiO_2 remains limited due to its high recombination rate of electron-hole pairs. Different strategies were envisaged to improve its photocatalytic response like cationic or anionic doping, coupling with C allotropes or changing semiconductor morphology. In this respect, previous studies made by our group showed that 1D TiO_2 nanotubes (TNT) provides a better separation of photogenerated charges while the coupling with graphene oxide (GO) allows transfer of photoelectrons to GO making more holes available for photooxidation reaction. However, GO was also found to be unstable when combined with TiO_2 under irradiation through overreduction of oxygen functional groups contained in graphene layers, leading to a complete loss of beneficial effect of adding GO after long photocatalytic runs.
The solution envisaged here is to use a different 2D conductive material, MXene sheets ($Ti_3C_2T_x$), to separate physically the semiconductor (TNT) producing photoelectrons from an electron-acceptor component (herein, copper) to improve both the photocatalytic response and the stability under irradiation conditions. Applications are envisaged for both photooxidation reactions and H_2 production.

Materials and Methods

$Ti_3C_2T_x$ MXene layers were obtained by HF etching of Ti_3AlC_2 MAX precursors to remove aluminium. GO was synthesized according to a modified version of the Hummers method. TNT was obtained under hydrothermal alkaline conditions. Two series of impregnation are performed: first, GO or MXene were impregnated onto TNT while $Cu(NO_3)_2.3H_2O$ was then impregnated onto the resulting materials. Photocatalytic tests were performed for the photodegradation of formic acid (FA) and for the H_2 production.

Results and Discussion

To define the role played by $Ti_3C_2T_x$ MXene layers, several systems combining the TiO_2 semiconductor (TNT as compared to the P25 reference) with Cu and/or MXene were considered.
In the case of Cu doping of TiO_2, the formation of Cu_2O species with well-defined plasmonic properties was evidenced after adequate post-calcination treatment leading to improved photocatalytic activity for both photooxidation and H_2 production.
Adding $Ti_3C_2T_x$ MXene to TiO_2 semiconductors (TNT or TiO_2 P25) was also studied considering several parameters (the MXene loading, the HF concentration during etching or the size of the MXene sheets) showing that an optimized choice of $Ti_3C_2T_x$ MXene layers with adequate sheet size and appropriate etching can lead to high beneficial gain in activity.
In a last step, combining copper to the hybrid $Ti_3C_2T_x$ MXene/TiO_2 system allows an even more efficient separation of charges by beneficiating from the electric conductivity of the MXene layers to transport photoelectrons from the semiconductor to the Cu component with an activity twice higher than without MXene. This last result confirms the beneficial role played by $Ti_3C_2T_x$ MXene as a physical separator between donor and acceptor of electrons allowing a better separation of photogenerated charges.
Finally, comparison to the use of GO instead of $Ti_3C_2T_x$ MXene layers confirms the interest of both systems with their own advantages: higher stability of MXene layers under photocatalytic conditions but better flexibility of GO favoring a higher interaction with each other component.

Conclusion

The interest of using a physical separator between donors and acceptors of photoelectrons has been demonstrated using $Ti_3C_2T_x$ MXene layers as 2D shuttle conductive materials. The physical separation achieved between holes and electrons leads to more active photocatalytic systems for both photooxidation reactions and H_2 production opening the possibility to form a vast family of new, more efficient and more stable photocatalytic hybrid systems.

Rapid Energy Sharing at Atomically Thin van der Waals Interfaces During Charge Transfer Archana Raja; Lawrence Berkeley National Laboratory, United States

Charge and energy transfer processes at the junction of atomically thin, two dimensional (2D) materials are an area of burgeoning interest because van der Waals crystals allow for the creation of arbitrary, atomically precise heterostructures simply by stacking disparate monolayers without the constraints of covalent bonding or epitaxy. At a type II heterojunction between two 2D semiconductors, ultrafast charge transfer has been previously determined to occur on the order of 10's of femtoseconds after photoexcitation. However, the coupling between the lattice degrees of freedom of the photoexcited monolayers remains less understood. We use ultrafast electron diffraction to directly visualize lattice dynamics in the individual monolayers at the van der Waals heterojunction of WSe2 and WS2. We are able to track the transfer of energy from one layer to another by following the change in intensity of the Bragg peaks after photoexcitation. With the aid of first principles calculations, we uncover the role of layer-hybridized electronic states in enabling ultrafast charge and energy transport across atomic junctions through bidirectional phonon emission. This work is a result of fruitful collaborations with colleagues at various institutions including SLAC National Laboratory, Stanford, Berkeley Lab, UC Berkeley and NIMS Tsukuba.

Harnessing Nonlinear Optical and Photocurrent Responses in Two-Dimensional Materials Xiaofeng Qian; Texas A&M University, United States

Two-dimensional materials offer a unique platform with a plethora of novel physical properties and potential applications. Noncentrosymmetric 2D materials allow for second-order nonlinear optical and photocurrent responses that are absent in the centrosymmetric counterparts, suggesting the possibility for harnessing the 2nd-order responses for energy and optoelectronic applications such as bulk photovoltaics and electro-optical modulators etc. In this talk, I will present our recent theoretical effort on understanding and predicting nonlinear responses in 2D semiconductors and 2D quantum materials. First, I will present a theoretical study of second harmonic generation (SHG) in semiconducting 2D materials including monolayer group IV monochalcogenides and Janus 2D materials. SHG polarization anisotropy is strongly correlated with the intrinsic ferroelastic and ferroelectric orders, which leads to non-reciprocal shift and circular photocurrent whose direction can be controlled by both internal ferroic orders and external light polarization. Second, I will present a theory of ferroelectric nonlinear Hall effect in time-reversal invariant layered topological materials, discuss the complex interplay of symmetry, electronic structure, and Berry curvature, and briefly mention the experimental demonstration of Berry curvature memory effect. Our findings suggest the potential applications of 2D materials for bulk photovoltaics and quantum nonlinear electronics by harnessing their nonlinear optical and photocurrent responses.

3:30 PM EN04.06.02
One-Pot Synthesis of a Hierarchical-Octahedral $NiSe_2$ as a Co-Catalyst for Enhanced CO_2 Photoreduction Under Full-Spectrum Light Irradiation Haritham Khan, Hazina M. Charles, Rajendra C. Pawar, Plassidius J. Chengula, Jin-Goo Park and Caroline Sunyong Lee; Hanyang University, Korea (the Republic of)

Excess carbon dioxide emission accompanied by gross fossil fuel consumption has worsened the global warming crisis in recent decades. The photocatalytic conversion of CO_2 into hydrocarbons is a potential solution to mitigate both energy and environmental problems. However, conventional photocatalysts suffer low efficiency in CO_2 conversion with C1 and/or C2 products. Nanostructured perovskite oxides (titanates) have emerged as a class of high-performance photocatalytic materials because of their nontoxic nature, adequate chemical stability, tunable crystal structures, band gaps, and surface energies. Two-dimensional (2D) transition metal dichalcogenides (TMDs) are another emerging group of materials that got high attention due to their light absorption, high conductivity, low cost, and non-toxic properties. The design and fabrication of layered transition metal chalcogenides with high exposure of crystal layer edges is one of the key paths to achieving distinctive performances in their catalysis and electrochemistry applications. Nevertheless, the photocatalytic performance and CO_2 reduction efficiencies are still low due to severe charge recombination and sluggish kinetics. Therefore, the rational design and preparation of dissimilar dimensional materials have been extensively investigated for use to effectively increase photocatalytic performance. In this study, we report an effective strategy to synthesize a unique octahedron-shape $NiSe_2$ nanoparticles from a one-dimensional (1D) $NiTiO_3$ nanofibers (NFs) precursor. Firstly, the 1D $NiTiO_3$ NFs are prepared by electrospinning and then combined with Se powder through the solvothermal method. The 1D $NiTiO_3$ NFs acted bi-functionally, as both the Ni source and the substrate. The combined effect of $NiTiO_3$ NFs and $NiSe_2$ has been optimized by varying the loading amounts of Se powder. The varying amounts of Se powder play a vital role in optimizing the photocatalytic behavior of the $NiTiO_3$ NFs/$NiSe_2$. Among different $NiTiO_3$/$NiSe_2$ products, 0.09 wt.% loading of Se powder shows superior photocatalytic performance because of the unique octahedron-like morphology and enhanced active sites. The as-synthesized sample exhibits lower charge recombination, higher current densities, and outstanding photocatalytic conversion of CO_2 into CO, and CH_4 shows 90% selectivity. This enhanced photocatalytic performance should be attributed to its higher light absorption, efficient charge separation, and transfer as well as a relatively large number of surface-active sites. The structure and morphology of the octahedra with more surfaces endow the $NiSe_2$ favorable for more chemical reactions with exposed active sites. $NiSe_2$ acted as a novel cooperative co-catalyst to trap the electrons and improve charge separation efficiency. Hence, we presume that the synthesized one-dimensional $NiTiO_3$ NFs precursor-derived $NiSe_2$ nanoparticles have excellent potential to replace the noble-metal-based photocatalyst for enhanced photocatalytic activity.

3:45 PM EN04.06.03
Light-Induced Ammonia Generation over Defective Carbon Nitride Modified with Pyrite Judith Zander and Roland Marschall; University of Bayreuth, Germany

Mitigating the effects of climate change caused by continuously rising CO_2-concentrations in the atmosphere is one of the main challenges mankind is currently facing, and one that requires major changes in the energy supply for vehicles and industrial processes. Photocatalysis offers a way of directly employ solar light as an abundant and renewable energy source for the conversion of inert molecules, such as water, or nitrogen into fuels, or valuable chemicals. One of these is ammonia, that is required in large amounts for the production of fertilizers, that are in turn crucial for the nutrition of the world population.[1] Industrially, ammonia is produced in large, centralized power plants from hydrogen and nitrogen gas under elevated temperatures and pressures.[2] Photocatalysts that are able to selectively and efficiently convert atmospheric nitrogen into ammonia are therefore highly desirable. However,

currently known systems are as to yet unable to meet the strident demands, necessitating the development of new photocatalysts and the unveiling of reaction mechanisms and pathways.[3][4]
A promising material for photocatalytic NRR is defective carbon nitride, V_N-C_3N_4.[5][6][7] Carbon nitride is a low cost, non-toxic and easy to synthesize polymeric material with good visible light absorption, but also fast recombination of excited charge carriers.[8][9] Different strategies to improve the activity are widely explored, such as doping, defect engineering, or heterojunction formation.[9][10] Another promising approach for the development of new photocatalysts is based on observations from nature, specifically on the structure of nitrogenases, which are enzymes capable of reducing nitrogen under ambient conditions. The active centers of the different kinds of nitrogenases all have in common, that they mainly consist of sulphur and iron atoms.[11]
One of the simplest iron- and Sulphur-containing compounds is the earth abundant mineral FeS_2, which absorbs a broad wavelength range of visible light.[12] In this contribution we present the fabrication of a composite of V_N-C_3N_4 and FeS_2 that results in a significant activity improvement for the light-induced generation of ammonia, with hydrogen occurring as the only side-product. Crucial for the enhanced activity is the activation of the structure of V_N-C_3N_4 *via* coordination of and π-back-donation to cyano groups at defect sites to iron centers, resulting in an improved reduction of these groups to NH_3, similar to a Mars-van-Krevelen mechanism.[13]

2D MoS_2/BiOBr van der Waals Heterojunctions by Liquid-Phase Exfoliation as Photoelectrocatalysts for Hydrogen Evolution Mengjiao Wang and Teresa Gatti; Justus-Liebig-Universität Giessen, Germany

Photoelectrocatalytic hydrogen evolution from water is a promising topic for producing H_2 efficiently and environmentally friendly. However, the efficiency of hydrogen production in these photoelectrocatalysis systems is still low. Therefore, the discovery of more efficient phototelectrocatalysts has been considered as one of the important directions in the field of clean and renewable energy. 2D BiOBr is emerging as an interesting photoelectrocatalysts because of its unique internal electric field and band structure that facilitate the separation and mobility of the charge carriers[1,2]. However, pure 2D BiOBr suffers from low catalytic efficiency and photocorrosion from the light source. In order to optimize the catalytic efficiency and stability of 2D BiOBr, a 2D BiOBr/MoS_2 heterojunctions with 1 wt%, 5 wt%, 10 wt% and 50 wt% of MoS_2 were fabricated by a simple liquid-phase exfoliation method. Raman spectra prove the existence of strong interactions between the MoS_2 and BiOBr 2D nanosheets in the heterojunctions. The heterojunction containing 1 wt% of MoS2 shows the best performance and stability in photoelectrocatalytic hydrogen evolution than the other samples. The calculation of the heterojuntions shows a better charge transfer inside the heterojunction than the pure 2D materials as well.

Efficient Photoelectrochemical Water Splitting of $BiVO_4$ Nanosheets Vertically Synthesized on WO_3 Nanorods Roshani A. Jayarathna, Dong-Bum Seo, Sung-Soo Bae and Eui-Tae Kim; Chungnam National University, Korea (the Republic of)

$BiVO_4$ nanosheets (NSs) have recently attracted great attention as a promising visible-light responsive photocatalyst for photoelectrochemical (PEC) water splitting. The PEC reactivity of $BiVO_4$ NSs has been further improved by employing heterostructures, such as $BiVO_4/WO_3$ and $BiVO_4/TiO_2$, which enhance the separation and subsequent transfer of photogenerated electron-hole pairs via a built-in junction potential. To fully take advantage of the heterojunction effects of PEC reactions, the size and configuration of $BiVO_4$ NSs on nanostructure matrices, such as WO_3 nanorod (NR) substrates, should be optimized in a controllable manner. In this work, we report the synthesis and PEC performance of vertically-aligned $BiVO_4$ NSs on WO_3 NRs. WO_3 NRs were synthesized via hydrothermal reaction and decorated by $BiVO_4$ NSs through drop casting. The heterostructure of $BiVO_4$ NSs on 1D WO_3 NRs exhibited significantly promoted PEC performance because of beneficial heterojunction effects, improved photoabsorption, and increased reaction surface area. In addition, the heterostructure of $BiVO_4$ NSs/WO_3 NRs formed a desirable heterojunction leading to effective photogenerated charge transfer dynamics. Our study indicates that vertically-aligned $BiVO_4$ NSs on WO_3 NRs are promising candidates as nontoxic, inexpensive, and stable photoanodes for PEC water splitting.

Photoelectrochemical Valorization of Biomass Derivatives by Hematite Photoanodes Modified with Co-Catalysts Irene Carrai; University of Bologna, Italy

The conversion of sunlight into fuels represents one of the possible few solutions to the energy growing demand of the last century and can be considered as a good alternative to fossil fuels. Among all the possible methods to obtain such renewable energy, the photoelectrochemical (PEC) splitting of water into molecular hydrogen and oxygen is a very promising approach, as it allows to capture the intermittent solar energy and to store it in the form of chemical bonds. However, the oxygen evolution reaction (OER), is kinetically very slow and the product -O_2- lacks the economic value. For these reasons, the solar-driven oxidation of biomasses[1] started to be considered as a valid solution to water oxidation. Indeed, valuable chemicals can be obtained, which

can be used as monomers for the synthesis of industrially relevant compounds.
In this work, a PEC cell was employed to perform the photooxidation of 5-hydroxymethylfurfural (HMF) into furan dicarboxylic acid (FDCA). Because of its good stability, cost effectiveness and non-toxicity, a visible band-gap inorganic semiconductor[2] -i.e., titanium-doped hematite (Ti: Fe_2O_3)- was chosen as the photoanode. The experiments were performed in aqueous environments, using a 0.25M borate buffer solutions (pH=9) as the electrolyte. Also, the 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) mediator was employed, which resulted to be crucial, allowing the total consumption of HMF without promoting any parasite oxidative pathways. However, because of the highly competitive OER, full conversion into the final product -i.e., FDCA- was not achieved.
To overcome OER competition and to improve the selectivity towards FDCA, co-catalysts were electrodeposited on the surface of Ti: Fe_2O_3 photoanodes. The selected co-catalysts were cobalt-iron(oxy)hydroxide ($CoFeO_x$) [3] and cobalt-phopshate (CoPi)[4]. Then, these electrodes were tested for the HMF PEC conversion, and the results were compared with those of a naked Ti: Fe_2O_3 photoanode. Interestingly, the electrode modified with CoPi showed the best results, giving the highest efficiency and selectivity for the final product -i.e., FDCA. Further studies also revealed that CoPi could enhance the one-electron oxidation process, favouring the TEMPO-mediated HMF photooxidation, at the expense of OER. In the future, the proposed approach can be implemented in a tandem PEC cell, coupling the simultaneous reduction of H_2O or CO_2 at the cathode. In this way, an improvement in the conventional PEC technology can be achieved, providing a green and sustainable alternative for the energy conversion into valuable chemicals.

5:00 PM EN04.07.01

Selective, Stable, Bias-Free, and Efficient Solar Hydrogen Peroxide Production on Inorganic Layered Materials Je Min Yu, Jaejung Song, Jang Hyuk Ahn, Hyeonjin Cho, Jiyeon Oh, Hu Young Jeong, Changduk Yang, Jun Hee Lee, Ji-Wook Jang and Seungho Cho; Ulsan Natonal Institute of Science and Technology, Korea (the Republic of)

Hydrogen peroxide (H_2O_2) is one of the most significant chemicals and is in high industrial demand. Further, H_2O_2 is a potential energy carrier. Indeed, H_2O_2 has a comparable energy density (3.0 MJ L^{-1} for 60% aqueous H_2O_2) to that of compressed hydrogen (H_2) gas (2.8 MJ L^{-1} at 35 Mpa). Moreover, it is easily transported, owing to its high solubility in water, and can be produced in a centralized container on a very large scale. Currently, the anthraquinone process has been predominantly applied in industry to supply H_2O_2. However, this process is environmentally harmful and requires multi-step reactions with organic solvents, rare metal catalysts, and high energy inputs for hydrogenation and further oxidation of an alkylanthraquinone.
Alternatively, electrochemical catalysis of metal complexes has been extensively investigated for eco-friendly production of H_2O_2. The key challenge here is the development of oxygen reduction reaction (ORR) catalysts that exhibit high selectivity and activity for a two-electron ($2e^-$) pathway instead of a four-electron ($4e^-$) pathway. Co complexes have an intrinsic advantage of catalyzing the $2e^-$ reduction of O_2 to H_2O_2. This is because Co has high *d*-electron counts and their single Co atom configurations can suppress $4e^-$ ORR, which requires multi-atom sites. Typically, Co porphyrin structures have been used as redox catalytic agents for $2e^-$ ORR. These Co-macrocycles have attracted attention because of their good activity and notable selectivity towards the $2e^-$ ORR. However, these molecular catalysts have the disadvantage of nitrogen ligand degradation in the presence of H_2O_2. Carbon-based materials have also been widely investigated as another type of $2e^-$ ORR catalysts. However, they are limited by their unstable long-term stability, owing to carbon corrosion at high overpotential. On the other hand, metal catalysts such as Pt–Hg, Pd–Hg, and Au–Pd nanoparticles provide adequate stability under harsh reaction conditions, In H_2O_2 generation reactions, metal catalysts with engineered active sites have demonstrated excellent catalytic activity and selectivity. However, the processes are difficult to scale up to an industrial level because of the high cost of the catalysts.
Layered double hydroxides (LDHs) have been extensively investigated as promising electrocatalysts, owing to their unique two-dimensional lamellar structures and abundant constituent cations and anions. LDHs comprise a class of inorganic solids with metal hydroxide layers in which two or more types of metal cations are immobilized by hydroxide anion arrays and exchangeable interlayer anions. These inorganic solids are easily and economically synthesized in high purity and yield. Further, they are characterized by compositional variety, precise control of cation ratios, and the interspersion (rather than segregation) of cations within the hydroxide layers. Therefore, LDHs have great potential to tune active sites in the atomic scale for high catalytic efficiency.
In this study, for the first time, we report a highly $2e^-$ ORR pathway-selective cobalt-containing MgAl [(Co)-MgAl] LDH-based ORR catalyst (near-100% $2e^-$ ORR selectivity), wherein the single atomic Co configuration can be realized by simply controlling the precursor ratios in the synthesis. Moreover, to use an abundant energy source, sunlight for H_2O_2 production, we designed a compartmented photo-electrochemical cell with a membrane separator, in which two catalytic systems (an LDH-based electrocatalyst for H_2O_2 production and an LDH-passivated organic-semiconductor-based photoanode for photovoltage generation) are integrated. The cell generated a concentration of H_2O_2 (~108.2 mM $cm^{-2}{}_{photoanode}$ in 24 h) and a solar-to-chemical conversion efficiency (~3.24%) through sunlight illumination without any external bias. The concentration and solar-to-chemical conversion efficiency are the highest among all reported systems to the best of our knowledge.

Investigation of Vibrational and Thermal Properties of γ-GeSe Jinsub Park[1], Joonho Kim[1], Yugyeong Je[2], Joong-Eon Jung[1], Je Myoung Park[3], Hyeonsik Cheong[3], SangWook Lee[2] and Kwanpyo Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Ewha Womans University, Korea (the Republic of); [3]Sogang University, Korea (the Republic of)

γ-GeSe is a recently identified polymorphic configuration in group-IV monochalcogenides. Despite its great potential for electrical and thermal applications, the experimental confirmation of vibrational modes and thermal conductivity is yet to be reported. Here, we investigate the mechanical properties and thermal conductivity of γ-GeSe using the freestanding sample geometry. The mechanical vibrational modes of doubly-clamped γ-GeSe flakes are measured using optical interferometry. The indentation using atomic force microscopy is also used to measure the mechanical deformation and Young's modulus. By comparison with finite-element simulations, we find that γ-GeSe exhibits Young's modulus of approximately 100 GPa at room temperature. In addition, the laser-irradiation-induced local heating and temperature-dependent Raman peak shifts are used to measure the thermal conductivity of γ-GeSe. We find a low thermal conductivity of approximately 7 $Wm^{-1}K^{-1}$ at 440 K. These results suggest that γ-GeSe has excellent potential for flexible and high-efficient thermoelectric devices.

5:00 PM EN04.07.04
Enhancement of Seebeck Effect Measured in Multi-Stacked Two-Dimensional Film of $PtSe_2$ van der Waals Homo-Structure Jae Won Choi, Yun Ho Kim and Sang Kwon Lee; Chung-Ang University, Korea (the Republic of)

After the properties of graphene and thin film materials are revealed, two-dimensional (2D) film structure become a hot topic of material science. Such as stretchability, portability, variability, and other reasons promise 2D materials to be a candidate for new conformation of thermoelectric device. But the most promising point of 2D materials for thermoelectric device, especially transition metal dichalcogenide (TMDC) is abnormal electric properties that doesn't appear at bulk condition. In our research, electrical conductivity and Seebeck coefficient of TMDC depend on film's thickness, which could be key of break-through of classical trade off at power factor. Additionally, when a 2D material is deposited with a secondary film, the total Seebeck coefficient of the stacked layer is generally represented by a parallel conductor model. Based on the idea, we found the total Seebeck coefficient in the transverse direction may change in a single layer when TE material layers of the same thickness are stacked vertically. We observed an abnormal Seebeck effect in a stacked 2D semi-metallic $PtSe_2/PtSe_2$ homo-structure film, i.e. an extra in-plane Seebeck voltage was produced by wet-transfer stacking at the interface between the $PtSe_2$ layers under a transverse temperature gradient. This abnormal Seebeck effect is referred to as the interfacial Seebeck effect in stacked $PtSe_2/PtSe_2$ homo-structures. We confirmed that the in-plane Seebeck coefficient increases as the number of stacked $PtSe_2$ layers increase and observed a high Seebeck coefficient exceed approximately 188 mV/K at 300 K in a four-layer-stacked $PtSe_2/PtSe_2$ homo-structure.

ABSTRACT
Zinc ion batteries (ZIB) with aqueous electrolytes are promising next-generation energy storage systems due to their high safety, environmental friendliness, low cost, and high energy density. However, zinc anode has many issues, including dendritic growth, hydrogen evolution reaction (HER), and passivation. The electrode/electrolyte interface is significantly destabilized by dendritic growth and side reactions, which eventually reduce the electrochemical performance. Many studies are being conducted to overcome these problems by electrode structure design, interface modification, and electrolyte optimization.
In this research, we propose a protection layer of zinc metal anode with two-dimensional nanomaterials. Due to their unique structure and variety of physicochemical properties, zinc anode with two-dimensional nanomaterials protection layers have excellent electrochemical performance and cycle stability by restricting zinc dendrite growth. These results suggest that the protective layer based on two-dimensional nanomaterials for zinc anode can be applied in the highly stable energy storage systems.

A Binder-Free Electrode with 2D NiFe MOF/rGO as Bifunctional Catalyst for Rechargeable Zinc Air Battery. Chun-Shuo Huang, Yi-Pin Chan and Che-Ning Yeh; National Tsing Hua University, Taiwan

Zinc air batteries (ZAB) are regarded as a promising candidate for the next generation energy storage device due to its low-cost, high-energy density, and eco-friendliness. However, precious materials such as Pt and RuO_2 are commonly used as catalysts for oxygen reduction reaction (ORR) and oxygen evolution reaction (OER), and it is important to find alternative catalysts with high stability, low cost, and outstanding catalytic activity to replace the precious metals. Metal organic framework (MOF) is a promising catalyst candidate which has high surface area and abundant active sites to react with air. MOF generally exhibits relatively low conductivity, which lowers the Coulombic efficiency of the batteries. To solve this problem, MOF is commonly grown on conductive substrates such as Ni foam, reduced graphene oxide (rGO), carbon nanotube (CNT), etc. Previous studies have shown high OER performance of the NiFe bimetallic MOF, which is rarely used for ZAB. Also, catalysts are usually coated on the current collector using binder, which may block the mass transport and decrease the rate of electrochemical reaction. Herein, we used rGO as a conductive substrate for the growth of 2D NiFe MOF to prepare a binder-free electrode and studied the impact of precursor concentrations, reaction temperatures, and reaction times on the growth of 2D NiFe MOF. The OER and ORR performances of the binder-free electrode are remarkably higher than those of the electrodes containing binder. We anticipate that these results could open a new direction for the use of 2D NiFe MOF/rGO for zinc air batteries.

Strain-Exciton Coupling in Two-Dimensional Semiconductors SungWoo Nam; University of California, Irvine, United States

In this talk, I will present our work on deterministic manipulation and confinement of excitons in two-dimensional (2D) semiconductors. I will discuss predictable and reconfigurable strain modulation in 2D transition metal dichalcogenides (TMDs) via wrinkle architectures. Strain exerted on wrinkled 2D

TMDs was periodically modulated to tensile and compressive strain at peaks and valleys of the wrinkles, respectively. Furthermore, owing to the deformable nature of the wrinkle architecture, the applied strain can be tuned reconfigurably with the optical gap of TMDs dynamically modulated. We also observed exciton transport across apex and valley of strained TMDs as well as exciton localization at the apex due to strain gradient induced energy modulation of wrinkled TMDs. Finally, I will discuss an extension of our strain modulation approach to interlayer excitons in TMD vertical heterostructures where strain is used to tune both optical gap as well as interlayer coupling between the heterobilayers. I will share our perspectives on strain-exciton engineering toward quantum and energy devices.

Strong Light-Matter Interactions in Low-Dimensional Excitonic Semiconductors Deep M. Jariwala; University of Pennsylvania, United States

The isolation of stable atomically thin two-dimensional (2D) materials on arbitrary substrates has led to a revolution in solid state physics and semiconductor device research over the past decade. A variety of other 2D materials (including semiconductors) with varying properties have been isolated raising the prospects for devices assembled by van der Waals forces.[1] Particularly, these van der Waals bonded semiconductors exhibit strong excitonic resonances[2] and large optical dielectric constants as compared to bulk 3D semiconductors. .

First, I will focus on the subject of strong light-matter coupling in excitonic 2D semiconductors, namely chalcogenides of Mo and W. Visible spectrum band-gaps with strong excitonic absorption makes transition metal dichalcogenides (TMDCs) of molybdenum and tungsten as attractive candidates for investigating strong light-matter interaction formation of hybrid states.[3-5] We will present our recent work on the fundamental physics of light trapping in multi-layer TMDCs when coupled to plasmonic substrates.[6]

Next, we will show the extension of these results to halide perovskites[7, 8] and superlattices of excitonic chalcogenides.[9] These hybrid multilayers offer a unique opportunity to tailor the light-dispersion in the strong-coupling regime.[9] We will discuss the physics of strong light-matter coupling and applications of these structures. If time permits, I will also present our recent work on scalable, localized quantum emitters from strained 2D semiconductors[10] and control of light in magnetic semiconductors.[11]

Our results highlight the vast opportunities available to tailor light-matter interactions[11] and building practical devices with 2D semiconductors. I will conclude with a broad vision and prospects for 2D materials in the future of semiconductor opto-electronics and photonics.

High Electrical Conductivity and Spin-Orbit Coupling Observed in γ-GeSe Joonho Kim[1], Jeongsu Jang[1], Dongchul Sung[2], Jong Hyuk Kim[1], Joong-Eon Jung[1], Sol Lee[1,3], Jinsub Park[1], Chaewoon Lee[1], Heesun Bae[1], Seongil Im[1], Kibog Park[4,4], Young Jai Choi[1], Suklyun Hong[2] and Kwanpyo Kim[1,3]; [1]Yonsei University, Korea (the Republic of); [2]Sejong University, Korea (the Republic of); [3]Institute for Basic Science, Korea (the Republic of); [4]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Group-IV monochalcogenides have recently shown great potential for their thermoelectric, ferroelectric, and other intriguing physical properties. The electrical properties of known group-IV monochalcogenides exhibit a strong dependence on the chalcogen type. For example, GeTe exhibits metallic behavior, whereas S-based and Se-based chalcogenides are semiconductors with sizable bandgaps. In this study, we investigate the electrical and thermoelectric properties of γ-GeSe, a recently identified polymorph of GeSe. γ-GeSe exhibits high electrical conductivity (approximately 10^6 S m^{-1}) and a relatively low Seebeck coefficient (9.4 μV K^{-1} at room temperature) owing to its high p-doping level (5×10^{21} cm^{-3}), which is in stark contrast to other known GeSe polymorphs. Based on first-principles calculations, we attribute the high p-doping level to the abundant formation of Ge vacancies in γ-GeSe polymorphic configuration. The magnetoresistance measurements also reveal weak-antilocalization because of spin-orbit coupling in the crystal. Our results demonstrate that γ-GeSe is a unique polymorph in which the modified local bonding configuration leads to substantially different physical properties.

10:15 AM EN04.08.04
Monolayer Molybdenum Disulfide Photovoltaics with Carrier Selective Contacts for High Open-Circuit Voltage Rachel Tham[1], Cora Went[2], Joeson Wong[3] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]Rewiring America, United States; [3]The University of Chicago, United States

While the efficiencies of ultrathin transition metal dichalcogenide (TMDC)-based photovoltaics have shown significant progress due to their intrinsically strong light-matter interactions, little work has demonstrated that TMDC-based photovoltaics can achieve high photovoltaic performance with technologically useful active areas. In this work, we show that a vertical carrier selective contact architecture combined with gold-assisted exfoliation of TMDCs enables millimeter-area, monolayer molybdenum disulfide (MoS_2) photovoltaics. First, we show that under one-sun illumination, photovoltaic devices with a bulk TMDC active layer result in an open-circuit voltage of 523 mV; however, the non-radiative losses associated with the indirect bandgap in multilayer TMDCs limit the achievable open-circuit voltage. We designed a solar cell that leverages the high radiative efficiency of direct bandgap monolayer MoS_2, combined with the electron- and hole-transport layers, C_{60} and poly[bis(4-phenyl)(2,4,6-trimethylphenyl)amine] (PTAA), respectively, to increase the achievable open-circuit voltage. To synthesize MoS_2 on arbitrary substrates, we develop a photoresist transfer process that minimizes the impact of polymer residues on the device performance. Through Raman and photoluminescence measurements, we show comparable optoelectronic quality between gold-assisted and traditional direct tape exfoliated MoS_2 monolayers on silicon dioxide/silicon, which exhibit similar photoluminescence emission with peaks between 1.84 and 1.86 eV, with a linewidth of 0.13 eV, similar to results seen for MoS_2 monolayers directly exfoliated onto silicon dioxide. Raman measurements indicate a similar E^1_{2g} to A_{1g} frequency difference and peak linewidth of less than 8 cm^{-1}. Our methods and results demonstrate the possibility for high efficiency monolayer photovoltaics and opens the door to large-area scalability.

10:30 AM EN04.08.05
2D Chalcogenide Thermoelectric Materials for Enhanced Solar Collection Lindsey Gray, Gabriel Marcus, Robert Link and David Carroll; Wake Forest University, United States

Even for high efficiency photovoltaics (PVs), a considerable amount of energy is lost as waste heat. One of the largest areas of loss is incoming photons with energy below the photovoltaic bandgap. These photons, not contributing to the performance, only heat up the PV, which has been shown to decrease efficiency. A method of capturing this waste heat is to place a thermoelectric behind the photovoltaic. With one side in contact with the back of the solar cell, and the other exposed to the open environment, this can create a sufficient temperature gradient to produce a voltage, and ultimately power. In this work, we present flexible 2D chalcogenide thermoelectric films adhered to the back of traditional planar photovoltaics as a method of heat management. With the benefit of being both lightweight and requiring minimal post processing, the photovoltaic-thermoelectric devices are suitable for both terrestrial and extraterrestrial environments. Tested films include bismuth telluride and antimony telluride, with increasing amounts of silver and copper doping, to improve thermoelectric performance.

10:45 AM EN04.08.06
First-Principles Study of Low-Dimensional Chalco-Halides for Photovoltaic Applications Cibrán López Álvarez, Edgardo Saucedo and Claudio Cazorla; Polytechnic University of Catalonia, Spain

Low-dimensional chalco-halides (LDCH) with general formula ABX (A=Bi,Sb, B=Se,S and X=Br,I) conform a new family of van-der-Waals materials with great promise for applications in critical energy fields like photocatalytic hydrogen production, thermoelectricity and sunlight energy conversion. However, due to their novelty and very recent synthesis, the physical and functional properties of LDCH have been little characterized thus far. We are interested in exploiting the potential of LDCH in state-of-the-art photovoltaic technologies able to compete with current single silicon junctions in terms of conversion efficiency and solar-cell costs. For this end, we present here an exploratory and comprehensive first-principles study based on density functional theory (DFT) calculations on the structural, vibrational and optoelectronic properties of LDCH. Our theoretical calculations for eight different compounds reveal, among other findings, energy band gaps within the range of 2.1-1.6 eV and remarkably large absorption coefficients of 580000 cm^{-1}, thus confirming the adequacy of LDCH for photovoltaic applications. The obtained theoretical results are compared with recent experimental measurements and complemented by photovoltaic device simulations.

Photoelectrochemical Hydrogen Evolution Reaction in Heterojunction TMD Nanoscroll Rapti Ghosh[1], Ya-Ping Hsieh[1], Guang-Yu Guo[2], Mario Hofmann[2] and Yang-Fang Chen[2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

The photoelectrochemical (PEC) hydrogen evolution reaction (HER) could produce carbon-neutral fuel from two of the planet's most abundant resources – water and sunlight. However, a number of technical and economic challenges prevent the scalable use of conventional catalyst materials. The atomically thin 2D transition metal di-chalcogenides (TMDs) are emerging as promising catalysts because of their tunable electronic structure and unique mechanical properties. In particular, the rolling of 2D TMD nanosheets into 1D scrolls induces bending strain and produces a confinement for electronic and photonic interactions. The resulting heterojunctions produce strong internal fields and enhance photocarrier dissociation. This causes a 3-fold enhanced electrochemical performance compared to planar heterojunctions. Strain-induced modification of the band alignment in this quasi-1D MoS_2/WS_2 heterojunction nanoscrolls leads to a novel hybrid charge transfer process which helps in achieving a reduced Tafel value of 39 mV dec^{-1}, and an exchange current density up to 1.44×10^{-4} Acm^{-2}, outperforming any 2D material catalyst.[1]

Large-Scale Fabrication of Lateral MoS_2 – MoS_2/WS_2 –WS_2 Heterostructures by Two-Step Chemical Vapor Deposition Majvor Z. Mack, Stephen Boandoh, Yu-Tsung Tsai and Norbert Nickel; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

In the research on two-dimensional (2D) crystals new directions and possibilities have evolved by combining different monolayer materials to lateral and vertical heterostructures. These new functionalities have opened up the fields that lead to field-effect transistors, *pn*- and Schottky solar cells [1] and light-emitting diodes employing transition metal dichalcogenides (TMDs) heterostructures. In the presented work two-dimensional TMDs are grown on Si – SiO_2 substrates using a chemical vapor deposition (CVD) technique with two separated steps as a simple large-scale fabrication methodology. Despite of its simplicity, the two-step CVD technique presented here allows the fabrication of well-defined interfaces over large areas.
In the first step MoS_2 monolayer triangles are grown and in the second step the heterostructures are formed by growing WS_2 at the perimeter of the MoS_2 triangles. Optical microscopy, Raman scattering and mapping show that the two-step CVD process can be used to grow in-plane heterostructures with three-dimensional growth observed at the MoS_2 – WS_2 interface. The change in growth mode from two-dimensional to layered growth is determined by the change of the chemical potential D*m* of the growing layer. A major contribution to D*m* is the presence of strain at the interface between the two different materials, leading to either Frank-van der Merwe growth or Volmer-Weber growth [2]. The presented work provides a deeper understanding of the growth mechanisms taking place at the interface and gives a good starting point to tune the growth parameters for a large-scale fabrication applicable in the field of energy conversion and photocatalysis [3].

Plasma-Enhanced Atomic Layer Deposition – a Swiss Army Knife for Producing Tailored Molybdenum Sulfide Catalysts for HER Miika Mattinen[1,2,3], Wei Chen[2], Marcel Verheijen[2,4], Rebecca A. Dawley[5], Marta C. Figueiredo[2], Emiel J. Hensen[2], Erwin Kessels[2] and Ageeth A. Bol[5,2]; [1]University of Helsinki, Finland; [2]Eindhoven University of Technology, Netherlands; [3]Stanford University, United States; [4]Eurofins Materials Science Netherlands, Netherlands; [5]University of Michigan–Ann Arbor, United States

Electrocatalytic water splitting is an attractive route to produce clean hydrogen (H_2) for a variety of applications.[1] Its successful realization requires highly active, stable, and low-cost hydrogen evolution reaction (HER) electrocatalysts produced in scalable manner. Molybdenum sulfides in different forms (MoS_x) are promising HER catalysts in acid. Layered MoS_2, a prototypic 2D material, displays high activity on its edges, while MoS_2 basal planes are inactive for HER.[2] Thus, maximizing edge-to-basal plane ratio and activating basal planes for HER via doping, defects, strain, and phase engineering are commonly pursued.[3] In addition, amorphous MoS_x (a-MoS_x), which exists in a range of stoichiometries, is a highly promising HER catalyst due to its excellent activity, stability, and availability of low-cost preparation methods.[4] Yet, improved deposition methods are needed for industrial applicability as well as improved understanding and tunability of the HER activity of MoS_x.

Herein, we present a scalable plasma-enhanced atomic layer deposition (ALD) process producing different kinds of MoS_x catalysts. ALD is a gas-phase method based on sequential self-limiting surface reactions that offers accurate and reproducible thickness control and excellent uniformity on large-area and three-dimensional substrates. We show that by modifying the deposition conditions, such as temperature (100–450 °C) and plasma chemistry, a range of amorphous (a-$MoS_{2.7–4.6}$) and crystalline MoS_2 films of varying morphologies and microstructures can be prepared on glassy carbon. Their HER performance has been systematically evaluated in 0.5 M H_2SO_4.

We demonstrate tailoring of the HER activity of 2D MoS_2 by modifying crystallinity and morphology such that their overpotentials at 10 mA/cm^2 (η10) range from 300 to 500 mV. The MoS_2 catalysts were stable during HER with no changes in the structure, morphology, or composition observed.

All of our a-MoS_x ($2.7 < x < 4.6$) catalysts were highly active with η10 and Tafel slope values of 210–250 mV and 40–50 mV/dec. These values compete with some of the best MoS_x catalysts on flat substrates.[4,5] The stoichiometry of a-MoS_x had only a minor effect on activity. Detailed characterization of the catalysts before and after HER revealed that all the amorphous catalysts lost sulfur under HER conditions until MoS_2 stoichiometry was reached. Following this rapid (<5 min) in-situ electrochemical activation, the a-MoS_2 catalysts showed good stability when applying a constant current density of 10 mA/cm^2 for 24 h. To gain a better view into the activated a-MoS_2 catalysts, "quasi in-situ" X-ray photoelectron spectroscopy measurements avoiding exposure of the catalysts to air were performed. Changes in Mo coordination during the activation were attributed mostly to increased disorder, while sulfur was observed to be lost predominantly in the form of bridging S_2^{2-} species. The structure of the activated a-MoS_2 catalyst was observed to depend on the starting stoichiometry.

Controllable Growth and Defect Tolerance Charge and Thermoelectric Transports in Irregular Architected 2D Conducting Metal-Organic Frameworks Hio-Ieng Un; University of Cambridge, United Kingdom

Two-dimensionally (2D) conjugated metal-organic frameworks that represent an emerging class of materials with rich chemistry and physics have shown great potential in electrochemical, optoelectronic, and catalytic applications. These 2D conducting MOFs can be synthesied in a “solution-processed” mild manner. However, unlike organic semiconductors in which microstructure and ordering can be reconstructed during fabrication, 2D conducting MOFs are neither soluble nor meltable at general conductions once made. Therefore, precise (chemical and positional) structural control in solid state during synthesis at various length scales are of particular importance.
In the first part, we will present a general on-surface synthesis method towards highly conductive thin films of nitrogen-coordinated 2D conducting MOFs. The universality of this method is demonstrated with fours materials systems with different pore sizes and different carrier types (hole and electron). Two of them exhibit record electrical conductivity (100 – 200 S cm^{-1}) and power factor (5 uW m^{-1} K^{-2}) for this nitrogen-coordinated MOF family. Their electronic and thermoelectric stabilities are also investigated. The universal method reported here provides access to understanding the fundamentals and potential in applications.
In the second part, we will focus on the interplay between (chemical and micro) structure, defects, and charge and thermoelectric transports. A range of sulfur-coordinated material systems with different chemical compositions are synthesied through liquid-liquid interfacial method. Unexpectedly, these MOFs exhibit irregular nano- and micro-architecture. The origin and the nature of the chemical defects and their vertical distributions will be discussed. Such chemical defects further lead to structural (positional) disorder. Notably, however, no evidence indicates that these defects may hinder electronic delocalization, which is different from many organic and inorganic (semi)conductors. Lastly, a possible transport mechanism for these 2D conducting MOFs will be discussed.

Synthesis, Structure, and Properties of New Solid Solution 2D Transition Metal Carbo-Chalcogenides Ahmad Majed[1], Andrey Krayev[2] and Michael Naguib[1]; [1]Tulane University, United States; [2]Horiba, United States

Two-dimensional transition metal carbo-chalcogenides (TMCCs) is a novel 2D family of materials that can be viewed from the atomic perspective as a merge between the features of two well-known 2D families; transition metal carbides/nitrides (MXenes) and transition metal dichalcogenides (TMDCs). Recently, we reported on 2D Nb_2S_2C and Ta_2S_2C, the first members of TMCCs, and we found that Nb_2S_2C is a superconductor.(1) Herein, we report on expanding the family of 2D TMCC to include continuous solid solutions in the Ta-Nb systems, viz., $Ta_xNb_{2-x}S_2C$ (where $2 > x > 0$). The multilayers $Ta_xNb_{2-x}S_2C$ were synthesized using a large-scale solid-state synthesis approach at ambient pressure. Then, exfoliation was achieved by electrochemical intercalation of lithium followed by sonication in water. The effect of different transition metal on the stability and properties of TMCCs will be discussed. Electrochemical performance of the newly discovered materials as electrodes for energy storage and conversion will be presented. Tip-enhanced Raman spectroscopy was used to study the newly synthesized materials and provide chemical imaging of surfaces at the nanoscale.

5:00 PM EN04.10.01
In Search of Alternative HER Electrocatalysts - Studies on Mo-P/C Films Mateusz Szczerba, Agnieszka Brzozka, Joanna Kapusta-Kolodziej and Grzegorz D. Sulka; Jagiellonian University, Faculty of Chemistry, Department of Physical Chemistry and Electrochemistry, Poland

In recent years, scientists have been increasingly eager to find safe, clean and efficient energy sources that will be able to reduce the progressive environmental degradation and cope with the growing global energy demand. One of the main candidates for future energy supply is molecular hydrogen (H_2), prized for its high energy density compared to commonly used fossil fuels. Electrocatalysts are currently being sought to efficiently produce gaseous hydrogen in the environmentally friendly water electrolysis. Prominent among these are materials based on transition metal phosphides, including molybdenum phosphide [1,2].
In this work, a method for the electrodeposition of Mo-P films on graphite electrodes is proposed with the aim of finding a catalytic material that reduces the overpotential necessary to drive efficiently the hydrogen evolution reaction (HER). The study is distinguished by the fact that moves away from aqueous solvents and uses a deep eutectic solvent (DES) based on choline chloride and ethylene glycol. Several experiments were carried out to determine the effects of Mo and P precursor concentrations, working electrode potential and electrodeposition temperature on the composition and morphology of the obtained Mo-P/C films. It was noted during the study that the obtained materials have a tendency to crack, and an excessive amount of molybdenum relative to phosphorus is present in the resulting deposits. Preliminary results indicated, however, that the Mo-P/C films possess electrocatalytic properties towards HER.

Electrodeposited Mo-Se/C Films as Potential Electrocatalysts for Hydrogen Evolution Reaction Daniel Piecha, Agnieszka Brzozka, Joanna Kapusta-Kolodziej and Grzegorz D. Sulka; Jagiellonian University, Faculty of Chemistry, Department of Physical Chemistry and Electrochemistry, Poland

The production of energy from renewable sources and its efficient storage are very relevant aspects that relate to the problems of the modern world, such as atmospheric pollution from the products of burning fossil fuels. One of the most prospective fuels is gaseous hydrogen. It is a renewable energy source that is widely available in nature. A common method used for production of hydrogen is the electrolysis of water. However, this process requires a large energy input to split water molecules. A reduction of this energy barrier is possible through the use of suitable electrocatalysts [1]. Alternatives to platinum-based materials are being explored for compounds that are able to significantly increase the efficiency of the Hydrogen Evolution Reaction (HER) process. In this work, we explore the synthesis of Mo-Se/C films by the electrochemical constant-potential deposition from a deep eutectic solvent (DES) based on choline chloride and ethylene glycol. The effects of temperature and working electrode potential on the composition and morphology of the deposits were investigated. It was shown that simultaneous electroreduction of Mo and Se on graphite substrates is possible. Appropriate optimization of the electrodeposition process, which was the main objective of the research conducted, makes it possible to obtain a material with a chemical composition close to stoichiometric and an interesting morphology. The performed preliminary tests confirmed the electrocatalytic properties of the obtained films.

Highly Aligned Liquid Crystalline $Ti_3C_2T_x$ MXene Film for High-Performance Supercapacitors and Hybrid Ion Capacitors Seoyeon Yuk, Seo Jin Woo and Dongju Lee; Chungbuk National University, Korea (the Republic of)

Supercapacitors (SCs) have considered significant device for energy storage system due to high power density, fast charge/discharge rates and long cycle life. Recently, hybrid ion capacitors are more attracting attention as next-generation of supercapacitors because of their improved energy density compared to conventional supercapacitors. Two-dimensional (2D) $Ti_3C_2T_x$ MXene with outstanding conductivity, broad surface area, abundant functional group and high flexibility is promising electrode material for electrochemical energy storage. However, the self-restacking problem of MXene nanosheets due to their van der Waals interactions limits the electrochemical performances. To overcome this problem, it is considered to add the spacer materials that improve structural stability of maintaining the large interlayer spacing.
In this work, the effect of addition of catecholamine on film structure and electrochemical performances was investigated. The prepared freestanding composite film exhibit widened interlayer spacing and highly aligned structure in parallel direction enabling to improve electrolyte ion and electron transportation. The optimized film exhibited outstanding supercapacitors performances including high specific capacitance and outstanding cycle stability. Additionally, the film electrode with these structural advantages is expected to storage many multivalent ion for high-energy hybrid ion capacitors. These

results suggest that the structural design of two-dimensional materials have great potential as electrodes for various energy storage systems.

Facile and Gram-scale Synthesis of $Cu_{2-x}S$ Nanoplate for Photothermal Application by Sonochemical-assisted Reaction Based on High-concentration Copper Ion Complex Precursor Hee Yeon Jeon[1], MiJeong Park[1], Myeongjun Ji[1], Cheol-Hui Ryu[1], Seungheon Han[1] and Young-In Lee[1,2]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]The Institute of Powder Technology, Korea (the Republic of)

Recently, to solve the environmental issue caused by fossil fuels and the global energy crisis, numerous research on the conversion and utilization of solar energy are in progress. Humans mainly benefit from solar power by using solar cells, which mainly use a visible region of solar light. Because infrared ray occupies about half of the total sunlight, however, for efficient use of solar energy, it is important to absorb a wide region of light from solar radiation and convert it into as much energy as possible. Among others, photothermal materials attract a lot of attention and are developing because they provide a platform for low-cost and efficient light-to-heat conversion. This energy conversion occurs by localized surface plasmon resonance(LSPR), especially in nanoscale metallic materials. Generally, LSPR has been studied on noble metals that show LSPR in the visible region and have high carrier densities. However, they can show the photothermal effect only in a specific incident light range, which is determined by the size and shape of noble metal nanostructures. In addition, the application of noble metal photothermal materials is limited to wide applications due to their high cost.
Copper-deficient p-type semiconductors, Copper sulfide($Cu_{2-x}S$) attract attention as new photothermal conversion materials because of the low bandgap(~2.2eV) and strong LSPR in the NIR region. Furthermore, they have not only high photostability and low toxicity but are cost-effective due to their lower prices than other noble metals. Although many studies have been conducted on methods for synthesizing $Cu_{2-x}S$ nanoplate like hydro-solvothermal, hot injection, and electrodeposition, they require harsh synthetic conditions such as high temperature and vacuum, many reactants, and complicated steps. Above all, since nanoplates are synthesized by suppressing the growth using a low concentration of precursor, the final synthesis yield is very poor. The limitations of existing synthetic methodologies with inefficient productive yields act as obstacles to the commercialization of photothermal conversion systems of $Cu_{2-x}S$ nanoplates.
According to the homogeneous nucleation and growth theory, the critical nuclear radius and critical nucleation free energy are inversely proportional to the supersaturation of the system. This means that a small diameter and many nuclei and initial nanoparticles can be synthesized even under low energy by using high-concentration precursors. However, as the supersaturation of the system increases, there is a limit to the control of nucleation reaction, hard aggregation, and growth rate due to thermodynamically high interfacial and surface energy. Therefore, a methodological breakthrough that can achieve mass production of uniform nanoplates is required to solve these problems.
In this study, we suggest the sonochemical-assisted reaction method based on a high-concentration metal ion complex precursor solution at room temperature and atmospheric pressure. The ultrasound energy allows for burst homogeneous nucleation and subsequent growth is controlled by the diffusion of growth species because the concentration of the growth species reduces below the minimum concentration for nucleation by the burst nucleation. And the metal ion complex acts as a dispersant to prevent particle agglomeration and growth. Large-scale synthesis of $Cu_{2-x}S$ nanoplates with controlled size and shape for a photothermal conversion is successfully demonstrated by the facile and versatile method. We systematically investigated the effect of the precursor concentration on the size and shape of the $Cu_{2-x}S$ nanoplates by Field Emission Scanning Electron Microscopy(FE-SEM), Dynamic Light Scattering(DLS), X-ray Diffraction(XRD), X-ray photoelectron spectroscopy(XPS), and UV-vis spectroscopy. Furthermore, the photothermal conversion efficiency of the nanoplates is confirmed under the Xenon lamp and the 808nm laser.

Anisotropic Transport Property Study of 2D Layered Heterostructures Yu Wang[1], Hannah Blackwood[2], Steve Cronin[3], David C. Johnson[2] and Arun Majumdar[1]; [1]Stanford University, United States; [2]University of Oregon, United States; [3]University of Southern California, United States

Heterostructures made of two-dimensional materials has been attracting much attention because of their unusual electrical, thermal, and optical properties. While in-plane transport properties of 2d heterostructures has been intensively studied, the physical properties in the cross-plane direction are still underexplored. Here, we measure both in-plane and cross-plane transport properties in 2d heterostructures, revealing highly anisotropic behavior. Furthermore, quantum many-body effects such as charge density wave have also been explored in temperature dependent electrical and thermoelectrical measurements. The findings point out that the interfaces between layers in heterostructures play an important role in transport properties, especially in the cross-plane direction.

2D Materials for Near-Unity-Absorption, Polarization, and Phase Modulation Souvik Biswas, Joeson Wong, Samuel Seah, Melissa Li, Claudio Hail and Harry A. Atwater; California Institute of Technology, United States

van der Waals semiconductors have gained a lot of attention for opto-electronics based multifunctional, energy-efficient devices. To harness maximal benefits, strong interaction of light, on-demand control of optical properties as well as efficient extraction of photo-generated carriers are needed. In this talk, we will discuss how excitons in layered materials can enable such a diverse set of functionalities.
First, we will highlight how 2D semiconductors, up to the monolayer limit, coupled with photonic structures can enable near-unity absorption (>90%) of light at room temperatures. This strategy – primarily enabled by the large optical density of states at the excitonic resonances – to maximize light absorption in the active layer is the basis towards building 2D solar cells and requires careful balancing of the radiative (γ_r) and non-radiative (γ_{nr}) rates of the excitonic transition. Next, we will discuss how in a field-effect heterostructure such rates (γ_r ,γ_{nr}) can be actively tuned, thereby strongly modulating the light-scattering properties of the semiconductor. The first example will illustrate how black phosphorus (a birefringent layered material) can be electrostatically gated to generate tunable dichroism and further coupled with optical cavities to enable a polarization modulator with high-dynamic range across the entire Poincare sphere – from linear-horizontal to vertical and circular. The results inspire future metasurface designs to actively steer beam with polarization selectivity, generate optical vorticity and control Pancharatnam-Berry phase. As a second example, we will highlight how optical cavities,

otherwise needed to enhance light-matter interaction, can be eliminated by making 2D materials “perfect” for active metasurfaces. This is achieved by operating at low temperatures (~5K) to suppress non-radiative (γ_{nr}) decay channels and using local electrostatic gates to define spatially-varying amplitude and phase gradients across a monolayer of $MoSe_2$. Such structures allow large tuning of the complex refractive index at the excitonic frequencies and show one-dimensional beam steering.

Quantum Energy Conversion in 2D Materials from Atomic to Wafer Scale Hari C. Manoharan; Stanford University, United States

We present three examples of energy conversion processes imaged and manipulated in two-dimensional (2D) materials using ultrahigh-resolution scanning probe microscopy combined with atomic manipulation. These examples span length scales in which material structure is controlled from atomic up to wafer scales.

In recent experiments, we have been able to detect a special class of quantum-mechanical forces arising from non-local interactions mediated by a background particle field due to alterations in the zero-point energy. A famous member of this class is the Casimir effect, where the force is mediated by quantum fluctuations of the bosonic field of photons. In condensed matter, forces of this class can be mediated by a fermionic field. We show the detection and quantification of this force in real space, and demonstrate nanostructures in which 2D electrons can interact and exchange energy with a designer potential energy landscape to amplify this force.

To show that such quantum forces and energy conversion processes can be extended beyond the atomic and nanometer length scale, we present a study in which the underlying 2D electron system can be encapsulated with a monolayer of hexagonal boron nitride (hBN) using a new wafer-scale growth process. We show that the electronic states remain homogeneous in energy and spectral weight, and that the hBN overlayer acts as a protective yet remarkably transparent window on low-energy structure and quantum energy conversion processes below.

Finally, we present an ‘artificial atom’ concept via nanopatterning of monolayer molybdenum disulphide, demonstrating that a synthetic superlattice of these building blocks forms an optoelectronic crystal capable of broadband light absorption and efficient funneling of photogenerated excitons to points of maximum strain at the artificial-atom nuclei. Such 2D semiconductors with spatially textured band gaps represent a new class of materials, which may find applications in next-generation optoelectronics or photovoltaics.

Enhanced Energetic Performance of Metal Nanoparticles and Metal/Polymer Composite Fuel with Multi-Functionalized Graphene Yue Jiang[1], Haiyang Wang[2], Jihyun Baek[1], Dongwon Ka[1], Andy Huynh[1], Yujie Wang[2], Michael Zachariah[2] and Xiaolin Zheng[1]; [1]Stanford University, United States; [2]University of California, Riverside, United States

Metal fuels such as aluminum (Al) and boron (B) have been used for energetic applications ranging from space propulsion and exploration, and materials processing, to power generation for nano- and microdevices due to their high energy density and earth abundance. Recently, the ignition and combustion performance of Al and B particles were found to be improved by graphene-based additives, such as graphene oxide (GO) and graphene fluoride (GF), as their reactions provide heat to accelerate Al and B oxidation, gas to reduce particle agglomeration, and fluorine-containing species to remove native oxide shell. However, GF is not only expensive but also hydrophobic with poor mixing compatibility with metal particles. Herein, we report a multifunctional graphene-based additive for metal combustion, i.e., perfluoroalkyl-functionalized graphene oxide (CFGO), which integrates the benefits of GO and GF in one material. We compared the effects of CFGO to GO and GF on the ignition and combustion properties of Al and B nanoparticles using thermogravimetric analysis, differential scanning calorimetry, temperature-jump ignition, Xe flash ignition, time-of-flight mass spectrometry, and constant-volume combustion test. These experiments confirm that CFGO, with controllable oxygen and fluorine functional groups, generates fluorine-containing species, heat, and gases, which collectively lower the ignition threshold, augment the energy release rate, and reduce the combustion product agglomeration of nanosized Al and B particles, outperforming both GO and GF as additives. Moreover, this multi-functionalized graphene additive was further incorporated into boron/ hydroxyl-terminated polybutadiene composite, which is a typical composite fuel for air-breathing propulsion. The effect of CFGO on the burning and mechanical behaviors of the boron/polymer composite was also investigated. This work shows the great potential of using multi-functionalized graphene as an integrated additive for enhancing the energetic performance of metal nanoparticles and metal/polymer composite fuels for advanced propulsion and energy conversion applications.

Effects of Quantum Size on Thermoelectric Properties of Bismuth Lei Sun[1,2], Changyi Wu[3], Haoran Gong[1] and Fei Gao[2]; [1]Central South University, China; [2]University of Michigan, United States; [3]Hunan First Normal University, China

At present, a large number of experimental and theoretical studies have shown that the low-dimensionalization of materials will greatly improve their thermoelectric properties, which will make it possible to reuse a large amount of waste thermal energy. The reason for the high potential thermoelectric capability of two-dimensional materials is still unclear. In this study, from the perspective of quantum size effect, we combined first-principles calculations and Boltzmann transport equations, taking Bi as an example, to analyze the relationship between its size effect and thermoelectric performance. Finally, it was found that only below the nanometer scale can two-dimensional materials have better performance than bulk materials.

2D-Pt Nanodendrites with Manipulated Crystal Facets: Intimately Coupled Electrocatalytic Heterointerface for Hydrogen Evolution Reaction Yu-Rim Hong; Pohang university of Science and Technology (POSTECH), Korea (the Republic of)

Despite notable signs of progress in Pt-catalyzed alkaline hydrogen evolution reaction (HER) via hybridizing with oxophilic metal-hydroxide surface, maximization of Pt’s reactivity alongside operational stability are still unsatisfactory due to the lack of well-designed and optimized interface structure. Herein, by devising atomically-flat 2D-Pt nanodendrite (2D-PtND) under the deployment of our strategized 2D-nanospace-confined synthesis, it offers all sorts of Pt features to tackle the poor-and-insufficient interfacial impacts in HER catalysis by simultaneously realizing an area-maximized and firmly-bound lateral heterointerface with NiFe-layered double hydroxide (LDH). In particular, the accompanied well-oriented (110) facet exposure of Pt has recognized a massive electronic interplay that certainly bestows strong LDH-binding. As a result, the charge-relocated interfacial bonds in **2D-PtND/LDH** acted favorably in accelerating the hydrogen generation steps and reaching about one of the highest reported Pt-mass-activity improvements (~11.2 times greater than 20 wt% Pt/C) with a substantially enhanced long-term operational stability. This work uncovers the importance of the shape and facet of Pt in feasible heterointerface creation to strengthen the catalytic synergies for efficient hydrogen production.

BiSe(Br,I): New van der Waals Semiconductors for Energy Conversion Applications Edoardo Maggi, Ivan Caño Prades, Alejandro Navarro, Joaquim Puigdollers, Jordi Llorca, Lluis S. Turu and Edgardo Saucedo Silva; Universitat Politècnica de Catalunya, Spain

Emerging quasi-1D (Q1-D) van der Waals materials have the potential to become a breakthrough in photovoltaics (PV) and photocatalysis (PC) applications among others, aiming to overcome some of the main issues affecting even the more mature PV and PC technologies. Despite this family of materials has been rarely investigated for PV and PC implementations, mixed chalco-halide compounds such as BiSe(Br,I) fit the urgent necessity of innovative and renewable sources of energy based on earth-abundant, low-toxicity, thermally stable, and defect-tolerant materials.

This class of material has the peculiarity to present a crystallographic structure in which the atoms along one of their crystallographic directions are held together via strong covalent bonds and via weak van der Waals bonds along the other two directions. This creates a highly anisotropic material formed by nano/micro-ribbons with peculiar conductive properties when properly oriented. The high tuneability of the materials and the results obtained in the present work locate the BiSe(Br,I) semiconductors in the spotlight for a broad number of applications, namely next-gen PV tandem and transparent application, piezoelectric, thermoelectric, and photocatalytic applications.

The nano/micro-ribbon structure together with the extremely uniform single-crystal phases lead to an increased amount of photons that reach the space charge region, and the light trapping effect is reported as a reduction in reflection. This type of morphology not only can boost the optoelectronic properties of BiSe(Br,I)-based solar cells but also enhance the photocatalytic activity of BiSe(Br,I)-based photocatalysts. Indeed, the current state-of-the-art of hydrogen production employing photocatalytic methods is still showing low apparent quantum yields (AQY), which can be boosted by Q1-D systems. The dense coverage of properly oriented nano/micro-ribbons determines an increase in the surface area, one of the key parameters to improving the AQY, allowing the synthesis of an efficient, photoactive, photostable, and nontoxic photocatalyst. Moreover, the estimated BiSe(Br,I) band gap is ~1.9 eV, making BiSe(Br,I) active to visible light and determining a big step forward compared to titanium dioxide (TiO_2), the most studied compound for photocatalytic applications so far, but inherently limited by a ~3eV band gap.

The theory is representative of what can be achieved with this technology, not so broadly investigated yet. Up to date, no mixed chalco-halide compounds have been synthesized through physical vapor deposition (PVD) techniques, due to the complexity of the material and the different vapor pressures involved. The present work presents the very first successful attempt to synthesize and explore Q1-D van der Waals BiSe(Br,I)-based semiconductors, through an innovative methodology implying the co-evaporation of chalcogenides followed by high-pressure annealing under halogen atmosphere. Different characterization techniques (X-Ray Diffraction, X-Ray Fluorescence analysis, Scanning Electron Microscope, Raman spectroscopy) demonstrated the high tunability of the morphology of this family of compounds by modifying the annealing conditions and confirming the possibility to synthesize high-quality single-phase material with PVD techniques for the first time. The versatility of the system allows us to obtain optimal nano/micro-ribbons distribution in terms of height, thickness, density, and orientation, according to the final device use, proving how these novel compounds are a sliver of light in terms of advanced PV and PC applications. The first working devices for both technologies will be presented and discussed.

11:00 AM EN04.11.08
Energetic Characteristics of Exfoliated Magnesium Boride Nanosheet Dongwon Ka, Yue Jiang, Andy Huynh, Jihyun Baek, Rui Ning and Xiaolin Zheng; Stanford University, United States

Boron combustion has garnered much attention due to its extremely high gravimetric and volumetric energy density. However, several inherent characteristics of boron prohibit fast response on heating and complete combustion. In this work, a boron-rich two-dimensional (2D) nanosheet is studied in order to overcome the limitations of boron ignition and combustion. Boron-rich MgB_2 nanosheet is prepared by exfoliation from bulk magnesium diboride (MgB_2) with Mg etching; then, its oxidation behaviors and energetic performances are analyzed by material characterizations in slow heating and fast heating conditions. This work reports that MgB_2 nanosheet is oxidized more favorably in slow heating conditions than bulk MgB_2. Even under fast heating conditions like Xenon (Xe) flash ignition, MgB_2 nanosheet has lower minimum flash ignition energy, higher combustion efficiency, and faster pressurization rate than bulk MgB_2, boron nanoparticle, and boron/magnesium mixture. This result shows MgB_2 nanosheet can be regarded as a promising 2D solid fuel with extraordinary energetic characteristics.

Two-Dimensional Energy Nanomaterials Studied by in situ TEM Dmitri Golberg[1,2]; [1]Queensland University of Technology (QUT), Australia; [2]National Institute for Materials Science (NIMS), Japan

Two-dimensional (2D) nanomaterials, *i.e.* graphenes, boron-nitrines, molybdenum and tungsten disulfides, and MXenes, are studied in a high-resolution transmission electron microscope (HRTEM) equipped with various *in situ* TEM holders which allow for probing their structural, electrical, mechanical, thermal and optoelectronic properties. Current-voltage characteristics, elasticity, bending and tensile strength, and fracture toughness, photo-current responses and field-emission properties of 2D nanostructures are evaluated during delicate manipulations with them inside the pole piece of the electron microscope using piezo-driven metal probes and/or optical fibers. Performance of diverse nanomaterials as electrodes of Li- and Na-ion-batteries is also evaluated through constructing the prototype *in situ* electrochemical setups. Electrode swelling, formation of new crystal phases during ion-insertion, and secondary electrolyte layers crystalization during charge-discharge cycles are analyzed. The author is grateful to the Australian Research Council (ARC) for a financial support of the *in situ* TEM projects in the frame of a Laureate Fellowship FL160100089, a LIEF grant LE190100081 (QUT double-aberration-corrected laser compatible HRTEM) and the projects members - Drs. D.M. Tang, X.L. Wei, M.S. Wang, J. Fernando, K. Firestein and C. Zhang for their key experimental contributions.

2:00 PM *EN04.12.02
Aberration-Corrected Scanning TEM for 2D Materials at Ultrahigh Resolution Michel Bosman[1,2]; [1]A*STAR (Agency for Science, Technology and Research), Singapore; [2]National University of Singapore, Singapore

The physical and chemical properties of 2D materials are strongly determined by atomic-scale defects and dopants [1]. The process of characterizing this class of materials therefore often necessitates a tool that can visualize and characterize these materials at the atomic scale. The highest-resolution tool we have available for this is aberration-corrected electron microscopy. The new class of electron lenses called 'aberration-correctors' revolutionized electron microscopy, both transmission electron microscopy (TEM) and scanning TEM (STEM). For the first time, it has become possible to correct focus distortions that were previously considered inevitable. Without these distortions, the details that can be resolved are now several times finer than what used to be the case. Suddenly, it has become possible to visualize the individual atoms in 2D films in real space, making this new generation of microscopes an ideal tool for this rapidly-growing class of materials.

This presentation will introduce recent developments in aberration corrected electron microscopy that are relevant to 2D materials. In particular, aberration-corrected STEM is an experimental platform with an enormous potential for new 2D materials applications. It delivers a resolution well below 0.1 nm, with a high beam brightness and monochromaticity for various types of local spectroscopy.

The local distribution of defects and dopants in 2D films can now be quantified by atomic-resolution, real-space imaging with aberration-corrected STEM. It makes this an invaluable tool for gaining insight into the structure-property relationship of these materials. Advances are currently being made in new and optimized imaging methods. These include differential phase-contrast [2] and 4D-STEM mapping for visualizing the atomic structure as well as local electric, magnetic, and strain fields [3]. Moreover, further improvements in resolution, quantification and spatial accuracy are being developed with electron ptychography in the STEM [4,5]. New scan techniques and fast detectors are also under development for very low-dose measurements. These tools can be combined with a gentle beam energy and dedicated sample holders for in-situ experiments, making it possible to observe sample dynamics at the atomic scale, as they happen.

The enormous versatility, sensitivity, and resolution makes aberration-corrected STEM a critical tool for the study of two-dimensional materials for energy applications. The ongoing developments in observing ongoing chemical and physical changes at the atomic scale, and ongoing rapid improvements in hardware and data processing are also making aberration-corrected STEM an indispensable experimental platform for future research on new materials.

The presented work would not have been possible without the invaluable contributions from Hue Thi Bich Do (National University of Singapore, NUS), Loh Leyi (NUS), Zhang Xinyue (NUS), Jagadesh Rangaraj (NUS), Dr. Ning Shoucong (NUS), Prof. Goki Eda (NUS), Daria Kieczka (IMRE, A*STAR), Dr. Zhao Meng (IMRE, A*STAR) and Prof. Wu Lin (SUTD). Funding from the Ministry of Education (MOE) Singapore, under AcRF Tier 2 (MOE2019-T2-1-179), and AcRF Tier 1 (R-284-000-179-133) is kindly acknowledged.

3:00 PM EN04.12.03
Correlating Induced Defects in 2D MoS_2 with Raman Spectroscopy to its Electrocatalytic Performance Holly Fruehwald and Rodney Smith; University of Waterloo, Canada

The excellent performance of two-dimensional materials such as MoS_2 and WS_2 for electrocatalytic reduction reactions such as the hydrogen evolution reaction (HER) has driven the development of diverse synthetic protocols for 2D electrocatalysts. The bulk structure of materials synthesized by these diverse approaches are often similar, but fine structural details such as the degree of lattice strain or the concentration and identity of structural defects often remain unclear. Such understanding is critically important in understanding the differences between synthetic protocols because strain and defects are known to alter electrochemical properties of 2D materials. Raman spectroscopy is highly sensitive to defects in solid-state materials, but 2D materials exhibit a limited number of peaks in Raman spectra and each type of strain or defect is known to alter each feature in a unique way. Our research attempts to quantify the effect of individual defect types on Raman spectroscopic features by combining systematically varied synthetic protocols with a correlation based analysis. This talk will focus on a series of MoS_2 samples that were post-synthetically modified by swift heavy ion irradiation to introduce pores within individual 2D sheets of the MoS_2. Characterization by techniques such as photoluminescence microscopy, electrochemical measurements, and electron microscopy reveal the influence that these defects have on the structure and properties of the series. Subsequent correlational analysis then links the structural of behavioral parameters to quantitative features in the Raman spectra – namely the width, location and intensity of individual peaks. The overarching goal is to establish sufficient correlational maps that a single Raman spectrum can be used as a map for confident defect analysis. Such capabilities will provide the community with a low-cost and user-friendly analysis tool increases the compatibility of the diverse and varied studies being published – a feature that will greatly expedite the development of 2D materials as electrocatalysts.

3:15 PM EN04.12.04
Seebeck Coefficient Measurement of High Mobility Organic Semiconductors Guantong Wang[1,2] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, China; [2]Advanced Biomedical Instrumentation Centre, China

Abstract

Thin film-based organic materials are widely used in field effect transistors (FET), thermoelectric device applications, and solar cells. Recently, small molecule 2,9-Didecyldinaphtho [2,3-b:2',3'-f]thieno[3,2-b]thiophene (C_{10}-DNTT) has drawn a lot of attention in the organic FET (OFET) community due to its high mobility up to 15 $cm^2 V^{-1} s^{-1}$ and ultrathin single molecular layer thickness. To date, the contact resistance between electrode and semiconductor as well as the cross-plane resistance of semiconductors are still the major research directions.

To improve the performance of FET, and explore the intrinsic mobility of organic semiconductors (OSCs), Seebeck coefficient or thermoelectric effect, electromotive force that generate across a material with temperature difference, can provide valuable information on estimating the carrier density, intrinsic mobility and other electric properties of the thin film. By comparing hole mobility and effect mobility measured by field effect measurement, it not only allows us to determine the trap states in OSCs, but also help us to optimize the molecule design for future FET and thermoelectric devices.

In this work, we prepared C_{10}-DNTT monolayer organic field effect transistor (OFET) by solution shearing method on SiO_2 substrates. The Seebeck measurement is performed via providing a temperature gradient from 0.3K to 1.6K along the channel with a length of 135 μm. The results show that Seebeck coefficient of monolayer C_{10}-DNTT reaches 450 μV/K when no gate voltage is applied. With applying gate voltage gradually into -90V, the Seebeck coefficient shows descent trend regularity down to 300 μV/K. We evaluated the carrier concentration and noticed the Seebeck coefficient exhibited a logarithmic decrement dependence as an increase in carrier concentration. Eventually, further improvement in measuring Seebeck mobility and field effect mobility will be done to estimate traps states in OSC, and provide attractive approach for designing OSC materials in FET and thermoelectric devices.

KEYWORDS: Seebeck coefficient, mobility, trap states

3:30 PM EN04.12.05
Assessment of the Electrochemical Stability of 2D MoS_2 for Hydrogen Evolution Reaction Raquel Aymerich Armengol[1], Miquel Vega Paredes[1], Andrea Mingers[1], Rajib Sahu[1], Christina Scheu[1], Siyuan Zhang[1] and Joohyun Lim[2]; [1]Max-Planck-Institut für Eisenforschung, Germany; [2]Kangwon National University, Korea (the Republic of)

2D molybdenum disulfide (MoS_2) is regarded as an excellent Pt-alternative electrocatalyst for hydrogen evolution (HER). Several approaches have been reported to enhance the activity of MoS_2 catalysts, e.g. 1T phase selection, dopant introduction and substrate engineering. Nevertheless, the electrochemical stability of such MoS_2-based materials remains controversial. Herein, we present new development on methods to assess the HER stability of 2D MoS_2-based catalysts. Beyond thorough characterization by high-resolution (scanning) transmission electron microscopy ((S)TEM) and associated characterization techniques, the corrosion of 2D MoS_2 electrodes on different conducting substrates is studied in operando by scanning flow cell coupled to an inductively coupled plasma mass spectrometer (SFC-ICPMS). This method allows us to compare the effect of different conducting substrates and dopants on the stability as a function of HER current and overpotential. To gain further insights on the corrosion mechanisms and the evolution of the phases and morphology of the 2D MoS_2 catalysts, this data is complemented by performing electrochemical measurements in identical location (S)TEM conditions (IL-STEM). Based on the methodology, we provide new perspectives on the stability of 2D MoS_2 catalysts and shed light on their HER degradation mechanisms.

Thermoelectric-Mediated Selective Ion Transport in Liquid-Exfoliated Molybdenum Sulfide Thin Films for Applications in Novel Filtration and Energy Devices Gabriel Marcus[1], David Carroll[1], Aisling Baragry[2] and Mary Brooks Hall[3]; [1]Wake Forest University, United States; [2]Trinity College Dublin, The University of Dublin, Ireland; [3]Forsyth Country Day School, United States

Molybdenum sulfide (MoS_2), a member of the widely studied transition metal chalcogenide family of compounds, may play a role in novel applications for water desalination, biomedicine and energy storage thanks to its propensity for ionic transport. By exploiting its thermoelectric capability, and the respective properties of its 1T/2H crystalline phases, liquid-exfoliated MoS_2 can serve as a medium for selective capture and movement of ions from solution. Here, we introduce our work undertaken to synthesize and characterize thin films of this material alongside utilizing it for Seebeck-driven water purification and rechargeable battery technologies. Prototype chambered desalination devices incorporating MoS_2 films were constructed and tested to determine changes in electric potential and solution osmolarity following exposure to temperature gradients. In these systems, two salts (NaCl and KBr) were studied at various concentrations to assess MoS_2's potential for ion transport under different conditions. Furthermore, some analysis of film deterioration and attempts to mitigate this problem using polymers or other chalcogenides were explored. Results from these studies indicate that thermoelectric MoS_2 films can effectively filter ions, thereby generating significant voltages across their surfaces via combined carrier/ionic transport. However, ion contact with the film surface and subsequent movement through the film bulk may lead to destabilization, erratic fluctuations in electric potential and impaired transport. Deposition of PVDF on the film surface provides some protection from this breakdown, and studies of hybrid chalcogenides like molybdenum disulfide/antimony telluride that aid in maintaining film integrity are ongoing. Battery architectures that make use of MoS_2 films as both intercalating storage matrices and separation membranes, and recharge through application of thermal gradients, are under investigation as well. We will discuss some of our recent efforts in this area, specifically, design, construction and testing of thermoelectric batteries. While some hurdles remain, MoS_2-based filtration and energy devices can make a significant contribution to solving problems like freshwater scarcity and increasing energy costs facing the world today.

Bulk Photovoltaic Effect in Graphene-α-In_2Se_3-Graphene van der Waals Heterostructures Shahriar Muhammad Nahid[1], Edmund Han[1], Gillian Nolan[1], Paolo F. Ferrari[1], Andre Schleife[1], Pinshane Y. Huang[1], SungWoo Nam[2] and Arend M. van der Zande[1]; [1]University of Illinois Urbana Champaign, United States; [2]University of California Irvine, United States

The photoelectric efficiency in p-n junction solar cells is fundamentally constrained by the Shockley-Queisser limit. Ferroelectrics surpass the limit because their lack of inversion symmetry leads to a bulk photovoltaic effect. Van der Waals ferroelectrics, such as α-In_2Se_3 have two features which make them compelling candidates for bulk photovoltaic solar cells. First, the band gap is 1.4 eV, close to the ideal bandgap for utilizing the solar spectrum, and much smaller than most ferroelectric oxides with bandgaps of 2.5-4 eV. Second, they naturally exist at nanoscale dimensions, with thicknesses 10-50 nm, well below the mean free path of hot carriers. The key goals are to characterize the domain structures of α-In_2Se_3 and understand how the ferroelectric domains and switching affects the performance of nanoscale solar cells utilizing the bulk photovoltaic effect in α-In_2Se_3.
Here, we first use scanning transmission electron microscopy (STEM), and piezoelectric force microscopy (PFM) to characterize the domain configuration of α-In_2Se_3. We observe uniform domains of α-In_2Se_3 which possess a net dipole moment due to the crystal asymmetry leading to the out of plane ferroelectricity. In addition, we observe the existence of atomically sharp lateral charged domain walls, where the polarization of opposite direction meets to form head to head or tail to tail domain boundaries. Our PFM measurement indicates that the converse piezoelectric coefficient enhances by 800% in the charged domain wall region due to the electrostatic potential in the wall.
Finally, we fabricate sandwiched graphene-α-In_2Se_3-graphene heterostructures, where the top and bottom graphene serve as the electrodes, to characterize and compare how the ferroelectric domains affect the device transport in dark, and under illumination with scanning photocurrent microscopy. In the absence of light, the current vs voltage curve shows an asymmetric resistance. The value of the resistance is 200 MΩ or 2GΩ as an electric field of 0.05 V/nm is applied along or against the polarization direction. Under the illumination of 532 nm laser, the heterostructures display an open circuit voltage of approximately 400 mV. The short circuit photocurrent density scales as intensity$^{\alpha}$, where $\alpha = 0.73$ and reaches a peak value of 0.8 mA/cm^2 under 1 W/cm^2 power. Moreover, we modulate the polarization of the material by sweeping from -0.1 V/nm to +0.1 V/nm and observe a modulation of zero-bias short circuit current from -0.5 nA to 1.5 nA. Both the short circuit current and open circuit voltage demonstrate considerable bulk photovoltaic effect of α-In_2Se_3. These values are similar to the ones observed in other 2D bulk photovoltaic material. Finally, we observe that the existence of charged domain walls enhances the photocurrent generation by more than an order of magnitude.
Our study demonstrates the potential utilization of bulk photovoltaic effect in van der Waals α-In_2Se_3 to realize next generation solar cells.

4:30 PM EN04.12.09
Interface Structure and Properties of 2D Metal-Graphene Supported on Periodically Poled Lithium Niobate Arturo Medina, Marshall Frye, Ian C. Graham, Lauren M. Garten and Faisal M. Alamgir; Georgia Institute of Technology, United States

In this study, we present on the controlled growth of 2D confined metals (2D-M) under heteroepitaxial relations with single-layer graphene (Gr). Using a ferroelectric material, such as periodically polled lithium niobate (PPLN), as a support, external electric/strain fields can be applied to the surface metal via the Gr conduit. With such external fields, non-Faradaic manipulation of electrocatalytic reactions on the metal-graphene structure can be carried out. We explore the architecture of a 2D metal-graphene (2D M-Gr) on top of the PPLN to determine the impact of polarization orientation on the catalytic response of the 2DM-Gr. We conduct atomic force microscopy (AFM) measurements, piezoelectric force microscopy (PFM) and Kelvin probe force microscopy (KPFM) measurements to determine the surface morphology after graphene transfer onto the substrate as well as the polarized states of the poled domains where graphene allows these polarization effects to propagate. PFM and KPFM show that a clear domain structure propagates through the 2D M-Gr. We further present the effect of the piezo/ferroelectric field on the catalytic and electrocatalytic performance of the 2D M-Gr systems and the efficacy, in general of proximity control of catalytic properties through a graphene interface.

4:45 PM EN04.12.10
Energetic Characteristics of Aluminum/Graphene Oxide Composites with Optical Activation Yue Jiang[1], Sili Deng[1,2], Sungwook Hong[3], Jiheng Zhao[1], Sidi Huang[1], Ken-ichi Nomura[3], Ying Li[4], Subodh Tiwari[3], Rajiv Kalia[3], Priya Vashishta[3], Aiichiro Nakano[3] and Xiaolin Zheng[1]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States; [3]University of Southern California, United States; [4]Argonne National Laboratory, United States

Aluminum (Al), with high specific energy density (31 kJ/g) and earth abundance, is a widely used fuel in solid energetic materials to generate heat, gas, and thrust for applications ranging from space propulsion and pyrotechnics to microelectromechanical systems (MEMS). Al-based energetic materials are typically ignited at a single point by a hotwire, flame, or spark. In comparison to point ignition, optical Xe flash ignition occurs across the illuminated area and provides high heating rates, potentially increasing the energy release rate and changing the reaction dynamics of Al. However, micron-sized Al (μ-Al) particles, which are widely used in practical applications, cannot be ignited by a low-energy Xe flash due to poor light absorption properties and high ignition temperature. In this work, we demonstrate that graphene oxide is an effective additive to enhance the optical ignition and combustion properties for μ-Al particles (3–4.5 μm). The results indicate that 3 wt % of GO addition is sufficient to enable the flash ignition of μ-Al particles, for which the normalized minimum ignition energy can be reduced to 44% with 30 wt % of GO addition. The constant-volume combustion test results also show that 20 wt % of GO addition can optimally enhance the combustion performance after flash ignition. The Al/GO (80/20 wt %) composites are superior to the commonly used Al/nanosized metal oxide in terms of higher Al content, lower minimum optical ignition energy, higher peak pressure, faster pressurization rate, and longer overpressure duration during combustion. The energetic nature and enhancing mechanisms of GO were revealed by thermogravimetric analysis, differential scanning calorimetry, Fourier-transform infrared spectroscopy, and reactive molecular dynamics (RMD) simulation. Optically activated GO was experimentally shown to undergo photothermal disproportionation and oxidation reactions, which release heat to initiate the oxidization of Al by air and generate gaseous products to reduce the agglomeration of the solid-phase oxidation products and promote the pressure rise during combustion. The RMD simulation results further confirm that the addition of GO promotes the oxidation of μ-Al particles by exhibiting catalytic effects on the dissociation of oxygen molecules and providing a direct diffusion pathway for the dissociated O atom to reach and react with Al. Overall, the enhanced effects of GO can be attributed to the coupling heat release, catalytic effect, and gas generation. The low mass density of GO can also effectively advance the application of μ-Al particles as energetic materials via the form of Al/GO composites with the advantage of preserving higher Al content, reducing dead mass, and maintaining the high energy density. All of these results confirm that GO is an effective additive to enhance the energetic performance of Al with optical activation.

SESSION EN04.13: Virtual Session
Session Chairs: Hong Li and Damien Voiry
Wednesday Morning, April 26, 2023
EN04-virtual

8:00 AM EN04.13.01
Ni_xMo_y alloy/Graphitic Carbon Nitride(g-C_3N_4) Composites for Hydrogen Evolution Reaction in Alkaline Electrolyte Yu-Chin Shen[1], Jow-Lay Huang[1,1], Sheng-Chang Wang[2] and Yu-Min Shen[1]; [1]National Cheng Kung University, Taiwan; [2]Southern Taiwan University of Science and Technology, Taiwan

Hydrogen energy is regarded as the most promising renewable and clean energy to replace the fossil energy. The noble metals (i.e. Pt, Ru, Ir) were widely utilized to split the water into H_2 and O_2 due to the low Gibbs free energy, however, the high cost and limited availability hinder the commercialization. Recently, transition-metal-based catalysts were developed and achieved good performance and attracted a lot of attention from many research groups. Although these materials have high abundance, they have poor anti-acid corrosion. The cost and instability of catalysts limited the widespread applications in future. Hence, we study HER (hydrogen evolution reaction) in alkaline electrolytes to develop highly efficient and durable electrocatalysts in alkaline electrolytes. Graphitic carbon nitride has been studied intensively, but, it has poor conductivity and few active sites for HER. Therefore, we synthesized Ni_xMo_y alloy/g-C_3N_4 composites to replace the platinum electrode in 1.0 M KOH electrolyte in this study. A wet chemistry method and calcination were utilized to synthesize NixMoy alloy/g-C_3N_4 composites. Firstly, melamine was polymerized at 550°C, and the yellow product of g-C_3N_4 was fabricated. Secondly, nickel and molybdenum precursors are dispersed into diethylene glycol, DI water, and ammonium hydroxide to synthesize $Ni_xMo_yO_z$ and then reduced at 400°C in Ar-H_2 gas atmosphere to obtain Ni_xMo_y alloy/g-C_3N_4 composites. The result showed that the 5-10 nm Ni_4Mo alloy particles were distributed randomly in the surface of sheet-like g-C_3N_4 forming which the (121), (310), and (312) planes of Ni_4Mo were investigated by high-resolution TEM. In NBED and XRD, we found the preferred orientation was (121) of Ni_4Mo. The electrochemical results showed that the overpotential at -10 mA/cm^2 of Ni_4Mo alloy/g-C_3N_4 is 462 mV and the Tafel slope is 95 mV/dec. According to the above result, the Ni_4Mo has active sites for HER. In (121) of Ni_4Mo, there are Ni atoms and Mo atoms and therefore we presumed that the Ni atoms are the dissociation sites for H_2O and Mo atoms are the adsorption sites of hydrogen. In future, we will study the electrochemistry performance of different Ni/Mo ratios and alloy/g-C_3N_4 ratio composites. Further, we will prove that Ni was the active site and Mo was the absorption site toward hydrogen by in-situ Raman spectroscopy. We will also investigate in-situ TEM for studying the transformation of electrocatalysts during HER.

8:15 AM EN04.13.03
Enhancement of Electrocatalytic Activity of $Ti_3C_2T_x$ MXene by *in-situ* Tunable Interfacial Anion Doping and Structural Modification for Hydrogen Evolution Reaction Anand P. Tiwari, Andrew B. Hamlin, Md Saifur Rahman, Julia E. Huddy and William J. Scheideler; Dartmouth College, United States

2D-layered MXenes have attracted increasing attention as promising low-cost, stable electrocatalysts for hydrogen production through electrolysis. However, poor intrinsic chemical activities, and limited active site densities currently inhibit MXenes as practical electrocatalysts for hydrogen evolution reaction (HER). Herein, these limitations are overcome by *in-situ* tunable interfacial chemical doping and structural modification with nonmetallic electron donors—by nitrosulfurization through simple heat treatment with thiourea as a nitrogen and sulfur source in 2D titanium carbide ($Ti_3C_2T_x$) MXene. Through this process, XPS analysis indicates that the substitution of nitrogen and sulfur occurs at the basal plane with controllable chemical compositions ranging from 2 - 4 at. % (Sulfur), and 5-15 at. % (Nitrogen). It is observed by HRTEM, SEM, and AFM that structure of the MXene is changed from planar nanosheets to hexagonal-nanoplate-decorated nanosheets. Moreover, it is confirmed by XRD that the interlayer spacing is increased after interfacial doping, which is expected to increase the diffusivity of electrolytes into the layers and enhance the electrocatalytic activity. The optimal modified $Ti_3C_2T_x$ MXene exhibits a high concentration of Ti-S and Ti-N bonds as well as the lowest overpotential of –260 mV and a Tafel slope of 85 mV/dec at a current density of 10 mA/cm^2 in 0.5 M H_2SO_4, which is three times lower than pristine MXene (overpotential: -770 mV, and Tafel slope: 247 mV/dec). This strategy to improve the electrocatalytic activity of $Ti_3C_2T_x$ MXene for hydrogen evolution by a simple *in-situ* interfacial chemical doping and structural modification will open the possibility of manipulating the electrocatalytic performance of a broad range of MXenes.

8:30 AM *EN04.13.04
Metallic Phase of 2D MoS_2 for Energy Storage Manish Chhowalla; University of Cambridge, United Kingdom

Batteries based on new chemistries that can store more energy than state-of-the-art lithium-ion devices will play an important role in enabling the energy transition to net zero carbon emission. Our previous work has shown that compact electrodes assembled from monolayered nanosheets of metallic 1T phase MoS_2 are highly conductive, lyophilic, and are catalytically active. I will describe the realization of high-performance lithium-sulfur batteries using metallic 1T phase of two-dimensional molybdenum disulfide as binder-free conducting cathodes for hosting sulfur. The attributes of metallic 2D MoS_2 lead to > 85% utilization of sulfur due to improved adsorption of lithium polysulfides, enhanced Li^+ diffusivity, accelerated electrochemical reaction kinetics and superior electrocatalytic activity for polysulfide conversion. We have translated these properties into practical pouch cells, achieving areal capacities of 8.21 ± 0.07 mAh cm^{-2} and capacity retention in excess of 85% over 200 cycles. The metallic MoS_2-based ampere-hour-scale (1.3 ± 0.05 Ah) pouch cells can deliver gravimetric energy density of 402 Wh kg^{-1} and volumetric energy density of 721 Wh L^{-1}. These metrics compare exceptionally favourably with current state-of-the-art in Li-S batteries. Our results provide unique insights into new designs for Li-S cathodes based on electrocatalytically active and conducting two-dimensional (2D) materials.

9:00 AM *EN04.13.05
CVD Graphene: Growth Frontiers & Mass Production Zhongfan Liu[1,2]; [1]Beijing Graphene Institute, China; [2]Peking University, China

With 18 years history of graphene materials, there still exist lots of technical challenges towards graphene industry, including: 1) Low-cost mass production technology; 2) Batch peeling-transfer technology; 3) Transition from single-layer graphene component to macroscopic materials with retained intrinsic performances; 4) Dispersing technology into matrix materials; 5) Irreplaceable killer applications. Beijing Graphene Institute (BGI), established in 2018 and currently having nearly 300 employees, aims to solve these challenging issues by paying particular emphasis to mass production of high-quality CVD graphene materials and manufacturing equipments. BGI is devoted to providing the best graphene materials and related equipments to the market as well as the graphene-related R&D services to enterprises.
The current R&D emphasis on CVD graphene materials at BGI is laid on three different directions: 1) high-quality graphene films and wafers for general purpose; 2) graphene-skinned materials (GSM); 3) purpose-oriented graphene materials focusing on thermal managements, optical communications and medical applications. The star products into market are A3-size graphene films with mm grain boundaries, 4- and 6- inch single crystal graphene wafers, superclean graphene films with best thermal and electrical performances, graphene-skinned glass & fibers, graphene-skinned aluminum oxide fibers, etc. The graphene-skinned glass fibers have been used for deicing applications with extremely high electrothermal conversion efficiency up to 94%. At BGI, we are also working for the customized graphene growth depending on the special needs and requests from customers. There is a great space in this area, which is particularly important before graphene films and wafers find their practical application market in next ten years.

9:30 AM *EN04.13.06
Maximizing Magnetoelectric Energy Harvesting via 2D Material-Based Layer Transfer Jeehwan Kim; Massachusetts Institute of Technology, United States

Magnetoelectric (ME) energy converters utilize the magnetoelectric coupling effect to generate an electric response from an applied magnetic field, or vice versa. Although there are excellent piezoelectric and magnetostrictive materials with their highest coefficient, they cannot be stacked each other epitaxially due to their inherent mismatch in their crystalline structures. In addition, due to substrate clamping effects, those excellent piezoelectric and magnetostrictive thin film materials cannot outperform. In this talk, I will discuss about my group's strategy to maximize ME coupling efficiency by utilizing a 2D material-based layer transfer technique (2DLT). 2DLT is enabled by growing piezoelectric and magnetostrictive epitaxial films on graphene via remote epitaxy which allows to produce freestanding piezoelectric and magnetostrictive by peeling them off from graphene. Then both clamping-free membranes were bonded each other resulting in the best ME coupling devices. I will also discuss about other application spaces of 2DLT and remote epitaxy.

Conventional memristors typically utilize a defective amorphous solid as a switching medium for defect-mediated formation of conducting filaments. However, the imperfection of the switching medium also causes stochastic filament formation leading to spatial and temporal variation of the devices. Thus, it has been extremely challenging to reliably operate large-scale neural networks made of memristor crossbars. In this talk, I will discuss about our group's material strategies to enhance the reliability of memristor-based crossbar arrays. In addition, I present strategies to utilize small scale crossbar arrays for in-sensor/edge computing. Lastly, will introduce optical heterogeneous integration system that enables seamless 3D stacking of small-scale crossbar arrays to enhance the recognition capability.

Advances in Optical Coating Materials for CST Gema San Vicente, Angel Morales, Meryem Farchado and Aránzazu Fernández-García; CIEMAT, Spain

Solar reflectors are the first optical material on which solar radiation is incident in concentrating solar thermal (CST) technologies. They are in charge of reflecting and sending direct solar radiation into the solar receiver that will capture it to convert it into thermal energy. The optimal performance and characterization of this material, including the identification of degradation modes in each constituent layer, is a key point to establish the durability of the component. In this way, it is very important the definition of characterization protocols that might also permit lifetime prediction. Once the radiation is reflected in the reflectors, it reaches the solar receiver. In some cases, as parabolic-trough collectors or high-temperature pressurized gas volumetric receivers, a glass cover that minimizes the thermal losses but increases the optical losses protects the absorber. The application of an antireflective coating on the glass increases the receiver's optical efficiency and then the efficiency of the whole solar system. The design of this coating, usually composed of porous silicon dioxide, has to consider a compromise between its low refractive index to produce the highest transparency of the glass and the highest resistance to weathering (high temperatures, UV exposure, and abrasion). Moreover, these two optical components (glass covers and solar reflectors) have to maintain their surfaces clean to avoid radiation scattering and important optical losses. This implies significant economic investments associated with operation and maintenance work, as well as water consumption for cleaning the components. This is particularly remarkable taking into account that the sites with the highest solar irradiance are also those with arid climates, high concentrations of dust, and low water resources. The application of anti-soiling coatings on both components is one of the strategies to mitigate soiling, which is being studied in many research projects. Finally, the solar absorbers must absorb as much as possible of the radiation that hits them to transfer the thermal energy to the heat transfer fluid, increasing its temperature, without losing it through emission. This is achieved by using so-called selective coatings consisting of layers of different compositions which reflect very little radiation in the wavelength range of the solar spectrum but reflect highly in the infrared wavelength range. Depending on the technology and the operation temperatures, the receivers have different configurations and are made of different materials (316 stainless steel, 310 stainless steel, ceramic materials, etc.). The most common configuration is tubular as used in parabolic-through collectors (i.e. ANDASOL solar plant) or tower receivers that use molten salts as heat transfer fluid (GEMASOLAR solar plant). In the first case, a selective coating coats the tube but in the second one the tubular structure is coated with a back paint as no selective coatings, which withstand the operation conditions, are commercially developed. On the other hand, the next generation of CST technologies are looking to increase operating temperatures to obtain higher efficiencies, and then new concepts of receivers as volumetric receivers or particle receivers are being studied. Within the HORIZON 2020 COMPASsCO2 project, the integration of particle systems into highly efficient-CO_2 Brayton power cycles for electricity production is pursued. These particles are coated with black coatings to increase their solar absorptance and withstand high temperatures. In general, the big challenge is the development of coatings with both high optical properties and high durability at operation conditions.
In this talk, the advances in the development of optical coatings applied in components of CST as well as the development in characterization protocols will be presented.

11:00 AM EN05.01.02
Low-Emissivity Superhydrophobic Solar-Thermal Nanocoatings for Power Line Deicing Wei Ma[1], Yang Li[1], Weihong Li[2], Baoling Huang[1] and Shuhuai Yao[1]; [1]The Hong Kong University of Science and Technology, Hong Kong; [2]City University of Hong Kong, Hong Kong

Every winter in frigid regions, power outages caused by ice accumulation on overhead power lines seriously risk the reliability of electrical transmission. Power line deicing methods, which can completely clean the accumulated ice on the complex cable surface gently and efficiently, are highly desired but more technically challenging than those for flat surfaces. Photothermal superhydrophobic surfaces have demonstrated outstanding passive anti-icing and active deicing abilities in cold environments. However, the compatibility with complex curved surfaces and the solar-thermal conversion efficiency remains insufficient for timely ice and frost removal on power lines.
Herein, we report a low-emissivity solar-driven deicing nano-coating that comprises titanium nitride and superhydrophobic silica layers. Specifically, the solar-thermal layer offers strong resonance-enhanced solar absorption (90% on average) and low mid-infrared emission (6%), yielding boosted solar-thermal effects due to thermal radiation management. Enabled by the cooperation between the record-high solar-thermal performance (temperature rise of 72 °C under 1 sun) and the water repellency (contact angle of 173°), the nano-coating realizes effective deicing/defrosting on power lines at −15 °C. The versatility and mass-produced compatibility of this coating bring solar-driven deicing technologies closer to outdoor exposed surfaces in frigid environments.

11:15 AM EN05.01.03
Effect of Pulsed Bias on the Deposition of Multi-Layered $Cr_xAl_{1-x}N_y/Al_2O_3$ Solar Selective Coatings Tandem for High-Temperature Applications Ramon Escobar-Galindo[1], Miriam Sánchez-Pérez[2], T. Cristina Rojas Ruiz[2], F. Javier Ferrer[3,1], Meryem Farchado[4], Angel Morales[4] and Juan Carlos Sanchez-Lopez[2]; [1]Universidad de Sevilla, Spain; [2]Instituto de Ciencia de Materiales de Sevilla (CSIC-Univ. Sevilla), Spain; [3]Centro Nacional de Aceleradores (Univ. Sevilla, CSIC and Junta de Andalucía), Spain; [4]CIEMAT-PSA, Spain

Multilayered solar selective absorber coatings based on $Cr_xAl_{1-x}N_y$ layers with different stoichiometries were deposited on 316L steel and Inconel 625

using radiofrequency (RF) and high-power impulse magnetron sputtering (HiPIMS) technologies. A simultaneous application of DC-pulsed bias (average -100 V, 250 kHz) was applied to the substrates with the aim of increasing the film density and therefore, improving the oxidation resistance and thermal stability at high temperatures (> 500 ºC in air). By changing the synthesis parameters (i.e. sputtering power and gas flows), the chemical composition of aluminium chromium nitride layers was varied to generate i) an infrared-reflective and UV-Vis-NIR absorber layer (with low Al addition and N vacancies) and ii) two intermediate UV-Vis-NIR absorber layers with medium and high aluminium content (CrAl(Lo)N and CrAl(Hi)N). The stack was completed with a top aluminium oxide layer (Al_2O_3) deposited by radiofrequency (RF) magnetron sputtering to act as antireflective layer.
Microstructural characterization was carried out by grazing angle x-ray diffraction, cross-sectional scanning, and high-resolution transmission electron microscopy, while the chemical composition was assessed by Rutherford Backscattering Spectrometry (RBS) and Energy Dispersive X-Rays Spectroscopy (EDS). The solar absorptance (α) and emissivity (ε_{RT}) of the films were determined by UV-Vis-NIR and Fourier-transform infrared (FTIR) spectrophotometry, respectively. The multilayered stack has been heated in air for evaluating thermal stability, oxidation resistance, and optical changes. Coatings were stable after 200 hours of annealing at 600 ºC with an α = *93 and 92%* for samples deposited on steel and Inconel, respectively. The practical performance has been comparatively assessed with a similar solar selective coating deposited without bias assistance and commercial paint Pyromark as a reference. The additional ion bombardment during film growth provided by the bias assistance has led to an increment in the lifetime, thermal stability, and working limit temperature.

11:30 AM *EN05.01.04
Extremely Robust Photonic Nanostructures Andrej Lenert; University of Michigan, United States

The field of nanophotonics has made it possible to manipulate light from visible to infrared frequencies in unprecedented ways, which has improved our ability to harvest the energy of photons, specifically in solar-thermal and thermal-photovoltaic devices. This nanophotonic control is achieved by interfacing materials that have contrasting optical properties to form structures with varying degrees of complexity, ranging from nanoparticles to plasmonic arrays and three-dimensional photonic crystals. However, stabilizing these structures under the extreme thermal and environmental conditions encountered in thermal photonics has remained challenging.

This talk will describe our recent efforts to develop photonic materials that can tolerate operation at very high temperatures in air. Examples include multicomponent transparent refractory aerogels and epitaxial heterostructures of perovskite and rocksalt oxides. The focus will be on the fundamental design of photonic materials that can accomplish the desired photo-thermal conversion with high selectivity and durability, and the integration of such materials into devices that can achieve high performance.

SESSION EN05.02: Storage
Session Chairs: Andrea Ambrosini and Ramon Escobar-Galindo
Tuesday Afternoon, April 11, 2023
Moscone West, Level 2, Room 2010

2:00 PM EN05.02.01
Development of Core-Shell Structure Heat Storage Materials and Study of Their Adaptation to Cascade Heat Storage System Shenghao Liao, Seiji Yamashita, Mitsuhiro Kubota and Hideki Kita; Nagoya University, Japan

Reducing carbon dioxide emissions is an important issue that must be solved worldwide. From the perspective of carbon dioxide emissions in various sectors, factories account for the largest proportion and industrial furnaces account for the highest proportion. Therefore, improving the efficiency of industrial furnaces is of great significance for reducing carbon dioxide emissions. For example, in the regenerative burner system widely used in the industry, the heat storage temperature is exposed to a high temperature of over 800°C, and heat recovery is performed by switching between two burner systems in a short period. In addition to heat storage and dissipation characteristics in such thermally non-equilibrium conditions, the requirements are durability against repeated thermal shock, strength, and low cost.

Conventionally, solid alumina balls with a diameter of around 20 mm have been widely used as heat accumulators. In this system, a large number of alumina balls are placed in a heat storage tank to store heat using high-temperature waste heat gas, while the stored heat is used to convert air into hot air. Conventional solid alumina spheres have low thermal diffusivity at high temperatures, and it has been found that a short switching time does not transfer heat to the inside of the sphere, leaving the inside of the sphere as a dead zone with little contribution to heat storage.

To improve heat storage efficiency at high temperatures, we are developing latent heat utilization type heat storage balls using ceramics. It is possible to increase the energy density per unit volume and improve the output compared to the sensible heat type by utilizing latent heat. However, the latent heat-utilizing core-shell phase change material (EPCM, Encapsulated Phase Change Material) that can be used above 800 °C has many problems such as sealing technology, durability, and cost, and there is no successful example yet. we have developed a core-thin shell structure heat storage material with high heat storage density and good durability. Specifically, Using cheap alumina powder as raw material and adding a small number of additives to obtain an Al_2O_3 ceramic spherical shell through slip casting and high-temperature sintering, and using waste silicon as raw material, through injection molding and reaction sintering process, obtained Si_3N_4 ceramic spherical shell. On the other hand, for the core materials constituting the interior, we chose materials with different melting points, especially Al-Si, several copper-based alloys, and inexpensive NaCl. By arranging the EPCM having the melting point corresponding to the temperature gradient in the thermal storage tank (Cascade Heat Storage System), the waste heat can be utilized more effectively.

In this presentation, I will focus on thermal storage systems using NaCl. In the molten state, NaCl is highly wettable to ceramics, so it can leak out even the tiniest of crevices due to capillary action. We have found that even in the molten state, adding small amounts of alumina particles can prevent leakage. It was found that when the mixed powder with NaCl and Al_2O_3 as the core material was treated at a high temperature of 850°C, the Al_2O_3 particles rearranged in the molten NaCl and formed a network structure with each other.

In the present study, we investigated the rapid heat storage and heat release properties of heat storage materials with different compositions of core materials by adjusting the ratio of alumina and observed the microscopic morphology of core materials through microscopic analysis. In addition, the strength and thermal shock resistance were evaluated by three-point bending experiments. Based on these performances and primary durability test results, we plan to explain in detail the challenges and possibilities of EPCM using NaCl-Al_2O_3 as the core material.

Application of Type 316L Stainless Steel to High-Temperature Design of 700°C Thermal Energy Storage System Hyeong-Yeon Lee, Hyeonil Kim and Jaehyuk Eoh; Korea Atomic Energy Research Institute, Korea (the Republic of)

Type 316L stainless steel (hereafter 316L SS) has been applied as heat resistant structural material of pressure boundary components and piping in a large-scale 700°C thermal energy storage test facility (called TESET) under construction at KAERI(Korea Atomic Energy Research Institute). The TESET facility uses sodium as coolant with operation temperature of 700°C at atmospheric pressure for thermal energy storage from renewable energy sources such as concentrated solar thermal energy. For the design and construction of 700°C 316L SS thermal energy storage facility, French nuclear design rules of RCC-MRx have been used with supplementation of lack material properties and design coefficients around the temperature of 700°C for the readily available material of 316L SS. In ASME boiler and pressure vessel codes such as ASME Section VIII or Section III Division 5, elevated temperature material properties are not codified for 316L SS, which is why it is not possible to apply ASME codes while RCC-MRx provides codified material properties over high temperature in the creep range. However, because the high-temperature material properties such as creep rupture strength, fatigue strength and material strength are not provided up to the temperature of 700°C for 316L SS, a series of material tests on tension, fatigue and fracture toughness over the temperatures up to 700°C were conducted for the determination of lack material properties and design coefficients of 316L SS in RCC-MRx. Based on those works, feasibility on the application of Type 316L SS to 700°C pressure boundary components and piping in the TESET facility was investigated. The evaluation results based on a number material tests, supplementation works of lack material properties and design coefficients showed that an application of 316L SS to 700°C class thermal energy storage system was shown to be possible.

Electrochemical Control and Galvanic Corrosion Mitigation for Molten Chloride Systems Judith Vidal, Ph.D and Kerry Rippy; National Renewable Energy Laboratory, United States

Commercial deployment of high temperature molten salt thermal energy storage (TES) systems for third generation (gen3) of concentrating solar power (CSP) technologies is challenged by the high corrosion rates of molten chlorides. The ternary MgNaK chloride salt is a prime candidate for the thermal storage media because of its low cost, high thermal stability, and good heat transfer properties but it is very corrosive when in contact with traces of moisture and air. Without proper chemical control of the system, only expensive nickel superalloys can contain those fluids for several years. To reduce the capital cost and maintenance and operation costs of the Gen3-CSP plants, we developed corrosion control processes such as in-line electrolytic purification of the salt and to galvanic corrosion control in dissimilar alloys couples. We developed the use of magnesium as a sacrificial anode to mitigate the galvanic corrosion of alloys including Hastelloy C-276 (C276) and Haynes 230 (H230). Multiple corrosion experiments were run in MgNaK molten chloride salt to determine 1) baseline galvanic corrosion and 2) the efficacy of Mg as a sacrificial anode. These experiments provided preliminary results regarding the galvanic corrosion of alloys such as C276 and H230, and future studies can be conducted to provide further evidence for the effectiveness of Mg salt purification as a galvanic corrosion mitigation method.

Comparative Assessment of the durability of Glass and Polymer Mirrors for Concentrated Solar Thermal Technologies Christopher L. Sansom and Mounia Karim; University of Derby, United Kingdom

Mirror durability is crucial to the overall performance of Concentrated Solar Thermal installations, including Concentrating Solar Power (CSP) plants. The reflecting surfaces in the solar field need to maintain their good performance during the plant's lifetime, which can be considered to be between 25-35 years to ensure good profitability of the project.

Sites for CSP installations require high DNI and are often arid, desert-like regions. These dusty environments mean that particulate soiling and surface erosion phenomena remain the most common problems that affect the mirrors performance during their operational lifetime.
The degradation in reflectance caused by soiling deposition is a reversible degradation that can be fully recovered when adopting an appropriate cleaning process. However, it can sometimes lead to an irreversible degradation caused by erosion (due to the impact of airborne sand or dust particles) or by abrasion (due to contact cleaning).

For both degradation phenomena, the drop in reflectance is highly dependent on the environmental conditions (wind speed, wind direction, and sand/dust particle properties) as well as the surface characteristics of the mirror.

In the present work, a series of both outdoor exposures and experimental indoor simulation ageing tests have been conducted to evaluate the effect of soiling and erosion on mirror durability in order to highlight the impact of different influencing parameters on these degradation phenomena. Surface degradation of both polymer film and back-silvered low-iron glass reflecting solar concentrators have been tested and compared in this work. To simulate the real exposure conditions, sand and dust particles have been collected from different potential sites, prepared, analysed and used for the indoor simulation tests.

In this paper, soiling of solar mirrors is described from both a theoretical and experimental perspective. This includes an understanding of the conditions for particle impact with the surface that may lead to erosion, adhesion, or removal. The elemental composition of soiling particles has been analysed as it's a key variable in determining the adhesion force depending on the surface energy. In addition, some contact cleaning processes have been tested in order to evaluate the potential risk of abrasion due to cleaning using different parameters (different soiling particles, different brushes and different speeds).

In order to analyse the impact of erosion on soiling deposition rate, samples have been eroded in the lab before simulating the soiling deposition under different conditions.

Obtained results show that glass solar mirrors present better performance in comparison to polymer mirrors. This has been observed for both soiling and erosion phenomena and could be explained by the high mechanical properties of glass surfaces compared to the PMMA in the case of the polymer mirrors. Also, it has been shown that eroded surfaces accumulate more soiling deposition and the drop in reflectance is higher. This is because of the increase of surface roughness. Regarding contact cleaning simulation, it has been shown that there is a high impact of the brush properties on the degradation that can be generated during the cleaning process.

Efficient Generation of the Morphology of Organic Bulk Heterojunction Solar Cells Based on the Scanning Transmission X-Ray Microscopy Images Wenchao Yang; King Abdullah University of Science and Technology, Saudi Arabia

In organic bulk heterojunction (BHJ) solar cells, the morphology of the donor/acceptor (D/A) blend can significantly impact the charge generation efficiency and recombination losses, thus largely determining the device efficiency. In order to simulate the electronic processes in the working devices, near-exact reproduction of the morphology is very important but the method is still lacking. Here we developed an efficient way to reconstruct the morphologies of the DR3:OIDTBR solar cells under different annealing times by employing the 2 dimensional maps of the compositions (D/A percentage) along the thickness (z-) direction obtained by the Scanning Transmission X-ray Microscopy (STXM) technique. Considering the normalized pixel values in the STXM images as the probabilities for obtaining acceptor sites, the site types along each z-direction column in a 3-d cubic lattice are individually generated, and the same-type adjacent domains are merged to form larger domains. Then the Kawasaki-algorithm is applied to the morphology to smooth it and add lateral correlations to the domains. The average size, anisotropy and tortuosity of the domains are calculated and analyzed. The generated morphologies are further used for Kinetic Monte Carlo simulations of the internal quantum efficiencies, which are found to increase with the annealing time, being consistent with the experimental results. Our method provides an easy-to-implement and efficient mean to obtain a massive esemble of device morphology relative to the expensive ones like electron tomography, which can be used for simulating electronic properties of BHJ solar cells.

Searching the Fe-Mn-Ni-Al-Cr Composition Space for Materials with High Strength at High Temperature for Use as Solar Absorbers in Concentrating Solar Thermal Plants Andrew Pike and Geoffroy Hautier; Dartmouth College, United States

In order to increase the maximum efficiency of concentrating solar thermal plants, higher operating temperatures are necessary. One issue that arises when attempting to increase plant operating temperatures is that of finding a proper material for the absorber tube. It must be capable of having a long service life with acceptable levels of creep, tolerance to day/night thermal cycling, and resistance to degradation from the working fluid. The high entropy alloy (HEA) $Fe_{28.2}Mn_{18.8}Ni_{32.9}Al_{14.1}Cr_6$ has shown some promise for this use [1]. We will explore the composition space of this alloy to further optimize it for use as a solar absorber. To investigate any significant fraction of the 5-component composition experimentally is practically impossible. From density functional theory (DFT), we will perform a cluster expansion for the system and use this to account for disordered phases and temperature effects to explore the phase diagram computationally. We will specifically search for phases that are expected to have good performance at high temperatures.

Isovalent Doping Effect on Pd Exsolution in Perovskite-type Oxide for CO_2 Methanation Bonjae Koo; Sungshin Women's University, Korea (the Republic of)

The increase of carbon dioxide (CO_2) in the global atmosphere is a critical problem that accelerates global warming through the greenhouse effect, and a solution is needed to reduce carbon dioxide. Among the various carbon reduction technologies, CO_2 methanation can contribute to reducing CO_2 emissions by chemical reactions with hydrogen (H_2), and synthetic methane (CH_4) gas obtained by the reaction can be stored and transported through an advanced natural gas infrastructure. However, it is necessary to develop catalysts with high catalytic activity and durability in order to maintain methane production for a long time. Exsolution process in which metal ions doped in the perovskite lattice escape from the lattice and become nanoparticles on the surface is a synthetic technique that has been reported to ensure catalyst durability by strong bonding with supports and metal ions.
In this study, we aim to apply the isovalent doping effect in perovskite-type oxide to promote the exsolution of Palladium (Pd), which is known as a representative active catalyst for CO_2 methanation reaction. We evaluated the catalytic activity and durability of Pd exsolved $SrTiO_3$ catalysts by Ba doping in Sr sites against CO_2 methanation .

5:00 PM EN05.04.04
Calculation of Required Coolant Flow Rate for Photovoltaic-Thermal Module Using Standard Meteorological Data and Thermal Analysis Hyo Jae Jeong and Daegeun Park; Korea Institute of Industrial Technology, Korea (the Republic of)

Solar power generation efficiency is affected by weather factors such as temperature and wind speed. Note that the amount of power generation decreases because the module temperature increases in summer and the power generation efficiency decreases. A photovoltaic has been researched since the 1970s and has the advantages of generating heat together with power as well as preventing power generation efficiency and power reduction due to the temperature rise of the module. In this study, the amount of heat collected by season, time, and region for photovoltaic (PVT) modules were calculated using IWEC (International Weather for Energy Calculation) data provided by the American Society of Refrigeration and Air Conditioning. The PVT module applied in this study is installed at an angle of 20 degrees from the ground, and the certified power generation efficiency of the module is 17.83%. Therefore, the heat collection amount of the PVT module was assumed to be 82.17% of the solar radiation amount, and the heat collection amount according to the module angle was calculated using the following equation.
Qsc=Ac[0.8217GβFR(τα) - FR(UL)(TSC - Ta,in)]
where Gα is the total transfer strength, AC is the heat collection area (m2) of the PVT panel, FR(τα) is the heat dissipation coefficient, FR(UL) is the absorption rate (W/m2-K), TSC is the average temperature of the circulating refrigerant (K), Ta,in is the dry bulb temperature (K) of the outside. In this study, Ansys Steady-State Thermal solver was used to predict the PVT module temperature in accordance with the amount of heat collected. The grids of

15,720 were applied for numerical analysis. The external convective heat transfer coefficient was 10 W/m2-K and IWEC data values were applied as external temperatures. As the results, the required cooling load of the PVT module was predicted up to 605 W, and the range of cooling water required to improve power generation efficiency was calculated to be 0 to 217 cc/min.

8:30 AM EN05.05.01
Fabrication and Characterization of a Novel Carbon/Carbon Composite with Micro-channels for Concentrated Solar Power Gas Receivers Jose C. Cordeiro[1], Hema Ramsurn[1], Daniel Crunkleton[1], Todd Otanicar[2] and Michael Keller[1]; [1]University of Tulsa, United States; [2]Boise State University, United States

Concentrated solar power (CSP) gas receivers have recently been proposed due to their potentially higher efficiencies when combined with sCO_2 (super-critical CO_2) Brayton cycles. The state-of-the-art of modular micro-channel receivers are made with nickel-alloys. However, these receivers face thermal fatigue issues due to daily start-up operations, limiting their operating temperatures to around 560 °C. To overcome these challenges, a novel modular carbon/carbon (C/C) composite with micro-channels for CSP sCO_2 gas receivers is proposed. These composites offer comparable thermal and mechanical properties while having a significantly lower coefficient of thermal expansion. This mitigates thermal fatigue problems, allowing for much higher operating temperatures to be used (> 800 °C), which in turn can greatly increase efficiency. In addition, their lightweight nature can reduce installation costs.

In this work, the fabrication of the C/C composite modules starts by combining carbon fibers with a resorcinol-modified phenolic resin. Between the layers of carbon fibers, 3D printed PLA (polylactic acid) channels are placed, serving as a template for the desired micro-channel network. The resin is then cured in a vacuum bag and in-house designed and built autoclave setup (up to 150 °C, 160 psi) to produce a void-free prepreg. The novel approach of adding resorcinol allows the resin to be first B-stage cured at 50 °C, which is below the glass transition temperature of PLA (52.4 °C), preventing channel squishing due to the high pressure provided by the autoclave. Next, PLA is depolymerized under vacuum at 290 °C, leaving a cleared channel network in its place. The cured phenolic resin in the prepreg is then carbonized at 1000 °C under a nitrogen atmosphere where gas evolution causes a decrease in density. Due to matrix shrinkage, residual stresses build up between the carbon matrix and the fibers, which are alleviated through graphitization at 2200 °C. To obtain composites with the desired properties, a densification procedure is done by using a novel CVI (chemical vapor infiltration) method with methane above 900 °C and vacuum pressures below 250 mbar with processing times between 20-100 hours. During this process, methane is broken down to deposit carbon in the pores of the C/C composite, increasing the density of the material. The densified composite is then graphitized a second time at 2200 °C under argon, greatly improving its thermal conductivity.

Carbon materials are known to oxidize in air and CO_2 at temperatures above 500 °C. Thus, an anti-oxidative coating is applied to the C/C composite modules to prevent mass loss due to both outside air and the heat transfer fluid (sCO_2). A multilayered coating approach using pure SiC and a mixture of ZrB_2-SiC is shown to be effective due to their high temperature stability. Furthermore, the formation of oxides when exposed to air (SiO_2, ZrO_2, and $ZrSiO_4$) aids in protecting the substrate as well as providing self-healing abilities. The first layer consists of SiC, produced through pack cementation using a powder mixture (Si, C, Al_2O_3, and SiC) in a closed graphite crucible heat treated at 1800 °C. This SiC layer has excellent adhesion and acts as a buffer to alleviate thermal stresses between the C/C composite and the outer ZrB_2-SiC layer, which is in turn applied through a slurry/dip coating process. The slurry, in which SiC coated samples are dipped, consists of a mixture of ZrB_2 powders with a polymeric ceramic precursor. Once heat treated above 1000 °C, the precursor acts as a binder by forming SiC. Isothermal tests at 800 °C for 3 days were done and show that after an initial weight increase of around 3.4 wt% due to oxide formation, the specimens remain stable with no weight loss. A combination of SEM (scanning electron microscopy), SEM/EDS (energy-dispersive spectroscopy), XRD (X-ray diffraction) and TGA (thermogravimetric analysis) are used to characterize the produced C/C composites.

8:45 AM EN05.05.02
Machine Learning Accelerated Discovery of Thermal Energy Storage Materials with High Heat Capacity Ming Hu; University of South Carolina, United States

Existing machine learning potentials for predicting phonon properties of crystals are limited to either small amount of training data or a material-to-material basis, primarily due to the exponential scaling of model parameters with the number of atomic species or elements. This renders high-throughput infeasible when facing large-scale new materials. Unlike previous machine learning models with inherently limited training on small data and global properties, we develop Elemental Spatial Density Neural Network Force Field (Elemental-SDNNFF) with abundant atomic level environments as training data. Benefited from this innovation, we integrate >30 million atomic data to train a single deep neural network without increased expensive ab initio simulations. The effectiveness and precision of the Elemental-SDNNFF approach is demonstrated on a set of >100,000 inorganic crystalline structures spanning 63 elements in the periodic table by prediction of complete phonon properties. We then predicted the heat capacity of >50,000 inorganic crystalline structures with non-zero band gap screened from the Open Quantum Material Database. We gain deep insight into the correlation between heat capacity and structure descriptors such as space group, prototype, lattice volume, atomic weight, etc. Several tens of structures were predicted to possess high heat capacity, and the results were further validated with DFT calculations. We also identified a few special structures that exhibit extremely high heat capacity, even higher than that of the Dulong-Petit limit at room temperature. This study paves the way for accelerating the discovery of novel thermal energy storage materials by combining machine learning with minimal DFT inquiry.

9:00 AM EN05.05.03
Material Candidates for the Heat Exchanger Tubes for Solar sCO2 Brayton Cycles Marta Serrano-Garcia; CIEMAT, Spain

Currently, the research focus regarding CSP technology worldwide is related to the development of systems that can reach temperatures close to 1000°C. The concept of particle-based receiver is regarded as a promising candidate where solid particles are both heat-transfer and thermal energy storage media showing the potential to exceed 1000°C. Meanwhile, supercritical carbon dioxide (s-CO2) Brayton cycles offer advantages of its mass density, low viscosity and favourable heat transfer properties, which reduces the cost of concentrating solar power (CSP). The Horizon 2020 project COMPASsCO2 focuses on the efficient and reliable integration of storable solar energy by solid particles into s-CO2 Brayton cycles. In COMPASsCO2, the key component for such an integration, *i.e.* the particle/s-CO2 heat exchanger, will be validated in a relevant environment. One of the main technological challenges is the selection of the heat exchange tube materials as the operating parameters of s-CO2 heat exchangers are estimated around 700°C and 25

MPa at the internal wall.
In this work, the material selection criteria for the COMPASSCO2 heat exchanger tubes is summarized, the first results of the mechanical properties at high temperature of commercial alloys are discussed as well as the development of novel Cr nickel aluminide (NiAl) and Cr silicides superalloys.

9:15 AM EN05.05.04
Application of Silicone Based Heat Transfer Fluids in Parabolic Trough Collectors Loreto Valenzuela Gutiérrez[1], Guillaume Saliou[1], Christoph Hilgert[2], Kai Schickedanz[3] and Christian Jung[2]; [1]CIEMAT - Plataforma Solar de Almería, Spain; [2]German Aerospace Center (DLR), Germany; [3]Wacker Chemie AG, Germany

Despite leaning toward a lower LCOE [1], a higher operation temperature and less degradation products over time [2], silicone-based heat transfer fluids (HTF) have not yet been used in a commercial Parabolic Trough Collector power plant. In this work, a summary of the proof-of-concept process for the new HELISOL® line of silicone-based HTFs developed by Wacker Chemie AG is presented. Three generations of polydimethylsiloxane (PDMS) HTFs, HELISOL® 5A [3], HELISOL® XA and HELISOL® XLP, were successively operated for a loop scale demonstration at temperatures between 425 °C and 450 °C for 480 hours each at Plataforma Solar de Almeria (Spain). Prior to said qualification activities, the PROMETEO parabolic-troughs test facility, with a mirror surface of 1300 m^2, has been upgraded to withstand temperatures up to 450 °C. For each of the tests the plant was completely drained, cleaned and filled with 7 to 8 m^3 of the corresponding HELISOL® grade. HTF degradation and gas formation were determined, plant performances monitored, and operational behaviour and incidents documented while elaborating a guideline on the application of silicone-based HTFs in parabolic trough solar fields [4], which was the basis for developing and proposing an international standard in the IEC context.

Bridging Photoelectrochemical and Thermochemical Approaches for Solar Fuel Processing Sophia Haussener; Ecole Polytechnique Federale de Lausanne, Switzerland, Switzerland

Solar radiation is the most abundant renewable energy source available but it is distributed and intermittent, thereby necessitating its storage via conversion to a fuel or chemical commodity (e.g. hydrogen or carbohydrates) for practical use. Solar thermo-chemical and photo-electro-chemical approaches (and combinations thereof) provide viable, non-biological routes for the direct synthesis of solar fuels and chemical commodities. While solar thermochemical approaches utilize heat at high temperature to support an endothermic reaction, photoelectrochemical approaches utilize the photons (with sufficient energy) to drive the endothermic reactions.
I will review the state of the art of photoelectrochemical and thermochemical solar fuel processing approaches and comment on their specific challenges [1]. I will then highlight various approaches in which photo- and thermos-chemical approaches are combined. Specifically, I will discuss the utilization of concentrated solar irradiation and thermal integration for photoelectrochemical approaches and the potential to increase their performance [2]. As the large kinetic, ohmic and transport overpotentials limit the current density and therefore the power density of these approaches, I will further explore approaches for close thermal integration and high current density operation. Specifically, I will discuss the development of a modeling framework that assesses the possibility of high-temperature operation (temperatures > 400 K) of the photoelectrochemical approach in a solid state equivalent design [3]. Such devices would utilize ceramic electrolytes, earth abundant catalysts with small overpotentials, and high-temperature solar cells utilizing the thermionic emission principle. I will discuss requirements on materials (solid electrolyte, catalysts, semiconductor absorber and barriers, etc.), operating conditions and design for such approaches to be feasible and explore limiting efficiencies. I will then present the experimental implementation of such a solar-driven high-temperature electrolysis approach in a simpler integrational approach [4] before ending with discussing how electrochemistry can help in enhancing the performance of solar thermochemical cycles [5].

2:00 PM *EN05.06.02
Combined Experiment and Theory for Extracting Solar Thermochemical Material Thermodynamics Steven Wilson, Zoe Liberman-Martin, Ellen Stechel and Christopher Muhich; Arizona State University, United States

The ability for certain metal oxides to reduce at temperatures achievable with solar concentration, and subsequently re-oxidize upon exposure to H_2O or CO_2, thereby releasing H2 or CO, underpins solar thermochemical gas splitting technologies. However, the mere ability for a metal oxide to facilitate these coupled reactions is insufficient to achieve an efficient and commercialized process. Ideal materials should be able to reduce at as mild conditions (temperature and pressure) as possible while still converting as much H_2O or CO_2 to H_2 or CO as possible. This juxtaposition arises from the thermodynamics of the cycle, where the first reaction is favored at low metal oxide reduction enthalpies, while the latter is favored at high reduction enthalpies. Thus, a balance must be struck. In order to assess this balance, detailed thermodynamic properties of candidate active materials must be extracted. To-date this has generally relied upon experimental thermogravimetric analysis (TGA) coupled to van't Hoff or the compound energy formalism (CEF) analysis *or* computationally predicted properties, such as from density functional theory (DFT). Such methods are unsatisfactory for rapid material identification in that TGA + van't Hoff only characterizes one material at a time, while TGA + CEF requires complex fitting of many, often linearly dependent parameters. Additionally, both methods for extracting thermodynamics require extensive TGA data sets which are expensive and tedious to gather and are susceptible to enthalpy/entropy trade-offs when fitting, making the quality of the extracted properties ambiguous. Conversely, DFT methods are automatable and can give high quality enthalpy information, when done carefully. However, it is difficult to extract entropic information and thus predict experimental performance and it is costly to examine a wide range of reduction extents.
In this presentation, we will examine two methods to overcome existing challenges in reducible metal oxide thermodynamic characterization: 1) cross-fitting of the CEF to experimental and theoretical data to alleviate ambiguities and provide characterization across materials families; and 2) a Bayesian approach to selecting which data points should be collected. These methods are examined through the perovskite family ($ABO_{3-\delta}$) of materials where there is interest in knowing partial molar entropies and enthalpies (I.e. $\partial H/\partial \delta$ and $\partial S/\partial \delta$). Our cross-fit model allows both DFT and TGA to be directly incorporated into a CEF model. This development is key as the CEF terms, which are linearly dependent in free energy where TGA measured, are linearly independent in enthalpy, which is accessible by DFT. Thus, a reliable CEF can be constructed. Secondly, we examine the use of a Bayesian approach to selecting data points which should be gathered next. Data points to examine include measuring the non-stoichiometric at a particular temperature and pressure in a TGA and new calculated points, i.e. the energy of a particular composition and δ. The combination of these methods not only provides more reliable thermodynamic characterization, but can *a priori* identify critical points to examine in the temperature, O_2 partial pressure, compositional landscape, thus minimizing the number of points which must be examined.

Interacting Defect Equilibria—O Vacancy Formation in Oxides for Thermochemical Hydrogen Anuj Goyal and Stephan Lany; National Renewable Energy Laboratory, United States

First principles calculations of defect formation energies provide the basis for prediction of defect concentrations and equilibria. Previous extensions of the dilute defect model have focused on exchange of electronic charge between defects and the Fermi level, including the resulting attractive forces between oppositely charged defects that lead to the formation of pairs and complexes. In oxides for thermochemical hydrogen production, we encounter high concentrations of oxygen vacancies which are subject to a repulsive interaction. Unlike in case of attractive forces between different defects, this situation does not lend itself to description with a simple law-of-mass-action model. Instead, we formulate an approach that utilizes a statistical enumeration of pair and triplet configurations in supercells of varying size. The distribution of defect energies is then condensed into a temperature-dependent free energy of defect formation capturing both the enthalpies and configurational entropies of the statistical ensemble. In conjunction with ideal-gas chemical potentials for O_2, H_2, and H_2O, this model allows the simulation of the reduction and oxidation processes for solar thermochemical hydrogen production with $Sr_{1-x}Ce_xMnO_3$.

Photo-Electrochemical Conversion of CO_2 to Solar Fuels with Concentrated Solar Irradiation Mahendra Patel, Etienne Boutin and Sophia Haussener; EPFL, Switzerland

Photo-electrochemical (P-EC) carbon dioxide (CO_2) reduction can produce fuels and platform chemicals such as carbon monoxide (CO), methane (CH_4), or ethanol (C_2H_5OH) utilizing the energy available from renewable sources like (concentrated) sunlight, CO_2, and water. P-EC devices, i.e. composed of an integrated photovoltaics component (PV) and an electrolyzer component (EC), allow to overcome some of the challenges imposed by the solid-liquid interface in traditional PEC devices such as degradation. The challenges of these P-EC device demonstrations is to achieve higher operating current densities while maintaining high solar-to-fuel efficiencies.[1] We demonstrated that process in a custom-made, heat-managed integrated P-EC CO_2-to-CO conversion device operating with concentrated solar irradiation of up to 450 kW/m^2. That device constituted of a directly integrated concentrated PV triple junction cell and a zero-gap EC cell. An operando activation method was used to infuse the alkali metal cations (CsOH) into the gas diffusion electrode (GDE) to reduce the cathodic overpotential. At optimal conditions, the device operated at a solar-to-fuel and solar-to-CO conversion efficiency of 19 and 17%, respectively, with production rates of CO above 1 NL h^{-1}.[2]

In this contribution, we will present work that uses a similar, integrated and thermally-managed device concept for P-EC CO_2 conversion to the higher-value products CH_4 and C_2H_4. We use a Cu nanoparticle-based catalyst layer in a GDE arrangement. Cu-based catalysts are selective towards CH_4/C_2H_4 at high overpotentials but the selectivity depends on the nano-structure of the Cu nanoparticles. For example, Cu (111) surfaces are selective towards CH_4 production and Cu (100) surfaces towards C_2H_4 production.[3] We investigate if such selectivity tailoring – that is typically observed in H-cell designs – is translated also in solar-driven zero-gap GDE P-EC designs. The newly, implemented device incorporates the design and development of a new photoabsorber component with multiple in-series connected concentrated PV cells, providing a higher voltage for CO_2 reduction during the integrated operation. The device includes a thermal management approach to cool down the photoabsorber while preheating the reactant (water) before it enters the anodic flow stream, where the increasing temperature enhances the EC performance. We utilized the previously developed strategy of operando activation of alkali metal cations in the cathodic GDE to infuse the cations to enhance the overall device performance. The dark and integrated experiments show good performance for CO_2 reduction to C_2H_4 including high current density ~240 mA/cm^2 at 4V and product selectivity ~80%. We will show the detail performance characteristics of the new device, including efficiency, selectivity, and dynamic characterization.

This P-EC device demonstration opens a new efficient pathway towards renewable and economic industrial solar fuel production for various gaseous products at efficiency and power density utilizing concentrated solar irradiation.

Non-Stoichiometric Oxides for Redox Applications in Countercurrent Chemical-Looping Regenerative Reactors Brendan Bulfin and Aldo Steinfeld; ETH Zürich, Switzerland

Chemical redox reactions have thermodynamic limits on species conversion which play a major role in process design and efficiency. Unconverted feedstock often needs to be separated and recycled back to reactors, increasing the energy demand, process complexity and cost. Just as is the case for heat exchangers, countercurrent reactor systems can improve the thermodynamic limits on species exchange and conversion. This work demonstrates a countercurrent redox reactor system, which can be realized in a packed-bed chemical-looping reactor by storing the favorable oxygen chemical potential inclines using the unique properties of non-stoichiometric oxide. The concept is analogous to a regenerative heat exchanger (regenerator), but for oxygen exchange and storage, and so we use the term *regenerative reactor*. We apply this approach to the reverse water-gas shift reaction, which is a critical step in the processing of synthetic e-fuels. Modelling results indicate that the thermodynamic limits on conversion can be approximately doubled via this method. Furthermore, the CO is formed separately from the H_2 flow, allowing for the syngas composition to be finely tuned for downstream processing. The concept is modelled and experimentally validated via a lab-scale demonstration performed with CeO_2 at 1073 K, which resulted in a CO_2-to-CO molar conversion of 88%, compared to a thermodynamic limit of 58% for the conventional process at the same conditions. We discuss the outlook from a materials perspective for further development of this application of non-stoichiometric oxides, with focus on the production of solar fuels from H_2O and CO_2.

4:00 PM EN05.06.06
Solar Thermochemical Ammonia Production Via a Renewable Nitride Looping Cycle Andrea Ambrosini[1], Xiang Gao[2], Ivan Ermanoski[2], Nhu Nguyen[3], Hagan E. Bush[1], Suliman Rashid[2], Peter Loutzenhiser[3], Ellen Stechel[2] and James Miller[2]; [1]Sandia National Laboratories, United States; [2]Arizona State University, United States; [3]Georgia Institute of Technology, United States

Ammonia (NH_3) is an energy-dense chemical and a vital component of fertilizer, as well as a potential candidate for thermochemical energy storage for high-temperature concentrating solar power (CSP) and carbon-neutral liquid fuel. For over 100 years, ammonia has been synthesized by the Haber-Bosch process, which requires pressures of 150- 250 bar and temperatures on the order of 450-550 °C. Combustion of hydrocarbons provides the heat and mechanical energy required to drive the NH_3 reaction, and methane is the main source of hydrogen (H_2) and nitrogen (N_2) feedstocks. Overall, ammonia production via Haber-Bosch accounts for almost 1.5% of global CO_2 emissions. The development of a renewable pathway to ammonia production can greatly decrease, or eliminate altogether, these CO_2 side-products.
The aim of the Solar-Thermal Ammonia Production (STAP) project is to develop an advanced two-stage looping process utilizing concentrating solar heat to separate and shuttle N_2 from air for use in the renewable production of NH_3. In the oxide looping cycle, a redox-active metal oxide is thermally reduced via concentrating solar irradiation. Subsequent exposure to air re-oxidizes the material to its original form, removing O_2 and producing relatively pure N_2. The N_2 serves as a feedstock for NH_3 synthesis in a two-step, low pressure, metal nitride looping cycle. In the first step of the nitride cycle, renewably-sourced H_2 reduces a metal nitride, creating NH_3 in the process and resulting in a nitrogen-deficient metal nitride. In the second step, the purified N_2 from the oxide cycle is used to regenerate the reduced nitride to its original stoichiometry, thus closing the loop. The net result is ammonia produced from sunlight, air, and H_2, employing recyclable metal oxides and nitrides.
A series of ternary and quaternary metal nitrides was synthesized, characterized, and screened for reduction (ammonia producing) and re-nitridation activity. Several candidate nitrides demonstrated cyclic NH_3 production and regeneration at pressures an order of magnitude lower than traditional Haber-Bosch. The results, which will be presented in this talk, show the promise for NH_3 synthesis via the metal nitride looping process. By utilizing concentrating solar as a thermal resource and replacing hydrocarbon-sourced H_2 and N_2 with green alternatives, the large carbon footprint of ammonia production can be vastly reduced or eliminated altogether.

Recent Advances and Challenges in Spectrally Selective Coatings for High Temperature Solar Thermal Applications Harish C. Barshilia; CSIR-National Aerospace Laboratories, India

Solar radiation is an abundantly available clean source of renewable energy. It is estimated that one hour of solar radiation has energy equivalent to the world's annual energy consumption. Therefore, harnessing solar energy is one of the most important technologies in realizing carbon neutrality in the future as per the key goals of the COP26 summit. Solar energy can be harnessed primarily in two ways: (i) photovoltaic and (ii) solar thermal. In the latter case, solar radiation is converted into thermal energy and subsequently to electrical energy by solar thermal concentrating systems. Concentrated solar power systems use solar absorbers to convert sunlight to thermal electric power. Highly specialized coatings with very high absorptance in the solar spectrum region (that is, 0.3-2.5 microns) and low thermal emittance in the infrared region (2.5-50 microns) are required to harness the solar energy and these are called spectrally selective absorbers. No natural surface is an ideal selective surface and these surfaces are fabricated using a variety of deposition techniques. All the solar collectors are coated with solar selective coatings with high solar absorptance and low thermal emittance. From the operational point of view, absorber coatings can be divided into three categories. (i) Low temperature coatings, wherein the process temperature is less than 100 deg. C. These coatings are used for domestic hot water applications. (ii) Mid-temperature coatings, wherein the process temperature is between 100-350 deg. C and are used in industrial heat processes. (iii) High temperature coatings. The process temperature here is 400 deg. C and above and these coatings are used for power generation applications. As stated earlier, the basic requirements of a high temperature solar absorber are: it should have high solar absorptance and low thermal emittance as the radiative losses are proportional to the 4th power of temperature. The other most important requirement, however, is that the compositional stability should be very high at high operating temperatures (>400 deg. C). Due of these stringent requirements, there is a need to develop newer absorber coatings for solar power generation applications. Spectrally selective coatings, which are stable up to temperatures ~400 deg. C (in air and vacuum), have been developed in the past. However, in order to increase the efficiency of solar thermal power plants, solar selective coatings with high thermal stability are required. In recent years, great advances have been made in the field of nanostructured solar selective coatings with high solar absorptance and low thermal emittance at higher temperatures (T >450 deg. C). Amongst these, nanostructured transition metal nitride, oxide and carbide based tandem absorbers have emerged as novel high temperature solar selective coatings, which can be used for solar thermal power plants for electricity generation. Research is currently underway to increase the thermal stability of the coatings and to subsequently improve the efficiency of solar thermal power plants. This talk will present an overview of the sputter deposited mid- to high-temperature solar selective coatings used for solar thermal applications. It will address the usage of novel new generation 1D and 2D carbon- based nanostructures as selective absorbers along with the protocols for service life prediction of various spectrally selective coatings. The presentation will also describe in detail commercially available sputter deposited solar selective coatings for solar thermal power generation applications.

Supercooled Sugar Alcohols Stabilized by Alkali Hydroxides for Long-Term Room-Temperature Phase Change Solar-Thermal Energy Storage
Xiaoxiang Li; Shanghai Jiao Tong University, China

Seasonal thermal energy storage within organic phase change materials (PCMs) offers a promising way to solve intermittency of renewable energy, but the charged PCMs tend to undergo spontaneous crystallization and lose the stored latent heat to cold environment during storage. Herein, we report introduction of alkali hydroxides into sugar alcohols to increase the activation energy barrier for liquid-to-solid phase transition and stabilize the supercooling state, thereby realizing long-term phase change thermal energy storage. Owing to increased intermolecular hydrogen bonding interaction, the charged composites can maintain the supercooled state and conserve latent heat (~200 J/g) during storage at room temperature or extremely cold temperatures for months. Further compounding with polydopamine organic pigments, the composites demonstrate high solar absorptance (~91.6 %) and thus enable seasonable storage of solar-thermal energy as latent heat at room temperature. The stored heat can be readily released through adding seed crystals or applying mechanical deformation, which triggers cold crystallization of the supercooled composites and releases latent heat within a suitable temperature range of 40–60 °C. Such phase change composites not only eliminate complicated thermal insulation engineering required in conventional long-term thermal storage processes, but also unlock diverse application opportunities for thermal energy systems.

8:45 AM EN05.07.04
Sustainable Textiles Dying Process using Solar Thermal Energy Sameer Rahatekar[1], Syamala Jayanth Reddy[1] and Vishal Sardeshpande[2]; [1]Cranfield University, United Kingdom; [2]Sarvaay Solutions Ltd, India

The textile industry is one of the largest industries both in production and economically in the world. However, the textiles industry has two major challenges, first, it uses toxic dyes which cause significant river pollution, and second, it uses the water heating process during dying which consumes a lot of energy (typically non-renewable energy). Our current research was focused on addressing these two challenges. To address the challenge of the use of non-renewable energy for the textile dying process, we are using concentrated solar thermal energy to heat water between 70 to 90°C for textiles dying. To address the challenge of reducing pollution during textile dying, we used low-toxicity and sustainable dyes. The initial results indicated that the solar thermal heating process can be successfully used for dying textiles and fibers in a range of textile dyes. The tensile testing of the dyed fabrics showed that there was no damage to the fabric due to the solar thermal dying process. Similarly, Scanning Electron Microscopy analysis showed no damage to the textile fibres due to the solar thermal dying process. Our solar thermal heating process can potentially be scaled up for industrial use for sustainable textiles dying to help reduce carbon emissions from the textiles and the fashion industry.

Anode Interlayers and Composite Cathodes at Low Stack-Pressures in All-Solid-State Batteries Dominic S. Jolly, Xiangwen Gao, Varnika Agarwal and Peter Bruce; University of Oxford, United Kingdom

Lithium-free so-called anodeless solid-state batteries are attractive for manufacturing. However, at charge rates on the order of 1 mA cm^{-2} and above, plating of Li at the current collector/solid electrolyte interface can be inhomogeneous, and dendrites (filaments of Li metal) are observed to penetrate through the solid electrolyte resulting in cell failure. Recent work has suggested that introduction of an interlayer between the solid electrolyte and current collector can protect the solid electrolyte against dendrite growth whilst promoting more homogeneous deposition of Li metal. We investigate a carbon-based interlayer, revealing the structural changes within the interlayer and Li deposition behaviour during the processes of charge and discharge. We identify the origin of the failure of the interlayer at high rates.

It is a practical requirement that solid-state batteries operate under low stack pressures (≤ 2MPa), presenting challenges for performance including of the composite cathode. We investigate a composite cathode composed of a solid electrolyte, NMC811 active material, and carbon nanofibers at low stack pressures.

11:00 AM *EN06.01.02
Highly Cyclable Deposition-type Li Metal Anode For All-Solid-State Li Batteries Naoki Suzuki, Nobuyoshi Yashiro and Ryo Omoda; Samsung R&D Institute Japan, Japan

Lithium-ion batteries (LIBs) are currently used to power a wide range of portable devices and, in particular, a number of pure electric and plug-in hybrid vehicles. As the capacity of a graphite anode conventionally used in LIBs is approaching its theoretical limit, the use of Li metal anode is receiving serious attention.
Currently there are two major difficulties in using Li metal anode in a conventional lithium-ion battery: dendrite formation and low coulombic efficiency (CE). Although several approaches have been reported to mitigate Li dendrite formation, the phenomenon has not been sufficiently avoided so far. The low CE is induced by not only the dendritic growth of the Li metal, but also the subsequent destruction and rebuild of the SEI layer according to the cycle. The currently reported CE of the Li metal anode is ~99% at most, and it requires a large amount of Li reservoir, leading to the decrease of the energy density and the consumption of the electrolyte.
To overcome these difficulties, we use a deposition-type Li metal anode in an all-solid-state battery (ASSB). Since no SEI forms on the anode in an ASSB, high CE is anticipated. The existing challenge is that the short circuit cannot be prevented even by using a solid electrolyte (SE), because Li-metal is known to grow on the surface of the SE grains and propagates through the grain boundaries.
In this study, we found that such a short circuit phenomenon is largely inhibited by using a metal foil coated with carbon black (CB) as a substrate for the Li deposition. The CB electrochemically reacts with Li, but we set the capacity of the CB layer much smaller than that of the cathode, and hence a large part of the Li ions are to precipitate as Li metal on the anode during the charge, and works as a Li metal anode.
We fabricated the ASSB in the following way. First, we made a slurry of carbon black by mixing it with a PVdF binder in NMP, and coated it on a Ni foil. The SE layer was made from Argyrodite-type Li_6PS_5Cl powders spread over non-woven cloth, and the cathode sheet was made from the mixture of NCM, Argyrodite SE, conductive agent and PTFE binder. They were stacked and enclosed in a pouch cell, comprising an all-solid-state battery.
This CB-based anode effectively suppressed short circuit of the cell, and an ASSB with this anode showed an excellent cycle property of over 150 cycles at 0.5 mA/cm^2 (0.1C) with good capacity retention. From measurements involving cross-sectional scanning electron microscopy, deposited Li metal layer was observed at the CB/Ni interface.
It was also found that the addition of metal particles in the CB-based anode drastically improves cell performance by extending the cycle life. An ASSB with an Ag/CB-based anode is operated over 700 cycles at 3 mA/cm^2 current density (0.5 C) with a capacity retention of ~86% after 700 cycles.

11:30 AM EN06.01.03
Control of Ionic Conductivity by Lithium Distribution in the Cubic Oxide Argyrodites $Li_{6+x}P_{1-x}Si_xO_5Cl$ Alexandra Morscher, Benjamin Duff, Guopeng Han, Luke Daniels, Yun Dang, Marco Zanella, Manel Sonni, Ahmad Malik, Matthew Dyer, Ruiyong Chen, Frederic Blanc, John Claridge and Matthew Rosseinsky; University of Liverpool, United Kingdom

Current battery technology used in electric vehicles could soon reach its physicochemical limit and alternative ‘next generation batteries’ are needed to further increase energy density. By replacing the liquid electrolyte with a solid, All Solid-State Batteries (ASSBs) could provide increased energy densities whilst addressing the safety concerns related to the current use of flammable liquid electrolytes.[1]

The discovery of novel solid electrolyte materials with lithium ion conductivities suitable for application remains one of the main challenges in the commercialisation of ASSBs. Recently, argyrodite materials have attracted attention by displaying superionic Li ion conductivity; *i.e.* $Li_{6+x}Si_xSb_{1-x}O_5Cl$ ($x = 0.6$, 14.8×10^{-3} S cm^{-1}).[2] These superionic argyrodites crystallise in Li site disordered (*F*-43*m*) structures in which the precise control of Li distribution and disorder is crucial in determining their ionic conductivities. However, all highly conductive argyrodites are sulphides and suffer from poor stability to air and moisture and their electrochemical stability against Li metal is limited. Oxide argyrodites could provide a solution to these stability issues. However, the only two reported oxide argyrodites, Li_6PO_5X (X = Cl, Br)[3] and $Li_6SiO_4Cl_2$[4], adopt Li site ordered structures which results in ionic conductivities of ~10^{-9} S cm^{-1} that are below usable levels.

We present a newly discovered cubic Li-rich (where Li content is >6) oxide argyrodite, Li_7SiO_5C, that crystallises with an ordered cubic ($P2_13$) structure at room temperature, undergoing a transition at 473 K to a Li site disordered *F-43m* structure, consistent with the symmetry adopted by superionic sulphide argyrodites. Four different Li tetrahedral sites are occupied in Li_7SiO_5Cl: T5, T5a, T3, and T4. Most sulphide Li argyrodites contain Li on T5 and/or T5a sites and only few materials have been reported with additional occupancy of T2 and T3 or T2 and T4 sites. This is the first time such a simultaneous site combination (T5, T5a T4 and T3) sites has been reported in Li argyrodite materials.

This disordered *F-43m* structure can be stabilised to room temperature via substitution of Si^{4+} with P^{5+} in the $Li_{6+x}P_{1-x}Si_xO_5Cl$ ($0.3 < x < 0.85$) solid solution, which retains the same combination of occupied Li sites. The observed variation of ionic conductivity with composition in $Li_{6+x}P_{1-x}Si_xO_5Cl$ is directly connected to structural changes occurring within the Li sublattice which are characterised by diffraction and NMR methods. These structural changes are closely linked to the distribution of Li over the available sites giving rise to a unique composition-structure-property relationship within the new $Li_{6+x}P_{1-x}Si_xO_5Cl$.

The delocalisation of Li sites through occupation of T3 and T4 sites leads to a maximum room temperature ionic conductivity of $1.82(1) \times 10^{-6}$ S cm^{-1} at $x = 0.75$, which is three orders of magnitude higher than any other oxide argyrodite. These materials present superior atmospheric stability over analogous sulphide argyrodites significantly facilitating ease of handling.

The ability to control the ionic conductivity through structure and composition emphasises the advances that can be made with further research in the underexplored field of oxide argyrodite materials. This talk will describe the synthesis, characterisation and properties of these new materials, providing a complete explanation of how composition control of structure determines ionic conductivity in $Li_{6+x}P_{1-x}Si_xO_5Cl$.

Lithium-Alloy Anodes in Solid-State Batteries Mauro Pasta; University of Oxford, United Kingdom

The lithium metal anode limits solid-state cell performance because of its intrinsic properties including diffusion kinetics [1], mechanical properties [2], and surface chemistry [3]. Lithium-rich alloys have been proposed as a potential route to address these issues [4,5,6]. Nonetheless, there is little understanding of the impact of alloying on physical properties, electrochemical performance, and especially the link between the two. In my talk I will present an investigation framework to synthesise alloys, quantify fundamental material properties, measure key electrochemical performance metrics, and characterise cells after cycling using the Li-Mg binary system as a model. We intend this framework to be applicable to multiphase alloys going forward, enabling the rapid development of alloy anodes to overcome the challenges in solid-state battery development.

Solution-Processed Non-Crystalline Solid Electrolytes for Advanced Energy Storage Alex Rettie; University College London, United Kingdom

Advanced batteries containing a Li metal anode (LMA) are needed to enable the clean economy and meet ambitious climate targets. Currently, LMA batteries are limited by dendrite propagation due to the non-uniform plating and stripping of Li, which is detrimental to cell performance. The non-crystalline solid electrolyte (SE), lithium phosphorus oxynitride (LiPON) is unique in demonstrating stable Li plating/stripping at appreciable rates, but its synthesis requires costly and slow vacuum deposition methods. We use aqueous precursor solutions which are rapidly condensed during spin coating and gently annealed to produce dense, flat, Li metal oxide films without long-range order. However, such solution-processed SEs typically exhibit ionic conductivities (σ_{ion}) too low for energy storage applications (~10^{-8} S cm^{-1}) and far lower than vacuum-deposited LiPON (~10^{-6} S cm^{-1}).

We will discuss various approaches to increase the σ_{ion} of these non-crystalline Li-containing oxide films, including compositional engineering and controlled processing conditions. Structure-property relationships have been elucidated using pair-distribution-function (PDF) analysis of grazing incidence X-ray total scattering data and interphase formation against Li evaluated by time-dependent electrochemical impedance spectroscopy and in situ X-ray photoelectron spectroscopy. Electrochemical testing of these films deposited onto a current collector in an anode-free cell will be used to evaluate their ability to facilitate stable deposition and stripping of Li.

Initial exploration of processing parameters have yielded σ_{ion} values > 10^{-7} S cm^{-1} [1] and the presence of medium-range order (nanocrystalline domains) in some compositions. As only limited chemical compositions and processing conditions of these glassy SEs have been reported, with no corresponding structural studies, our work provides insight to enable the optimisation and discovery of scalable glassy SEs for advanced batteries.

2:15 PM EN06.02.03
Origins of the Ionic Conductivity in Amorphous Lithium Phosphorus Oxynitride (LiPON) Solid Electrolytes Rafael B. Nuernberg[1], Annie-Kim Landry[2,1], Racha Bayzou[1], Anass Benayad[2], Olivier Lafon[1], Brigitte Pecquenard Le Cras[1] and Frédéric Le Cras[2,1]; [1]CNRS, France; [2]CEA, France

Lithium phosphorous oxynitride ion-conducting glasses, prepared by radio-frequency magnetron sputtering, were a key constituent for the first all-solid-state (thin film) lithium batteries on the market, thanks to a particular combination of properties. Indeed, this solid electrolyte is compatible with both high voltage cathodes and the lithium metal anode, has negligible electronic conductivity and a good ionic conductivity. In the context of the development of new all-solid-state systems, it can now become a useful tool used to mitigate interfacial electrode/electrolyte reactivity. The origins of its outstanding ionic conductivity compared to their crystalline counterparts as well as the interplay between structure and ionic transport in this electrolyte has remained so far somewhat elusive. In this study, we have applied for the first time to this class of materials a methodology based on impedance spectroscopy (EIS) analyses to isolate the distinct energetic contributions to the ionic conduction process namely, the enthalpies for defect formation and migration. The variation of these enthalpies as a function of the nitrogen content is correlated with structural aspects unveiled by Solid-State Nuclear Magnetic Resonance (SS-NMR) and X-ray Photoelectron Spectroscopy (XPS) depth profiling. Our results indicate that the amorphous structure generates a striking decrease of the enthalpy related to defect formation, while the nitrogen incorporation in the material tends to decrease the enthalpy of migration.

2:30 PM EN06.02.04
Intermediate-Stage Sintered LLZO Scaffolds for Li-Garnet Solid-State Batteries Faruk Okur[1,2], Huanyu Zhang[1,2], Kostiantyn Kravchyk[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The quest for non-flammable and high-energy-density electrochemical energy storage systems has led to a surge of reports on novel batteries based on garnet-type LLZO solid-state electrolyte. LLZO*, inter alia*, is appealing because of its high thermal stability, high Li-ion conductivity, and wide electrochemical window of 0-6 V *vs*. Li^+/Li, which allows direct use of metallic Li as a negative electrode.[1, 2] While significant progress has been achieved in the field of Li-garnet solid state batteries, their further development, however, is hindered by the formation of cavities (Kirkendal voids) at the LLZO/Li interface at practically relevant current densities and areal capacities exceeding 1 mA cm^{-2} and 1 mAh cm^{-2}. As a result, the cells exhibit limited cycling stability due to the inhomogeneous distribution of the applied current density and therefore the formation of the Li dendrites. Another aspect, which is of high importance, is associated with the development of the fabrication methodology of thin LLZO electrolytes for achieving high energy density of Li-garnet solid-state batteries.[3, 4]
To contribute to these two challenging aspects, in this work, we present the facile intermediate-stage sintering method of thin (*ca*. 50 μm) and porous (*ca*. 40% of open porosity) LLZO membranes with mean pore size of 2.5 μm. The employment of such porous LLZO membranes not only provides an effective means of mitigating the formation of voids at the LLZO/Li interface due to the increased LLZO/Li surface area, but also enables to maximize achievable energy densities. We demonstrate that fabricated porous LLZO membranes measured in Li/LLZO/Li symmetrical cell configuration exhibit a high critical current density of up to 1.15 mA cm^{-2} and demonstrate long cycling stability of over 1480 h at current density of 0.5 mA cm^{-2} with areal capacity limitation of 0.1 mAh cm^{-2}.

Unlocking the Hidden Chemical Space in Cubic Phase Garnet Solid Electrolyte for Long-Term Stable Solid-State Batteries Sung-Kyun Jung[1,2], Hyeokjo Gwon[2], Hyungsub Kim[3], Gabin Yoon[2], Dongki Shin[4], Jihyun Hong[4], Changhoon Jung[2] and Jusik Kim[2]; [1]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of); [3]Korea Atomic Energy Research Institute, Korea (the Republic of); [4]Korea Institute of Science and Technology, Korea (the Republic of)

Solid-state batteries (SSBs) are attracting considerable attention as energy-storage devices for electric vehicles owing to their high safety and potential high volumetric energy density compared to conventional lithium-ion batteries. All these advantages of SSBs are attributed to the development of solid electrolytes, and among solid electrolytes, oxide-based garnet ($Li_7La_3Zr_2O_{12}$, LLZO) is regarded as a promising candidate owing to its high reduction stability against lithium metal in comparison to alternative solid electrolytes (sulfides or halides). However, cubic phase stabilization between two polymorphs of cubic (10^{-4}~10^{-3} S/cm) and tetragonal phases (10^{-7}~10^{-6} S/cm) is essential to achieve high ionic conductivity up to ~10^{-4} S/cm. In particular, the tetragonal phase is thermodynamically more stable than the cubic phase at high concentration of lithium in the garnet (Li≈7) owing to the Li–Li repulsion. The critical vacancy concentration to stabilize enthalpy formation energy of cubic phase has been revealed theoretically and experimentally as $n_{c,vac}$=0.4–0.5. It is generally believed that the formation of Li-vacancy is inevitable for stabilizing the cubic phase so far, therefore, most of the Li-vacancy formation has been introduced by aliovalent substitution in Li ($Li_{7-3x}M_xLa_3Zr_2O_{12}$, M=Al, Ga) or Zr site ($Li_{7-x}La_3Zr_{2-x}M_xO_{12}$, M=Nb, Ta) to surpass the instability of cubic phase by alleviating the Li–Li repulsion.
Here, we successfully stabilized the cubic-phase without vacancy formation at a maintained Li composition of Li = 7 in the garnet for the first time by incorporating various dopants (Hf, Sn, Sc, and Ta) in the Zr site, considering the defect formation energy, site-exchange energy, and charge balance, unlike that in the conventional strategy. Unexpectedly, this cubic phase is stabilized by increased entropy-driven by not the phonon vibrational or configurational entropy that is usually shown in high entropy alloy, but the other entropy such as electronic entropy or electronic configurational entropy. We revealed the effect of lithium/vacancy concentration on structure and ionic conductivity by exploring hidden chemical space (Li>6.6). More specifically, this entropy-driven stabilization exhibited the lowest nucleation temperature of cubic-phase garnet as 400 °C in the solid-state reaction implying potential applicability in practically required low-temperature processing for cost-effective SSBs manufacturing.
Conventional vacancy-driven cubic phase stabilization of garnet is vulnerable against Li metal in terms of reduction stability. The cubic-phase garnet derived from the Li-vacancy formation suffered the inevitable phase transformation to the tetragonal phase at the Li/garnet interface owing to the reduced vacancy concentration below the critical value ($n_{c,vac}$<0.4–0.5) that resulted from the thermodynamic driving force for metal reduction and the lithiation into the garnet structure. Moreover, the metal reduction and the phase transformation from the cubic to tetragonal phase induced sluggish kinetics of the Li transport by increasing the interfacial resistance at Li/Garnet interface. However, our entropy-driven stabilized cubic-phase with high lithium contents (Li=7) exhibited superior reduction stability in kinetics aspect compared to that stabilized by vacancy formation (Li=6.6, $n_{c,vac}$=0.4). Compared to the vacancy-driven cubic phase, the entropy-driven cubic phase displayed a tenth of the reduction kinetic constant for Li metal owing to the high chemical potential of lithium in the cubic phase. Consequently, the SSBs developed using our designed garnet electrolyte delivered remarkable long-term cycle performance with 92% capacity retention after 700 cycles, with high areal capacity of 2.92 mAh/cm^2 at 60 °C. Our discovery can provide an intuition for designing the cubic-phase garnet solid electrolyte with high reduction stability against Li metal for long-term stable SSBs.

Understanding and Rational Design of Super-Ionic Conductors by First-Principles Computation and Machine Learning Yifei Mo; University of

Maryland, United States

Super-ionic conductors exhibit exceptionally high ionic conductivities and are highly desired as solid electrolytes or electrodes for energy applications such as batteries and fuel cells. However, while multiple ion-conduction mechanisms are proposed for super-ionic conductor materials, the fast ion-conduction mechanisms are still not fully understood, impeding the capability to rationally design these materials. In this presentation, we will illustrate how we combine atomistic modelling, machine learning, and physics analytics to provide an enhanced understanding of the super-ionic conductors and to rationally design new super-ionic conductor materials, using a number of emerging or newly discovered materials systems as examples. We will demonstrate that the combination of atomistic modelling and machine learning extend and empower conventional physics analytics for unravelling fundamental mechanisms and for guiding material design.

Bridging the gap between experiment and computation in LGPS solid electrolyte with machine-learning potentials Gavin Winter and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

$Li_{10}Ge(PS_6)_2$ (LGPS) is a highly concentrated solid electrolyte, and the Coulomb repulsion between neighboring cations has been hypothesized as the underlying reason for concerted ion hopping, a mechanism common among superionic conductors such as $Li_7La_3Zr_2O_{12}$ (LLZO) and $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ (LATP). While first principles simulations using molecular dynamics (MD) provide insight into the Li^+ transport mechanism, historically, there has been a gap in the temperature ranges studied in simulations and experiments. Here, we used a neural network (NN) potential trained on density functional theory simulations, to run up to 40-nanosecond long MD simulations to characterize the ion conduction mechanisms across a range of temperatures that includes previous simulations and experimental studies. We have confirmed a Li^+ sublattice phase transition in LGPS around 400 K, below which the *ab*-plane diffusivity D^*_{ab} is drastically reduced. Concomitant with the sublattice phase transition near 400 K, there is less cation-cation (cross) correlation, as characterized by Haven ratios closer to 1, and the vibrations in the system are more harmonic at lower temperature. Intuitively, at high temperature, the collection of vibrational modes may be sufficient to drive concerted ion hops. However, near room temperature, the vibrational modes available may be insufficient to overcome electrostatic repulsion, thus resulting in less correlated ion motion and comparatively slower ion conduction. Such phenomena of a sublattice phase transition, below which concerted hopping plays a less significant role, may be extended to other highly concentrated solid electrolytes such as LLZO.

Understanding Ion Transport and Electrochemical Stability of Sulfide-Based Solid Sodium Electrolytes Varun Shreyas, Sabina Chertmanova, Selim Halacoglu, Hui Wang and Badri Narayanan; University of Louisville, United States

Solid-state sodium (Na) batteries (SSSBs) using sulfide-based solid electrolytes (SEs) has been attracting a lot of attention due to their high theoretical specific capacity, enhanced safety, and abundant resources. Especially, Na_3SbS_4 shows tremendous potential as a SE owing to its good Na^+ ion conductivity of ~1 – 3 mS cm^{-1}. Despite its promise, electrochemical performance of SSSBs based on Na_3SbS_4 SE remain far from commercialization. The major roadblock thwarting progress in SSSBs is the lack of fundamental understanding of atomic-scale mechanisms underlying (a) interfacial reactions with Na anode, and (b) Na^+ ion conduction (especially in the presence of dopants). Here, we employ ab initio molecular dynamics (AIMD) simulations to identify key reactions occurring at the $Na|Na_3SbS_4$ interface. Our AIMD simulations indicate that addition of an ionic liquid interlayer results in a stable solid-electrolyte-interphase (SEI) composed mainly of NaF, in excellent agreement with our synthesis and characterization experiments. Similarly, our DFT studies show that Se doping increases the electrochemical stability window of Na_3SbS_4. In terms of Na^+ conduction, we employ AIMD simulations, and nudged elastic band calculations to understand the effect of (a) valence, and (b) size of cation dopants that partially replace Na in Na_3SbS_4. These cations introduce charge compensating Na-vacancies in the SSE, which in turn, enhance Na^+ ion conduction. However, size of the cation dopant has a profound impact on the extent of increase in Na^+ ion conductivity. For instance, Ca-doped Na_3SbS_4 ($Na_{2.75}Ca_{0.125}SbS_4$) showed Na^+ conductivity of ~10 times that of pristine Na_3SbS_4 (r_{Ca}2+ / r_{Na}+ = 0.98). On the other hand, larger Ba^{2+} as dopant (r_{Ba}2+ / r_{Na}+ = 1.35) in $Na_{2.75}Ba_{0.125}SbS_4$ hinders Na-ion hops owing to local strain, thereby, yielding a Na^+ conductivity ~5 times that of Na_3SbS_4.We will discuss these findings in the context of developing solid-state electrolytes for emerging SSSBs.

4:30 PM EN06.02.09
"Dirt Cheap" Electrolytes for Solid-State Energy Storage Erik D. Spoerke[1], Stephen Percival[1], Martha Gross[1], Leo J. Small[1], Amanda Peretti[1], Ryan C. Hill[2] and Yang-Tse Cheng[2]; [1]Sandia National Laboratories, United States; [2]University of Kentucky, United States

Identifying cost-effective, solid state electrolytes with high ionic conductivity at ambient temperatures would enable a growing number of electrochemical energy storage systems. Here, we describe a "dirt cheap" approach to developing solid state separators, utilizing sodium-based clays as easily-processed, highly-conductive ionic materials. Our clay-based system employs phyllosilicate minerals formed of crystalline sheets, regularly stacked, but separated by hydrated, nanoscale interlayer spacings. Populating these interlayer spaces are mobile, charge-compensating cations, such as sodium. We highlight the sodium ionic conductivity on the order of 0.1mS/cm at room temperature, and we investigate the key structural and chemical properties responsible for this impressive performance. We further assemble functional devices and investigate the feasibility of these materials as solid-state electrolytes for electrochemical storage, demonstrating and assessing ionic shuttling between electroactive electrodes during electrochemical cycling. These studies uncover untapped potential from these earth-abundant, low-cost, easily processed materials and their prospects as a new class of solid-state electrolytes. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Coupling of Ionic Hopping and Anharmonic Phonon Dynamics in Superionic Conductors for Solid State Electrolytes Olivier Delaire, Jingxuan Ding, Mayanak Gupta and Hung-Min Lin; Duke University, United States

The design of new solid state electrolytes (SSEs) hinges on identifying and tuning relevant descriptors. While static structural descriptors have been correlated with fast diffusion, the host framework flexibility and vibrations and their complex dynamic coupling with mobile ions remain less studied. Phonons describe the atomic dynamics in crystalline materials and provide a basis to encode possible minimum energy pathways for ion migration but anharmonic effects can be large in SSEs. Identifying and controlling the pertinent phonon modes coupled most strongly with ionic conductivity, and assessing the role of anharmonicity, could therefore pave the way for discovering and designing new SSEs via phonon engineering. Here, we investigate phonons in Na3MX4 and their coupling to fast Na diffusion, using a combination of neutron sca6ering, ab-initio molecular dynamics (AIMD), and accelerated molecular dynamics based on machine-learned potentials. We identify anharmonic soft-modes of the high-temperature phase that play an important role as precursors to mobile Na hopping. We also show how these strongly anharmonic phonon modes enable Na-ions to hop along the minimum energy pathways. Further, the quasi-elastic neutron sca6ering measurements, supplemented with large-scale molecular dynamics simulations, probe the Na diffusion constant and the diffusion characteristics. These results offer detailed microscopic insights into the dynamic mechanism of fast Na diffusion and provide an avenue to search for further Na solid electrolytes. These results will also be contrasted with studies of coupled dynamics of anharmonic phonons and fast diffusion of mobile ions in other superionic systems.

Towards Solid State Zinc-Air Batteries—Enabling Bio-Based Polymer Gel Electrolytes Estíbaliz García-Gaitán[1,2,3], Maica Morant-Miñana[1], Domenico Frattini[1], Daniel Gonzalez[2], Igor Cantero[2] and Nagore Ortiz-Vitoriano[1,4]; [1]Centre for Cooperative Research on Alternative Energies (CIC energiGUNE), Basque Research and Technology Alliance (BRTA), Alava Technology Park, Albert Einstein 48, 01510, Spain; [2]CEGASA Energía SLU, Marie Curie, 1, Parque Tecnológico de Álava, 01510, Spain; [3]University of the Basque Country, Barrio Sarriena, s / n, 48940, Spain; [4]Ikerbasque, Basque Foundation for Science, María Díaz de Haro 3, 48013, Spain

Electrochemical energy storage technologies can help mitigate the dependency from fossil sources and greenhouse gas emissions, enabling energy storage from renewable sources and their integration into the grid, thus driving energy transition worldwide. Presently, the most commercialized technology is lithium-ion, from small portable devices to electric vehicles, and up to stationary applications at grid level. However, its use in stationary energy storage systems involves a great cost, being necessary to seek new highly competitive technologies at lower cost. Therefore, it is strategically not convenient to rely only on this technology to implement electrochemical energy storage, but few valid alternative candidates can be foreseen considering the electrochemical window and energy density. Zn-air secondary battery is one of these; however, affordable development based on industrially and quantitatively relevant breakthroughs is required.

Zn-air batteries based on liquid electrolyte have been widely investigated but due to the open nature of the technology (cell is open to air), electrolyte leaks and/or evaporates causing a decrease in the performance and subsequent cell failure. As a result, recent research has mainly focused on developing synthetic biodegradable polymer-based gel polymer electrolytes (GPEs) due to their low cost and affordability (e.g., alkaline GPEs such as polyvinyl alcohol (PVA), polyacrylic acid (PAA), polyacrylamide (PAM), polyethylene oxide (PEO)). Much of the early, but also recent, work in metal air batteries (especially in Zn and Na air batteries) has been devoted to the study of biopolymer-based membranes, that act as separators and electrolytes to substitute liquid electrolytes.

In this work, the development of an emerging solid electrolyte, based on a natural, linear, and biodegradable polymer will be presented. The biopolymer is directly jelled in the liquid electrolyte solution to for a stable gel, that not only presents outstanding ionic conductivity, (same magnitude order as 8M KOH solution liquid electrolyte) but also mechanical stability, even after being subjected to a constant discharge until battery failure. The gel does not liquefy, and behaves as an elastic material till up to a certain applied compression load. In this study, its manufacture, mechanical characterization and electrochemical performance will be discussed.

9:30 AM EN06.03.04
Ultrafast-Sintered Self-Standing LLZO Membranes for High Energy Density Li-Garnet Solid-State Batteries Huanyu Zhang[1,2], Faruk Okur[1,2], Kostiantyn Kravchyk[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Towards building non-flammable and temperature-tolerant Li-ion batteries with high energy density, $Li_7La_3Zr_2O_{12}$ (LLZO) has recently attracted considerable attention as a compelling solid-state Li-ion electrolyte (SSE) due to its high thermal stability, Li-ion conductivity of up to 1 mS cm^{-1} (RT), and a wide electrochemical operation window of 0–6 V *vs*. Li$^+$/Li.[1, 2] Additionally, unlike other Li-ion soft solid conductors such as those based on sulfides, LLZO SSE can be manufactured with a bilayer dense-porous microstructure, which prevents the issues of dynamic volume change of the Li anode and the formation of voids at the Li/SSE interface during cycling and thus eliminates the need for external pressure.[3, 4] Here we report a facile, ultrafast sintering methodology for the fabrication of LLZO solid-state electrolyte in the form of self-standing bilayer dense-porous LLZO membranes. The thickness of the produced dense and porous layers was *ca*. 8 µm and 55 µm, which hypothetically allows to achieve high gravimetric and volumetric energy densities of Li-garnet batteries of 202 Wh kg^{-1} and 715 Wh L^{-1} (in combination with an NMC111/LiFSI-Pyr$_{13}$FSI cathode). Electrochemical measurements confirmed that produced LLZO membranes possess high critical current density up to 1.7 mA cm^{-2} and cycling stability of over 45 cycles at a current density of 0.1 mA cm^{-2}.

NMR Insights into Ion Conduction in Chloride Solid Electrolytes and Polymer Electrolytes Raphaële Clément; University of California, Santa Barbara, United States

Nuclear magnetic resonance (NMR) spectroscopy provides detailed insights into the working principles of ionic and mixed conductors used in rechargeable battery applications. Notably, NMR is sensitive to crystalline, disordered or even amorphous phases that arise during electrochemical cycling, and can provide atomic-level structural information, as well as insights into the dynamics of ion motion. In this talk, I will present our recent work on Li-ion and Na-ion conducting rocksalt halides [1, 2] and Li-conducting polymeric ionic liquids [2]. Using a combination of synchrotron X-ray diffraction/scattering, electrochemical impedance spectroscopy (EIS), solid-state NMR, pulsed field gradient NMR (PFG-NMR), NMR relaxometry, and first principles calculations, we provide a multiscale understanding of ion diffusion processes and link these findings to local structure features, crystallinity, and materials synthesis/processing conditions.

Polyethylene Oxide/$\mathrm{Na_{3.2}Ca_{0.1}Zr_{1.9}Si_2PO_{12}}$ as Gel Electrolyte for Quasi-solid-state Sodium-ion Batteries Hao-Yu Liu, Chia-Ching Lin and Han-Yi Chen; National Tsing Hua University, Taiwan

Recently, solid-state sodium-ion batteries (SSSIBs) have attracted wide attention as a choice for next-generation energy storage systems owing to several advantages. Firstly, the low cost of sodium metal and aluminum current collectors makes SIBs a prospective alternative for large-scale industrial use. Secondly, solid electrolytes possess high thermal stability, wide electrochemical window, and high mechanical strength which can suppress dendrite growth. However, high interface resistance between the solid electrolyte and electrode and low ionic conductivity limit the performance of SSSIBs. Hence, developing a gel electrolyte with low contact resistance and high ionic conductivity is the key to enabling the practical application of next-generation SIBs. In this work, a calcium-doped NASICON-type solid electrolyte, $\mathrm{Na_{3.2}Ca_{0.1}Zr_{1.9}Si_2PO_{12}}$ (NCZSP) was synthesized by a sol-gel method. Then, solvent casting was used to prepare a polyethylene oxide (PEO)/NCZSP film. The PEO/NCZSP gel electrolyte achieved high ionic conductivity of approximately 6×10^{-4} S $\mathrm{cm^{-1}}$ (n = 10) at room temperature. After, quasi-solid-state SIBs were assembled and tested with a high-entropy layered oxide (HEO) as cathode and sodium metal as anode under room temperature. The HEO||PEO/NCZSP||Na cells exhibited excellent electrochemical performance with a high discharge capacity of approximately 120 mAh $\mathrm{g^{-1}}$ under the current density of 0.1C and good retention of 78% after 100 cycles, demonstrating that PEO/NCZSP has a good potential as a gel electrolyte for SIBs.

11:00 AM EN06.03.07
An Experimental Technique for Directly Measuring Ultrafast Ion Hopping and its Inherent Correlations Kim Pham, Kimberly See and Scott K. Cushing; Caltech, United States

Ion hopping times can reach the picosecond timescales in superionic conductors and are a complex interplay of ion-phonon, ion-electron, and ion-ion correlations. In this presentation, we present a new experimental technique that can directly measure ultrafast ion hopping on its inherent timescale. As a result, the relative contributions of the different correlations to the many-body ion hopping Hamiltonian are determined. The technique sweeps a broad-frequency range laser from the UV to THz to perturb AC impedance measurements in the grain boundary and bulk ion hopping regimes. High GHz conduction traces measure the picoseconds change in the ion hopping following the perturbation. With proper renormalization, the changes give the relative ion-electron and ion-phonon coupling terms. We demonstrate the technique on $\mathrm{Li_{0.5}La_{0.5}TiO_3}$ (LLTO). For this material, we measure that the dominant ion hopping route is through a THz rocking mode (matching theoretical predictions). The relative role of ion-electron correlations relative to the ion-phonon correlations is also measured. Finally, we discuss how in the future the technique can be extended to measure ion-ion correlations.

11:15 AM EN06.03.08
Computational Study of Mechanism of Fast Ionic Transport in $\mathrm{Li_3YCl_6}$ (LYC): Role of Anharmonicity & Host Dynamics Ballal Ahammed and Elif Ertekin; University of Illinois at Urbana Champaign, United States

Understanding the mechanisms of ionic transport in solid electrolytes (SEs) is key to further tailoring their ionic conductivity and finding accurate descriptors for high throughput predictions. The link between vibrational dynamics and ionic diffusion offers a promising avenue to explore ion transport beyond static structural descriptors. However, strong anharmonic effects in SEs suggest the potential breakdown of the harmonic phonon picture and the importance of anharmonicity for facile ion migration. In this study, we investigate the role of vibrational modes, soft bonding, and strong anharmonicity in lithium ion migration in $\mathrm{Li_3YCl_6}$ (LYC), a halide lithium ion conductor that has gained interest for its wide electrochemical stability window, low electronic conductivity, and good stability towards oxide cathodes. The crystal structure of LYC is characterized by a rigid hexagonal close packed anion sublattice and a flexible disordered cation sub-lattice. We use a combination of ab initio molecular dynamics (AIMD), lattice dynamics, and nudged elastic band (NEB) methods to reveal strong lattice anharmonicity and vibrational coupling between the modes of the mobile and rigid sub-lattices. Ab initio molecular dynamics (AIMD) simulations are performed over different temperatures in order to understand the diffusive dynamics. By quantifying the similarities between phonon eigenvectors and AIMD trajectories, soft phonon modes that may be associated with lithium diffusion are identified. The anharmonic nature of these phonon modes is confirmed by mapping the potential energy surface. We demonstrate how the lithium dominated anharmonic modes enables in-plane lithium hopping while large amplitude in-plane motion of the rigid sub-lattice assists out of plane lithium migration.

Sustainable Production of Metal Sulfide Nanocrystals for Electrochemical Storage Applications via Cascaded Metathesis William Smith, Saeed Ahmadi Vaselabadi and Colin A. Wolden; Colorado School of Mines, United States

Sulfide-based solid-state batteries are among the leading candidates to displace conventional lithium and sodium ion battery technologies. Metal sulfides ($\mathrm{Li_2S}$, $\mathrm{Na_2S}$, $\mathrm{SiS_2}$, $\mathrm{TiS_2}$, etc.) are critical precursors for both the solid state electrolytes and the conversion type cathodes employed in these devices. The high cost of these materials hinders development and deployment of these technologies. Their high cost reflects the high temperature carbothermal reduction and solid state synthesis techniques currently employed. Herein we describe the production of these materials employing room temperature, solution-based metathesis. In the first step $\mathrm{Li_2S}$ is produced through metathesis of two low-cost precursors – LiCl and $\mathrm{Na_2S}$ – at ambient temperature in an alcohol solution, with salt as a byproduct. Trace impurities in metathesis $\mathrm{Li_2S}$ introduced by side reactions with the solvent can be removed by a low temperature purification step that retains the desired nanocrystalline morphology. The quality of $\mathrm{Li_2S}$ was validated through the production of argyrodite ($\mathrm{Li_6PS_5Cl}$) solid state electrolytes with state-of-the-art conductivity (> 4 mS/cm). In the 1970s researchers at Exxon showed that $\mathrm{Li_2S}$ was a powerful reagent that can be used for the metathesis of transition metal sulfides ($\mathrm{MoS_2}$, $\mathrm{TiS_2}$ etc.), but practical implementation of this approach was limited by exorbitant cost and quality of the $\mathrm{Li_2S}$ precursor. These reactions are typically conducted in an aprotic solvent and driven by the precipitation of LiCl. Herein we couple these two reactions in a process we've named cascaded metathesis. The net reaction is $n\mathrm{Na_2S} + \mathrm{MCl_n} \rightarrow \mathrm{MS_n} + 2n\mathrm{NaCl}$. Both the lithium chloride intermediate and the solvents are recovered and recycled in a circular economy. We demonstrate this approach through the cascaded metathesis of $\mathrm{SiS_2}$, which to our knowledge is the first time metathesis has been used to synthesize this compound. It is shown that ethyl acetate is the preferred solvent for conducting this reaction and that the reactivity of metathesis derived Li_2S is superior to its commercial counterpart. Finally, the metathesis-derived SiS_2 and Li_2S were employed as precursors in the synthesis of a glassy electrolyte that exhibited a conductivity of 0.11 mS cm^{-1} at 30 °C with a low activation energy of 20.2 kJ mol^{-1}, validating the promise of this method to enable the synthesis of silicon-based sulfide electrolytes for solid-state lithium-ion batteries.

Lithium Metal Halide Solid Electrolytes for All-Solid-State Batteries Jürgen Janek[1] and Linda F. Nazar[2]; [1]Justus Liebig University, Germany; [2]University of Waterloo, Canada

All-solid-state batteries (ASSBs) have emerged as promising alternatives to conventional Li-ion batteries for electrical energy storage, owing to their anticipated enhanced safety and higher energy densities. ASSBs are founded on high performance superionic conducting solid electrolytes, where the search for new, advanced materials hinges on determining the factors that dictate facile Li-ion (or Na-ion) transport. Incorporating them into highly functional ASSBs, however, relies on mastering the interface of the solid electrolyte with the electrode materials. While there has been much focus on the relative stability of various solid electrolytes against lithium metal as the negative electrode, the cathode-electrolyte interface has received comparatively less attention.

A fundamental understanding of the interaction of the surface of cathode materials with solid electrolytes is crucial to design practical ASSBs. Although sulfides (i.e., thiophosphates) are widely explored, they lack electrochemical stability above ~ 2.7 V vs Li^+/Li, whereas a new class of lithium metal chloride (Li-M-Cl) solid electrolytes are receiving rapidly growing scrutiny owing to their very high oxidative stability (> 4.2 V) in combination with good ionic conductivity and ductility. Because Li-M-Cl electrolytes typically contain resource-limited metals (M) such as indium or rare earths, work has focused on substituting M with more abundant elements such as zirconium and iron. However, a unified understanding of the materials design principles for such substitutions is still lacking, both with respect to voltage stability and ion/electron transport. This presentation will explore both concepts. It will focus on examination of the dynamic evolution of the interphase (via a combination of theory and experiment, including *operando* impedance measurements) at different upper cutoff potentials and degrees of delithiation at the surface of Ni-rich NCM cathode particles. The cathode is coupled to a range of different Li-(M_1,M_2)-Cl catholytes to assess the role of the central metal and the contribution of partial electronic conductivity in determining both chemical stability and high voltage electrochemical stability. Finally, the effect of crystal structure (layered vs spinel, etc) on ion transport will be presented. Overall, this approach establishes a platform for the metrics that can be utilized to efficiently evaluate new halide SEs in SSB cells.

Enabling High-Rate Lithium Metal Anodes by Tailored Structures and Interfaces Eric D. Wachsman; University of Maryland, United States

Oxide-based solid-state Li-batteries (SSLiBs) have the potential to be a transformational and intrinsically safe energy storage solution due to their non-flammable ceramic electrolyte that enables the use of high-capacity Li metal anodes and high voltage cathodes for higher energy density over a much wider operating temperature range. However, their progress has been limited due to electrode/electrolyte interfacial issues. In particular for Li-metal anodes concerns over dendrite formation/propagation and the requirement for elevated temperature and high stack pressure are still prevalent. To eliminate these concerns a rational design of tailored structures and interfaces in Li-metal anodes will be presented. In addition, progress toward full cells using these tailored structures and interfaces will be presented.

2:30 PM *EN06.04/EN08.06.03
Manufacturing Considerations for Solid-State Batteries based on LLZO Electrolytes Marca M. Doeff, Michael Tucker and Wooseok Go; Lawrence Berkeley National Laboratory, United States

Batteries based on LLZO (variants of $Li_7La_3ZrO_2$) are under consideration for vehicle applications based on promising characteristics such as high room temperature ionic conductivity (up to ~$5x10^{-4}$ S/cm) and good compatibility with metallic lithium. One of the biggest challenges is processing the material into battery components, including thin, dense films and porous scaffolds, which can be infiltrated with active electrode materials and conductive additives. Ideal processing techniques minimize cost, maximize throughput, can be scaled-up readily, and yield robust parts or devices that can withstand handling. For this talk, we will consider the pros and cons of various cell configurations, such as those utilizing thin (~20 um thick) dense LLZO separators with a secondary electrolyte on the cathode side, and bilayer (dense + porous LLZO) or trilayer (porous+dense+porous LLZO) arrangements.

High-entropy Garnet-type Oxide as Solid Electrolyte for All Solid-state Li-ion Batteries Chun Han Kuo, Ai-Yin Wang, Hao-Yu Liu and Han-Yi Chen; National Tsing Hua University, Taiwan

Li-ion batteries (LIBs) are well-known storage systems owing to their high energy density and long cycling life. However, the potential danger of explosion and fire poses a threat to the user safety of commercial production using LIBs. Therefore, more and more researchers devote themselves to developing all-solid-state Li-ion batteries (ASSLIBs). ASSLIBs are mainly composed of an anode, solid electrolyte, and cathode. The solid electrolyte is one of the key parts to determine the performance of an ASSLIB. Among several kinds of solid electrolyte materials, Garnet-type oxide solid electrolytes have been considerably researched because of their wide electrochemical window, good stability against Li, and high thermal stability.[1] The famous Ta-

doped $Li_7La_3Zr_2O_{12}$ was first reported by Li. et. al..[2] Despite the high ionic conductivity of $Li_{6.4}La_3Zr_{1.4}Ta_{0.6}O_{12}$ at 10^{-3} S cm^{-1}, the instability of structure due to the easily reaction with the air causes the decay of ionic conductivity.[3]
In our research, a multi-doped strategy was introduced to apply in garnet-type oxide, $Li_{7-a}La_3(ZrTaNbYW)_xO_{12}$ (LLZTNYWO), to improve the stability against ambient air. LLZTNYWO was successfully synthesized using a conventional solid-state method as a solid electrolyte for Li-ion batteries. With the multi-dopant in the crystal structure of garnet, the material exhibited high ionic conductivity and high air stability. The crystal structure and microstructure of LLZTNYWO was confirmed by X-ray diffraction, field-emission scanning electron microscope, energy dispersive spectroscopy, spherical-aberration corrected high-resolution transmission electron microscopy, and extended X-ray absorption fine structure. In addition, the electrochemical performances were investigated by electrochemical impedance spectroscopy analyses, cyclic voltammetry tests, and galvanostatic cycling tests. The results demonstrated that LLZTNYWO could form a single phase in the garnet structure and deliver high ionic conductivity, exhibiting a promising solid electrolyte in ASSLIBs.

Investigating Significant Bond Character Features in Superionic Metal Halides to Study Their Relationship with Cation Diffusivity Salma Ahmed; San Francisco State University, United States

Solid-state batteries have been a focus of much research because they are safer than batteries with organic electrolytes that are used commercially, but they are less conductive. This computational study focuses on the binary metal (Ag/Cu) halides to find the link between bonding character of the diffusive Ag or Cu with the halide static lattice and Ag/Cu conductivity. Maximally Localized Wannier Functions (MLWFs) are used to analyze the bond character (either polar covalent or ionic) of the system to see whether or not there are bond fluctuations between the mobile cation and the anion lattice. The bond character and diffusivity of the metal halides were analyzed in different crystal structures (alpha, beta, zinc-blende, rock-salt) and at different temperatures. The diffusion coefficient for the metal at each temperature was calculated using the mean squared displacement of the metal, and the diffusion coefficient at three temperatures was used to calculate the activation energy barrier of diffusion. Our calculated values followed experimental trends. The polarization for the halides and bond angle was determined using the MLWFs in order to analyze the abundance of polar covalent interactions and how it correlates to diffusivity. The angle and polarization distributions varied as the crystal structure, metal, or halide changed. These results point towards our hypothesis that bond character affects diffusivity. By systematically varying crystal structure and bonding interactions in superionic conductors, we can learn more about the interaction between the diffusion species and the anion lattice, and therefore better understand solid-state electrolytes.

5:00 PM EN06.05.04

Enhancing Ionic Conductivity by *In Situ* Formation of Li_7SiPS_8/Argyrodite Hybrid Solid Electrolytes Robert Calaminus[1,2], Sascha Harm[1,2], Douglas Fabini[1,3], Lucas Balzat[1,2], Anna-Katharina Hatz[1,2], Viola Duppel[1], Igor Moudrakovski[1] and Bettina V. Lotsch[1,2]; [1]Max Planck Institute for Solid State Research, Germany; [2]Ludwig-Maximilians-Universität München, Germany; [3]Massachusetts Institute of Technology, United States

Solid electrolytes (SEs) with high ionic conductivities are prerequisites to establish solid state batteries on a broad basis. Here we report a novel approach to thiophosphate SEs with improved ionic conductivities based on the in situ formation of LGPS-type *tetra*-Li_7SiPS_8/lithium argyrodite Li_6PS_5X (X= Cl, Br, I) hybrid SEs. Quantitative phase analysis reveals the formation of halogen-poor argyrodites $Li_{6+y}PS_{5+y}X_{1-y}$ next to the *tetra*-Li_7SiPS_8 majority phase and an amorphous side phase. EIS measurements indicate ionic conductivities of up to 7 mS cm^{-1}, which exceed those of the parent *tetra*-Li_7SiPS_8 and Li_6PS_5X (X = Cl, Br, I) phases as well as those of simple physical mixtures whose conductivities are well described by the effective medium approximation. In contrast to previous reports, no evidence for halide substitution of the PS_4^{3-} anions in *tetra*-Li_7SiPS_8 was found. Instead, the observed increase in ionic conductivity along with reduced grain boundary resistance is attributed to the directed growth of the *tetra*-Li_7SiPS_8 majority phase in the presence of an argyrodite side phase. As a result, a substantially increased isotropic Li diffusion radius is observed by PFG NMR, consistent with both more bulk-like Li transport within secondary particles and with reduced grain boundary resistance through more benign argyrodite interphases as compared to pristine *tetra*-Li_7SiPS_8. The microstructural changes induced by hybridization thus provide access to the bulk properties of *tetra*-Li_7SiPS_8.

5:00 PM EN06.05.05

Engineered Segmental Mobility in a Family of Solvent-free Single-ion Conducting Borate Network Polymer Electrolytes for Li-metal Battery Applications Jingyi Gao, Jiaming Zhou, Xiaoting Ma and Dong-Myeong Shin; The University of Hong Kong, Hong Kong

As the state-of-the-art energy storage technology, lithium-ion batteries have been attracting lots of attention, but finite energy densities of mainstream Li-ion batteries cannot satisfy the overwhelming demand for large energy storage and commercial flammable liquid electrolytes are also plagued by safety concerns. Many efforts have focused on developing solvent-free single-ion conducting (SIC) polymer electrolytes to solve these issues by covalently immobilizing anionic groups onto a polymer backbone, which only allows Li^+ cations to be mobile through the polymer matrix, leading to minimal dendrite growth during charging/discharging process. While the SIC polymer electrolytes hold much promise for next-generation batteries possessing high safety and high energy density, this approach typically yields a significant drop of ionic conductivity at ambient temperature compared to liquid electrolytes. In this work, we engineered the networking of a series of solvent-free anionic network polymer electrolytes to improve ionic transport for Li-metal battery applications and investigated influencing factors of Li-ions transport. A series of branched polyethylene glycol linkers was connected with tetrakis(4−(chloromethyl)–2,3,5,6-tetrafluorophenyl)borate to form a family of anionic network polymers via nucleophilic substitution where the lithium cations are the dominant contributors to ionic transport as all borate anion nodes are physically anchored within the polymer framework, acting as the single-ion conducting polymers. The segmental mobility in anionic network polymers could be tuned by varying synthetic parameters such as the interanionic distance and the number of tethered branches. As the segmental mobility is predicted to increase with the interanionic distance whilst increasing the number of tethered branches causes the segmental mobility to decrease, we have chosen the trimer and tetramer polyethylene glycol linkers with different numbers of repeating units to engineer the segmental mobility. The increasing segmental mobility offered an elevated ionic conductivity (up to 3.02×10^{-7} S cm^{-1} at room temperature), revealing ionic transport was mostly controlled by engineering the segmental mobilities of polymers, especially at the given interanionic distance. With the increasing of segmental mobility by adding branches at the given interanionic distance, there is a significant increase (at least 4-fold) in ionic conductivity. Notably, there was a restricted ionic transport in fast segmental dynamics of the network polymers featuring free branches, implying that the branching would less contribute to ionic transport compared to the interanionic distance likely due to the frustration in changing the coordination site. Standout network polymer exhibited notable ion selectivity in Li+ cation transport (~0.979) and high oxidative stability (up to 4.2 V). The result partially reveals the ionic transport rule within the interpenetrated network polymer and gives insights on the design of a new class of

highly conducting electrolytes.

5:00 PM EN06.05.06
Bacterial-Cellulose-Derived Composite Membrane Electrolytes for Long-Shelf-Life Solid Zinc-Air Batteries Joo Young Park, Sung-Hae Kim, Sambhaji S. Shinde, Nayantara K. Wagh, Seol-Hee Han and Jung-Ho Lee; Hanyang University, Korea (the Republic of)

The global energy crisis demands a new rechargeable battery with high energy density, low cost, and earth-abundant elements that are significantly challenging for the next-generation energy storage system. Zinc-air batteries (ZABs) can meet these goals due to their high theoretical energy density and earth-abundant zinc reserves, but the liquid electrolytic cells employing aqueous solutions limit the commercial versatility because of difficulties in bipolar cell stacking for upscaling with lack of bendability. All-solid-state ZABs can resolve these issues, but they require a much more difficult technical challenge due to their unique half-open system requiring air circulation from the outside. This feature makes solid electrolytes vulnerable to water evaporation, CO_2 contamination, cathode redox reactions, electrochemical/mechanical instability, and poor cycle life, compared to aqueous liquid electrolytes.
In our work, we present almost non-drying bacterial celluloses and poly acrylic acid (BC/PAA) derived composite alkaline membrane electrolytes formed by reinforcing the polymerization of acrylic acid with the BC pellicles. The grown BC/PAA membrane has a three-dimensional (3D) nanofiber intertwined composite structure with high mechanical strength and hydrophilicity. Further, we optimized the characteristics of BC pellicles by varying nutrient sources in a culture media. BC/PAA membrane revealed excellent dimensional stability, high toughness, water retention capability, and a low swelling ratio. Furthermore, the fabricated solid ZABs with BC/PAA polymer electrolyte rendered excellent charge/discharge performance and superior long-shelf life for commercial availability.

5:00 PM EN06.05.07
Breakdown of Soft Anharmonic Phonons Heralds Fast Ionic Diffusion in Lithium Argyrodite Jingxuan Ding[1,2], Mayanak Gupta[1,3], Carolin Rosenbach[4], Naresh Osti[5], Douglas L. Abernathy[5], Wolfgang Zeier[4] and Olivier Delaire[1]; [1]Duke University, United States; [2]Harvard University, United States; [3]Bhabha Atomic Research Centre, India; [4]University of Münster, Germany; [5]Oak Ridge National Laboratory, United States

A fundamental understanding of the atomic structure and dynamics enabling fast ionic transport in solids is essential for the development of next-generation solid-state electrolytes (SSE). Focusing on the promising SSE candidate Li_6PS_5Cl with argyrodite structure, we resolve the coupling between fast diffusion of Li^+ and vibrational dynamics of the host framework through extensive inelastic and quasielastic neutron scattering measurements, combined with machine-learned molecular dynamics (MLMD) simulations based on first-principles data. Our results establish that host lattice vibrations enable an order-of-magnitude increase in Li^+ diffusivity at ambient temperature. Our experiments and simulations both show a clear overlap and interplay of hopping dynamics and vibrational frequencies in the terahertz regime, with a continuous spectral evolution from harmonic phonons to strongly anharmonic overdamped vibrations, and fast Li^+ diffusion. We identify the key degrees-of-freedom enabling fast Li diffusion as low-frequency dynamics of PS_4^{3-} polyanions, which are distinct from the commonly assumed "paddle-wheel" scenario. Bringing together neutron measurements and large-scale MLMD simulations, our results build a "beyond phonons" picture of complex atomic dynamics in SSEs in terms of overdamped spectral functions. These results offer microscopic insights into the mechanism of fast Li^+ diffusion in lithium argyrodites and provide guidance for the design of future SSE materials.

5:00 PM EN06.05.08
First-principles Study of Argyrodites Solid State Electrolyte for Battery Application Noah Fourby and Santosh KC; San Jose State University, United States

There is a growing research interest in identifying ideal solid electrolyte materials that is electrochemically stable and exhibit a very high ionic conductivity. Argyrodites are promising solid electrolytes as they demonstrate their high ionic conductivity at room temperature, low cost, and compatibility with Li electrodes. However, in order to realize its practical application, detailed ion conduction mechanism, defect chemistry, and interface properties need to be understood. Moreover, they are not stable as exposed to air and moisture, posing challenges during their manufacturing, and designing process. Thus, using Density Functional Theory (DFT), structural, electronic, and ionic properties are investigated. Thus, this study will provide significant insights into ion conduction mechanisms and strategies that can tune the ionic conductivity and stability of argyrodite-based electrolytes.
This project was supported in part by COE SJSU, DOE NERSC.

A Study on Correlation Between Ln Cation Size and Hydration Properties in Layered Perovskite Oxides Sihyuk Choi; Kumoh National Institute of Technology, Korea (the Republic of)

A discovery on novel triple ionic/electronic conductor (TIEC) oxide is vital to reduce the cathodic polarization resistance for high performance protonic ceramic fuel cells (PCFCs) due to its simultaneous triple (H^+/O2-/e-) conducting properties. Recently, layered perovskite $PrBa_{0.5}Sr_{0.5}Co_{1.5}Fe_{0.5}O_{5+d}$ cathode with chemical formula of $AA'B_2O_{5+d}$ (A = lanthanide, A'= alkaline earth element, and B = transition metal) has been used as TIEC material. Generally, the layered perovskite structures are formed by size different between A-site and A'-site ions, consisting of sequential stacking layers …[A'O]–[BO_2]–[AO_d]–[BO_2]… along the c-axis. Thus, oxygen ion diffusivity is particularly fast from the formation of disorder-free channel in $A(Ln)O_d$ layer. However, most previous studies have only focused on the Ln cation effect on electrical properties and oxygen kinetics. Therefore, the aims of this study is to systematically investigate on the hydration properties with various Ln ions. Furthermore, we studied on the thermodynamic parameters based on hydration properties and electrochemical performance for PCFC devices.

Micro-Mechanical Testing of Highly Air-Sensitive Argyrodite and Argyrodite-Zirconia Composites by *In Situ* Nanoindentation and Micro-Cantilever Bending Johann Perera, Dominic Melvin, Ed Darnbrough, Peter Bruce and David Armstrong; University of Oxford, United Kingdom

All-solid-state-batteries (ASSBs) pave the way for safe use of lithium-metal electrodes due to their use of a solid electrolyte (SE). Short circuit failure caused by the penetration of lithium dendrites, resulting in the fracture of SEs, remains one of the largest challenges facing ASSBs; it is therefore essential to gain a better understanding of the mechanical properties of SEs. Due to the highly air-sensitive nature of SEs conventional mechanical testing techniques are not possible and as a result very little is known about their mechanical properties.

In this work, the mechanical properties of Argyrodite, an air-sensitive sulphide, was investigated using in-situ nanoindentation inside an enclosed Argon glovebox system. Both Berkovich and cube-corner nanoindentation testing procedures were used to measure elastic, plastic and fracture properties. A modulus of 20.4 GPa, hardness of 960 MPa and a fracture toughness of 0.76 MPa $m^{1/2}$ was measured. It has been shown that lithium dendrites are able to plate intergranularly through SEs, along the grain boundaries, leading to transgranular fracture of the grains. This led to the question as to what is the grain boundary strength of these SEs? Using an innovative technique, the grain boundary strength was measured to be 91.1 MPa. This was achieved by preparing a pentagonal microcantilever containing a single grain boundary at its fixed end and by bending the free end using cube-corner nanoindentation. This value demonstrates the pressure which the Li metal must exceed to be able to ingress into the SE along the grain boundary.

Our initial results show that to further advance the performance of SEs, their fracture properties must be improved. To facilitate this, Argyrodite-Zirconia composites were made to increase the fracture toughness. Using the same nanoindentation testing procedures, the mechanical properties of these composites were investigated. As the proportion of Zirconia was increased, so did the modulus and hardness values, as predicted by the Voigt and Reuss models. The modulus increased to 29.6 GPa and the hardness to 1.35 GPa; as further Zirconia was added, both modulus and hardness decreased. This trend was also observed for fracture toughness with an improvement to 0.96 MPa $m^{1/2}$ being achieved. These improvements in mechanical properties are also accompanied by improvements in our initial electrochemical test results, which show that increasing the proportion of Zirconia raises the current density needed to induce lithium dendrites.

5:00 PM EN06.05.11
Mechanistic Elucidation of Electrostatic Solvent Interactions within Composite Solid Electrolytes, with *In Situ* Safety Study Annie Y. Sun and Vilas G. Pol; Purdue University, United States

Lithium-ion batteries (LIBs) have spread throughout modern electronics rapidly since the technology’s advent in 1991. Since 2010, energy storage costs associated with LIBs have plummeted 88% from $1,100/kWh to $132/kWh today. Larger-scale electrochemical energy storage via LIBs is instrumental to the goal of decarbonization via electrification (especially in storing intermittently generated renewable energy) due to their higher energy density and efficiency than mechanical or chemical energy storage. The large quantity of energy storage required for stationary grid-scale applications also represents energy which may become dangerous if the components exothermically degrade over time. Commercially available LIBs hinge upon ion intercalation reactions through a liquid organic carbonate electrolyte. Liquid electrolytes are combustible, cannot inhibit lithium dendrites caused by lithium metal heterogeneously plating, and possess a limited electrochemical window of oxidative and reductive stability.

In addition to safety issues, these conventional LIBs may soon reach a point of diminishing returns in gains in energy density with current materials. A solid electrolyte in place of the liquid electrolyte and separator may fundamentally address these shortcomings. Solid electrolyte materials generally have superior thermal safety and facilitate the use of the lithium metal anode with exceptional theoretical capacity of 3860 mAh g-1 . High interfacial impedance, imperfect solid-electrolyte interphase (SEI) formation, and low room-temperature ionic conductivity (σ) present challenges to many current solid-state systems. However, composite solid electrolytes comprised of a polymer electrolyte, lithium salt, and solid inorganic electrolyte have shown great promise in creating a high-performance solid electrolyte.

Though current work in composite solid electrolyte systems acknowledge the presence of liquid solvent remnants within the system which are trapped by the interactions between the polar solvents and the dissolved ions, there exists a substantial knowledge gap into the detailed mechanism behind Li+ transport and how this mechanism is influenced by the residual solvent’s electrostatic interactions and coordination with the Li+ compared to the strength of a polar polymer chain’s association. This work designs novel electrolyte systems with composite quasi-solid-state electrolytes in which classes of compounds including phosphate esters and phosphoramides may function as a plasticizer and as a fire retardant within the composite polymer matrix. Characterizations and electrochemical tests fundamentally shed light upon the effect of electrostatic interactions when the dielectric constant of the solvent is well-matched with that of the polymer's crystalline phases.

We have established working principles for electrolyte design in which the composite strategy is seamlessly integrated into the greater quasi-solid-state system, and we have validated the performance and lifespan of the developed CQSSEs in with a variety of cathode chemistries. Finally, we have conducted thorough in-situ safety studies of functional cells in order to validate the thermal stability and fire suppressing properties of specified class of polar solvents. This framework for rationalizing the interplay of these electrolyte components may present a broad opportunities for boosting the viability of electrolytes in the solid state.

The Cluster of Competence for Solid-State Batteries (FestBatt) Felix Hartmann and Jürgen Janek; Justus Liebig University Giessen, Germany

We would like to introduce the German Competence Cluster for Solid State Batteries (FestBatt) to the participants and give an overview of the previous and current work and results in FestBatt. Our main goal is to drive the transfer of results between FestBatt and the academic world as well as industry. Due to the size of the cluster (>170 scientists), only selected highlights on solid electrolytes (based on thiophosphates, oxides and polymers), hybrid cell concepts as well as scalability and processing methods of these materials and cell design will be presented.The poster will be structured into i) current scientific challenges for solid electrolytes and solid-state batteries, ii) recent highlights from FestBatt, and iii) outlook/perspectives

FestBatt is a German research network funded by the German Federal Ministry of Education and Research (BMBF, German: Bundesministerium für Bildung und Forschung) under the umbrella concept "Research Factory Battery".

https://festbatt.net/en

5:00 PM EN06.05.14
High-Conduction Argyrodite Solid Electrolyte with Air-Stable Oxidized Shell for All-Solid-State Batteries Jong-Hyuk Bae[1,2], So-Ri Lee[1], Yoon-Cheol Ha[1] and You-Jin Lee[1]; [1]Korea Electrotechnology Research Institute (KERI), Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)

All-solid-state batteries have been widely recognized as a promising next-generation battery because they can meet the growing demand for high energy density and safe energy storage systems. Sulfide-based solid electrolytes are one of the most effective types of solid electrolytes due to their superior Li-ion conductivity compared to other solid electrolytes. However, the low atmospheric and chemical stability of sulfides limits their large-scale applications. Previous studies have reported that the stability of sulfide-based solid electrolytes can be improved by replacing some of the sulfur with oxygen. However, it was difficult to simultaneously achieve high electrochemical stability and high ionic conductivity by introducing oxygen into the sulfide-based solid electrolytes.
In this study, we synthesized the halide-excess argyrodite, $Li_{6-x}PS_{5-x}X_{1+x}$, with high-conduction core and air-stable oxidized shell by oxidizing the surface of the argyrodite, and the atmospheric stability of the surface-oxidized solid electrolyte was compared to that of the oxygen-doped solid electrolyte. The surface oxidation of the argyrodites was investigated by depth profiling of X-ray photoelectron spectroscopy, confirming the formation of an oxidized shell

on the surface of the solid electrolyte.
The surface-oxidized electrolyte showed higher ionic conductivity (> 5 mS cm^{-1}) than the oxygen-doped one, and improved retention of ionic conductivity (> 80 %) after 24 h air exposure. Moreover, in terms of the electrochemical cell performance, they exhibited higher specific capacity and better cycle performance than oxygen-doped and pristine electrolytes.
Consequently, oxygen-substitution, especially surface-oxidation method is effective in improving air and electrochemical stability of sulfide solid electrolytes. The core-shell structure prevents the reduction of ion conductivity in air and maintains the argyrodite structure inside, resulting in improved cell performance in all-solid-state-batteries.

5:00 PM EN06.05.15
Lithium-Based Metal-Organic Frameworks as Quasi-Solid-State Electrolytes Pravalika Butreddy and Hemali Rathnayake; University of North Carolina at Greensboro, United States

Solid-state electrolytes (SSEs) are essential to developing high-voltage batteries for a crucial breakthrough in the development of electric vehicles. However, they have significant drawbacks, such as low ionic conductivities ($<10^{-5}$ S/cm) at room temperature, oxidation at high voltages, and large ionic transfer resistance. Recently, metal-organic frameworks (MOFs)-based SSEs have gained massive attention due to their ability to hold charged ionic species in their porous networks, which could facilitate faster ionic transport. Due to their unique features, such as porosity, high surface area, ordered channels, and modular designability, MOFs are used as unique host materials for designing SSEs. Incorporating lithium ions into MOF architectures was mainly performed by post-synthetic modification of the secondary building units or via the anion binding sites by creating open-metal sites. However, using pristine lithium-based MOFs as solid-state electrolytes has not been explored much. Herein, we have developed three isoreticular lithium-based MOFs using carboxylate linkers (Li-MOFs) through a solvothermal approach. The framework expansion approach was used to increase the porosity of Li-MOFs by keeping the same topology to obtain highly crystalline Li-MOFs with permanent porosity and a robust framework that facilitate lithium-ion conduction via the porous network. The structural, morphological characterization and ionic conduction of lithium ions in the presence of plasticizer solvents are studied to evaluate the potential applicability of these Li-MOFs as quasi-solid-state electrolytes for lithium-ion batteries.

5:00 PM EN06.05.16
High Performance of Ce-Doped $Li_7La_3Zr_2O_{12}$ Garnet Electrolyte for Solid-State Lithium Batteries Purna C. Rath[1], Yu-Syuan Jheng[2], Tai-Chou Lee[2] and Jeng-Kuei Chang[1,2]; [1]National Yang-Ming Chiao Tung University, Taiwan; [2]National Central University, Taiwan

Solid-state lithium batteries (SSLMBs), employing a composite solid electrolyte (CSE), with high energy density and enhanced safety are promising choices for next-generation energy storage devices. However, the high electrode/electrolyte interface resistance and poor Li^+ conductivity of the solid electrolyte are the major issues that severely hinder the SSLMB's performance. To reduce the interface resistance, a facile and cost-effective tape casting method was used to coat a 20 μm thick CSE directly onto a model $LiFePO_4$ (LFP) cathode. The tape-cast CSE can effectively percolate through the cathode layer, establishing Li^+ conduction pathways and enhancing the cathode/CSE interfacial contact. The effects of tape casting parameters, such as the polymer/Li salt ratio, oxide filler fraction, and casting thickness, on battery performance are examined. The advantages of a tape-cast CSE over a freestanding CSE in terms of reducing the interface resistance and increasing the specific capacity of LFP are clearly revealed. To increase Li^+ conductivity, we synthesize $Li_7La_3Zr_{2-x}Ce_xO_{12}$ (LLZCO), ($x = 0–0.15$) with various Ce concentrations and use the resulting CSEs for a full-cell study. LLZCO−0.10 is the optimal composition among the Ce-doped samples in terms of the charge transfer resistance, charge–discharge capacities, and rate capability of the cell. The Ce doping also improves cell cycling stability, suggesting that Ce^{4+} at the Zr^{4+} site can mitigate the Zr^{4+} reductive decomposition upon contact with the Li metal electrode. We believe that the proposed interface enhancement and Ce doping strategies are feasible and cost-effective for greatly increasing SSLMB performance.

5:00 PM EN06.05.17
Proton Ceramic Fuel Cells with Thin Film ZnO-$BaZr_{0.2}Ce_{0.6}Y_{0.1}Yb_{0.1}O_{3-d}$ Composite Electrolyte Heon Jun Jeong, Dong Hwan Kim, Keun Hee Kim and Joon Hyung Shim; Korea University, Korea (the Republic of)

Solid oxide fuel cells (SOFCs) have advantages such as fuel flexibility and high efficiency. Recently, study of proton ceramic fuel cells (PCFCs) where an electrolyte contains protons has been actively conducted. Compared with SOFCs, the PCFCs has the advantage with a relatively low activation energy (<0.5 eV) producing high power at low operating temperatures below 600°C. Currently, majority of PCFCs electrolyte materials is barium-based materials including Y:$BaZrO_3$ (BZY), Y:$Ba(Zr,Ce)O_3$ (BZCY), (Y,Yb):$Ba(Zr,Ce)O_3$ (BZCYYb). However, due to the relatively low grain-growth of those Ba-based materials, problems of poor bonding and mechanical instability frequently occur in many of previous reports. In particular, this can cause low OCVs and gas leakages in thin-film-based PCFCs. In this study, the performance of thin-film BZCYYb electrolyte-based PCFCs with ZnO sintering agent was evaluated. Based on the slurry of ZnO-added $BaZr_{0.2}Ce_{0.6}Y_{0.1}Yb_{0.1}O_{3-d}$ (BZCYYb2611), an electrolyte thin film of about 5 μm thickness was prepared by spin-coating technique. As a result, it was confirmed that the grain growth of the ZnO-added electrolyte was significantly improved and the density was also increased. The sintering temperature is 1300$^{\text{o}}$C, which is 50°C lower than the optimal sintering temperature of BZCYYb, 1350°C. OCV showed a result close to the theoretical value at 500°C to 1.1V or more. The fuel cell output was also measured to about 0.5W/cm^2 at 500°C, confirming improvement up to 50% compared to BZCYYb-based PCFCs in the same conditions except the electrolyte material. In this presentation, we will discuss more specific results of this improved PCFCs with the ZnO-BZCYYb thin film composite electrolytes.

Liquid Crystals for Increased Ionic Conductivity in Solid Polymer Electrolyte for Lithium Metal Batteries Isaac Alvarez Moises and Jean F. Gohy; Catholic University of Louvain, Belgium

The forefront of research for new electrolyte materials for tomorrow's electrochemical energy storage technologies is based on thoroughly designed molecular architectures. Nanostructured, uncharged liquid-crystalline molecules having schiff base and cyano moieties have been developed for application in lithium-metal batteries as solid electrolytes. In this line, we report herein the development of a new class of polymer electrolytes. We designed a poly(ethylene oxide) based matrix comprising liquid crystals, which give orientational properties, whereas the ethylene oxide chains are responsible for the ionic conductivity. Furthermore, the introduction of liquid crystals is anticipated to improved simultaneously the lithium-ion transference number and the dynamic stability of the interface between the solid polymer electrolyte and lithium anode. The approach is to enhance the ionic conductivity, which obeys Arrhenius-type, via ion hopping along the amorphous structure in an ordered morphology, resulting from the assembly of the orientated mesogens and the flexible ethylene oxide chains. The designed polymer matrix and liquid crystals are miscible with lithium bis(trifluoromethanesulfonyl) imide (LiTFSI) salt up to 10:1:1 in molar ratio, and forms self-standing films with a conductivity of $1.8*10^{-4}$ $S*cm^{-1}$ at 60 °C. Focusing on the understanding of the structure-to-transport interplay and the demonstration of the proof-of-concept, we provide also strategies for their further development.

Effect of Oxygen Vacancies in Inorganic Fillers on the Performance of Composite Solid Electrolytes for All-Solid-State Li-Metal Batteries Heejun

Yun, Jinil Cho, Seonmi Pyo, Heebae Kim and Youn Sang Kim; Seoul National University, Korea (the Republic of)

All-solid-state Li-metal batteries (ASSLBS) are one of the most promising candidates for next-generation rechargeable batteries. Liquid electrolytes, which trigger the burning and explosion in conventional Li-ion batteries, are replaced with solid-state electrolytes in ASSLBs. These solid electrolytes make ASSLBs safer and more densely packable. Moreover, the solid electrolytes physically suppress the dendritic growth of Li-ion that penetrates the separator and finally causes cell failure. In detail, solid electrolytes are divided into three types: solid polymer electrolytes (SPEs), inorganic solid electrolytes, and composite solid electrolytes (CSEs). Among these three candidates, CSEs are the most fascinating components for ASSLBs. CSEs, which consist of SPEs and inorganic fillers, have all advantages (e.g., processability, chemical tunability, and cost-effectiveness) of solid polymer electrolytes in addition to the high ionic conductivity (10-10^2 folds than SPEs). However, the performance and stability improvement of the CSEs are stuck in a rut because of the complicated Li-ion conduction mechanism and properties in the CSEs.
Herein, we introduce that the oxygen vacancy (O_{vac}) in inorganic filler dominates the performance of the CSEs by creating a Li-ion-conduction percolation network. The highly ionic conductive (2.8×10^{-4} S cm^{-1} at 40 °C) and electrochemically stable CSEs are fabricated with poly(ethylene oxide) (PEO) and indium tin oxide nanoparticles (ITO NPs). In this CSE, the O_{vac}-rich ITO NPs immobilize the anion of the Li salt and make the Li ions conduct rapidly. Density functional theory (DFT) calculation of the binding energy between ITO NPs and anion of the Li salt verify the anion immobilization effect of the O_{vac} in ITO crystals. Furthermore, a series of electrochemical analysis and characterization tools (e.g., FT-IR, DSC, and solid-state magic angle spinning Li NMR) confirm the existence of a highly conductive PEO–ITO NP interface. Based on percolation theory, we demonstrate that the free Li ions, induced by ITO NPs, construct a Li-ion-conduction percolation network on PEO–ITO NP interface and enhance the electrochemical performance of the CSE. Also, the doubled Li transference number and long cycled Li symmetrical cell data (1204 cycles at 0.1mA cm^{-2}) verify that the introduction of O_{vac}-rich ITO NPs make a stable Li-ion flux in CSEs, even though ITO NPs cannot self-conduct Li ions (acting as passive filler). As a result, the LFP/CSE/Li cell exhibited unprecedented cycle stability and performance (154 mAh g^{-1} at 0.5C after 700 cycles). Furthermore, via UV-ozone oxygen-vacancy modification of the ITO NP surfaces, we directly confirmed that the O_{vac} of the inorganic filler governs the ionic conductivity of CSEs through the construction of Li-ion-conducting percolation networks. This fundamental finding of PEO–inorganic filler properties suggests a breakthrough that develops the advanced composite solid electrolyte and ASSLBs, which are practically usable.

Influence of Al/Ta Co-Doping by Molten Salt Synthesis Method on Li-Ion Conductivity of $Li_7La_3Zr_2O_{12}$ Solid Electrolyte Haeun Kang, Ji Hyeok Choi, Min wook Kim and Young Soo Yoon; Gachon University, Korea (the Republic of)

Oxide solid electrolytes with excellent lithium-ion conductivity and low interfacial resistance are essential for the development of lithium-ion battery as well as thermal battery and all solid state battery. In this study, we discuss molten salt synthesis (MSS) method for co-doped $Li_7La_3Zr_2O_{12}$ (LLZO) that can improve the Li ion conductivity of conventional oxide-based solid electrolytes. The synthesis method based on LiCl-KCl molten salt is easier to form the desired phase in a relatively short time and at a lower temperature than conventional solid-phase synthesis [1],[2]. MSS method has the disadvantage of forming an impurity phase during multi-component synthesis, but this can be overcome by Al/Ta co-doping. In addition, Al/Ta co-doping can theoretically induce more Li vacancies, and suppress 97h site substitutions that interfere with lithium ion conductivity during Al single doping. Particularly, the path of Li ions is expanded by inducing displacement to the Li 24d site. The production of pure cubic LLZO phases was carried out in the range of 900°C to 1000°C with a calcination process of less than 4 hr. The synthesized powder was pelletized and subjected to a heat treatment process for densification at 900°C for 6 hours. The morphology of the samples was revealed by scanning electron microscopy (SEM) and transmission electron microscopy (TEM) and the phase structure was characterized by X-ray diffraction (XRD). Li^+ conductivity was measured using Electrochemical Impedance Spectroscopy (EIS) in the frequency range of 10 Hz to 1 MHz The LLZO fine powder co-doped with Al/Ta by the MSS method was found to be particles 0.5 to 3 μm smaller than the similarly developed Al-LLZO and Ta-LLZO. As a result, the ion conductivity was $1 \sim 3.0 \times 10^{-4}$ S cm^{-1}, and a small amount of Al/Ta co-doping was sufficient to impart stability to the garnet structure of LLZO. This study demonstrates the possibility of a co-doping effect to deepen the understanding of the solid electrolyte prepared by the MSS method and improve the lithium ion conductivity.

***In Situ* and *Operando* XPS and Related Measurement Approaches for Interfacial Studies of Solid-Electrolyte Materials for Battery Applications**
Glenn Teeter; NREL, United States

In recent years there has been growing interest around *in situ* and *operando* approaches for studying interfacial phenomena, including charge- and mass-transfer processes relevant to solid-electrolyte systems and battery technologies in general. Laboratory-based X-ray photoelectron spectroscopy (XPS) and scanning Auger microscopy (SAM) are powerful techniques for analyzing surfaces and interfaces to reveal compositions and chemical states, including depth profiling and 2D mapping experiments. This presentation will discuss recent efforts by researchers at the National Renewable Energy Laboratory (NREL) to apply *in situ* and *operando* approaches to probe interfacial charge transfer and phase transformations relevant to the formation and evolution of the solid-electrolyte interphase (SEI) on novel solid-electrolyte materials. These experiments are enabled by the virtual electrode (VE) approach, in which electrochemical currents are driven during VE-XPS measurements on exposed interfaces via a combination of low-energy Li^+ ion and electron guns and ultraviolet-based photoemission.

8:45 AM EN06.06.02
A Two-parameter Space to Tune Solid Electrolytes for Lithium Dendrite Constriction Yichao Wang, Luhan Ye, Xi Chen and Xin Li; Harvard University, United States

Li dendrite penetration and associated microcrack propagation at high current densities is one main challenge to the stable cycling of solid-state batteries. The interfacial decomposition reaction between Li dendrite and solid electrolyte was used to suppress the Li dendrite penetration through a novel effect of "dynamic stability" recently. Here we use a two-parameter space to classify electrolytes and propose that the effect may require the electrolyte to occupy certain region in the space with a principle of delicately balancing two property metrics of both a sufficient decomposition energy with Li metal and a low critical mechanical modulus. Furthermore, we show that the position of electrolytes in such a space can be controlled by their chemical composition in our computational prediction by a combination of high-throughput computation and machine learning, with the compositions attainable by experimental synthesis through core-shell microstructures as well. The designed electrolytes following this principle further demonstrate a stable long cycling of 10,000 to 20,000 cycles at high current densities of 8.6 ~ 30 mA/cm^2 in solid state batteries, while in contrast the control electrolyte with nonideal position in the two-parameter space shows a faster capacity decay by at least an order of magnitude due to Li dendrite penetration.

Direct Measurements of Dendrite-Induced Stresses in Ceramic Electrolytes *via* Photoelasticity Christos E. Athanasiou[1], Cole D. Fincher[2], Craig Carter[2], Huajian Gao[3], Yet-Ming Chiang[2] and Brian Sheldon[4]; [1]Georgia Institute of Technology, United States; [2]MIT, United States; [3]Nanyang Technological University, Singapore; [4]Brown University, United States

The measurement of stress fields around lithium metal protrusions in solid electrolytes in operating conditions is critical for the design of next-generation, dendrite-resistant solid electrolytes. However, such stress measurements entail inherent experimental difficulties associated with acquiring accurate data at small scales in thin ceramic electrolytes.

By employing the principle of photoelasticity combined with electrochemical cycling in a plan- view cell the aforementioned challenges are bypassed, allowing not only to track the stress field as the dendrite events progress, but also to obtain full field stress information on a propagating dendrite in semi-transparent LLZTO electrolyte. This new experimental methodology allows for 1. quantification of the stress fields around the dendrite tip and 2. clear verification that the stress field observed at the experiments can be explained by linear elastic fracture mechanics.

Li$^+$ Conductivity Landscape in Lithium-Containing Argyrodites as a Function of Co-Doping on Lithium and Sulfur Sublattices Sokseiha Muy and Nicola Marzari; Ecole Polytechnique Federale de Lausanne, Switzerland

Lithium-containing Argyrodites with the parent phase Li_7PS_6 are among the most promising materials for solid-state ionic conductors in the next generation all-solid Li-ion battery. This material not only exhibits remarkable room-temperature ionic-conductivity (up to 24 mS/cm) but also great chemical flexibility, affording aliovalent substitutions on both anion and cation sublattices. In this talk, I will present detailed molecular dynamics simulations using the DeepMD neural network potentials trained on first-principle molecular dynamic data. The 'ionic conductivity landscape' of Li-containing argyrodites will be presented as a function of cation and anion doping on the Li- and S-sublattices with particular emphasis on the effect of the host lattice configurations on the computed ionic conductivity. The reliability of the trained neural network potentials with respect to the size and diversity of the training data will also be discussed. Finally, the extensive data from molecular dynamics trajectories will be analyzed along with the correlation analysis to shed new light on the mechanistic origins and the impact of various physical and chemical factors on the high mobility of Li-ion in this family of compounds.

The Mechanism by Which a Ag-Carbon Buffer Layers Improves Li Plating in Solid-State Batteries Gerbrand Ceder[1] and Howard Tu[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]Rochester Institute of Technology, United States

Recently, it has been shown that the introduction of a carbon+Ag buffer layer between the solid-state electrolyte and a current collector leads to highly efficient and uniform Li plating [1-2]. The mechanism by which the buffer layer improves Li plating is not well understood, and the current hypothesis attributing this to the different adhesion energy of the buffer layer with the solid electrolyte and current collector is almost certainly not correct.
In this presentation we report on a combined continuum + ab-initio modeling effort to understand how Ag nanoparticles regulate the Li nucleation and growth. The understanding from this work also enables a rational selection of which other metals may or may not work.

Synthesis and Characterization of Halide Solid State Electrolytes and Their Integration in All-Solid State Batteries Julien Porcq[1,2,3], Virginie Viallet[1], Jérémie Auvergniot[3] and Claude Guéry[1]; [1]Laboratoire de Réactivité et Chimie des Solides (LRCS), France; [2]Centre National de la Recherche Scientifique (CNRS), France; [3]Umicore, Belgium

Ionic conduction in a solid was first observed by M. Faraday in 1833 on silver sulfide[1]. This discovery launched a series of studies on ionic conduction in this family of solids. In the 1920s, the conductivity of the lithium ion in one of the simplest halogenated solids, LiCl, was calculated using different equations[2]. After several years of research to master the concepts of conduction in solids and to develop different measurement methods, solid halogenated electrolytes such as $RbAg_4I_5$ or LiI made it possible to build the first all-solid batteries[3]. As all-solid lithium batteries were developed, halogenated electrolytes were abandoned in favor of sulfides, oxides and polymers which, among other advantages, have much higher ionic conductivity[4]. However, this family of electrolytes is experiencing renewed interest in 2018 with the research of Asano *et al.* who succeeded in synthesizing Li_3YCl_6 and Li_3YBr_6 compounds and integrating them into all-solid state batteries[5]. These compounds stand out from other halide electrolytes reported until now, by demonstrating an ionic conductivity of the order of magnitude of mS/cm. This discovery has led to other good solid halide ionic conductors such as Li_3InCl_6[6], Li_3ErCl_6[7], Li_3YbCl_6[8], ou Li_3ScCl_6[9].
In this work, several halide electrolytes have been successfully synthesized including Li_3InCl_6, Li_3YCl_6, Li_2ZrCl_6, $LiAlCl_4$. The method used was mainly ball milling, whose parameters were adjusted and refined for the compound Li_2ZrCl_6. The ionic conductivities of these compounds were measured, the best

result obtained was for Li_3InCl_6 with an ionic conductivity of the order of 1 mS/cm at room temperature. It was also shown that this electrolyte was unstable against lithium metal, forming a Li-In alloy, this phenomenon has also been reported in the literature[10]. A full NMC811 *vs* Li-In battery has also been assembled with this electrolyte.

Extending Electrochemical Window of Na^+ Halide Solid Electrolyte for All-Solid-State Na Ion Battery Juhyoun Park, Jun Pyo Son, Yeji Choi, Hiram Kwak and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

All-solid-state Na ion batteries (ASNBs) using inorganic solid electrolytes (SEs) have attracted much interest owing to their combined potential advantages of improved safety and cost, compared to conventional lithium-ion batteries with flammable liquid electrolyte. Most studies on Na^+ SEs have focused on increasing ionic conductivity. Meanwhile, sulfide Na^+ SEs are highly attractive because they can be easily integrated into ASNB cells by simple cold-pressing-based fabrication. However, sulfide SEs are limited in operating low-voltage batteries due to their electrochemical instability over 2.5 V region (*vs.* Na/Na^+), which thus hinders achieving high energy density of ASNBs.
To alleviate this shortcoming, Na^+ halide SEs for 3 V class ASNB cells with $NaCrO_2$ have also been reported, but the number of the experimental reports is only a few: $NaAlCl_4$, Na_2ZrCl_6, $Na_{3-x}Er_{1-x}Zr_xCl_6$, and $Na_{3-x}Y_{1-x}Zr_xCl_6$.
In this presentation, our recent results on the development of new Na halide SE using interfacial Na^+ ion conduction with wide electrochemical window. Application to all-solid-state Na^+ ion batteries with operating voltage of 1.5-5.0 V (vs. Na/Na+) will be also presented.

Robust and Scalable Thin-Film Solid Electrolytes Processed in Open-Air Nicholas Rolston[1], Mohammed Sahal[1], Jie Molloy[2] and Xiaochuan Lu[2]; [1]Arizona State University, United States; [2]North Carolina A&T State University, United States

The ability to store electrical energy safely and inexpensively is a key component of future energy systems, long-range electric vehicles (EVs), and long-lasting electronics. Current Li-ion batteries employing liquid organic electrolytes have significant drawbacks in safety, reliability, capacity, and lifetime. Solid electrolytes (SEs) can replace flammable liquids, display improved (electro)chemical stability, and provide a physical barrier against short circuits caused by lithium dendrite propagation, leading to improved safety, prolonged battery life, and increased energy density. There has been increased focus by battery manufacturers and the automotive industry on the development of SEs and solid-state batteries (SSBs). However, a major obstacle to the commercialization of SEs and its implementation into SSBs is the inability to easily and scalably form thin films of this material with suitable ionic conductivity, mechanical, and interfacial properties to achieve SSBs with the desired cycling performance.
In this work, we process $Li_{0.3}La_{0.567}TiO_3$ (LLTO)as a thin film solid electrolyte due to improved air and moisture stability compared to other SEs. A scalable blade coating process is used with a rapid thermal sintering process at 1100 °C for 1 minute in ambient conditions to form dense and highly crystalline LLTO films. We perform cross-sectional backscattered electron imaging with microprobe analysis to detect the composition of the individual elements in the film. The film is fully dense with some noticeable segregation between lanthanum-rich and titanium-rich phases. A thin (~ 10 nm) surface layer that is carbonate rich is identified based on X-ray photoelectron spectroscopy. We introduce an open-air plasma system that has a reductive environment through the injection of forming gas to remove the carbonate layer and allow subsequent processing of a lithiated cathode with improved interfacial ion transport in anode-free all solid-state batteries. The resulting ionic conductivity of the SE as measured by impedance analysis is $1.1*10^{-4}$ S/cm, a value which is among the highest reported for undoped LLTO films. Furthermore, the LLTO film has a fracture toughness of ~20 J/m^2—a key metric for reliability—placing it among the most robust electrolytes and demonstrating promise for stable batteries.

Accelerating Materials Discovery for Solid-State Batteries via High-Throughput Computation and Automated Laboratory Yan Eric Wang[1,2] and Valentina Lacivita[2]; [1]Samsung Advanced Institute of Technology-America, United States; [2]Samsung Semiconductor Inc., United States

Solid-state batteries have attracted tremendous academic and industrial attention as the likely successor to lithium-ion batteries. The key component of solid-state batteries is the solid-state electrolytes with high ionic conductivity and great interfacial stability against battery electrodes [1]. Traditional discovery of solid-state electrolyte materials for high ionic conductivity often proceeds based on trial-and-error without an understanding of underlying structure-composition-property relationships, and so far only a handful of lithium and sodium conductors have been discovered with desired conductivity.

Computational modeling based on density functional theory has become a cornerstone of materials design, by providing insights into fundamental processes that are not easily accessible in experiments, and enabling fast and efficient prediction even before material synthesis. Such predictive power has made computational modeling a critical tool to design new solid-state ionic conducting materials with desired properties and accelerate the development of next-generation batteries with solid-state electrolytes.

In this talk, I will present our recent findings in the physical and chemical design principles for solid-state materials with high ionic conductivity and stability. More specifically, I will discuss crystallographic features which would enable fast ionic transport in inorganic solids, such as body-centered-cubic in sulfides and corner-shared-polyhedron frameworks in oxides [2], and demonstrate how high-throughput calculations can be applied with such features in the design and discovery of ionic conductors [3]. I will also discuss our most recent efforts at Samsung Advanced Materials Lab, where we are developing tools for inorganic battery materials discovery by combining high-throughput computation and automated laboratory.

Identification of Potential Solid-State Li-Ion Conductors with Semi-Supervised Learning Daniel B. McHaffie, Forrest Laskowski and Kimberly See; California Institute of Technology, United States

All-solid-state batteries (ASSBs) are a promising technology to enable enhanced safety, energy density, and power density over conventional Li-ion batteries [1]. Crucial to the operation of ASSBs is a stable Li-ion solid-state electrolyte (SSE) with ionic conductivity comparable to that of conventional liquid electrolytes. Although an SSE with these required properties has yet to be discovered, thousands of known Li-containing materials remain unexplored. In this work, we utilize a semi-supervised learning approach to accelerate the identification of superionic conductors.

We construct a repository containing the experimental ionic conductivities of 1,346 compounds digitized from over 300 publications. Each of the ~26 000 Li-containing materials from the Inorganic Crystal Structure Database and Materials Project is represented using 180 unique descriptor-simplification combinations. Agglomerative clustering is performed, and experimental conductivity values are used as labels to evaluate the effectiveness of each descriptor. A particular spatial descriptor, Smooth Overlap of Atomic Positions, is found to minimize composite intracluster conductivity variance, indicating a strong correlation to ionic conductivity. By examining high-conductivity clusters, 212 previously unexplored candidate materials are identified. Through additional screening using bond-valence site energy and nudged-elastic band calculations, Li_3BS_3 is chosen as a promising compound for experimental validation. We demonstrate that with defects engineered through aliovalent substitution and high-energy ball milling, Li_3BS_3 exhibits a room-temperature conductivity greater than 1 mS cm^{-1}. The described semi-supervised learning method for assessing descriptor performance and identifying novel materials can be broadly applied for expediting materials discovery.

2:15 PM EN06.07.03

Thermodynamics of the Fast-Conducting Li_3PS_4 Polymorphs from First Principles Ronald Kam[1,2], KyuJung Jun[1,2], Luis Barroso-Luque[2], Julia Yang[3], Fengyu Xie[1,2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Harvard University, United States

We present a first principles study of phase stability among the three Li_3PS_4 polymorphs (γ, β, α), among which the high temperature β and α phases have been demonstrated to be promising Li superionic conductors.[1] Despite experimental confirmation of phase transitions among these polymorphs, it is not yet understood why β can be stabilized at room temperature.[2] To model phase stability in this system, we treat configurational entropy contributions with density functional theory (DFT) calculations and the cluster expansion method, and vibrational contributions with harmonic phonon calculations. Analysis of DFT relaxations clarifies the nature of Li sublattices and ground state orderings. We predict $\gamma \rightarrow \beta$ and $\beta \rightarrow \alpha$ phase transition temperatures that are in good agreement with reported experimental values upon heating.[2] We find a strong competition between γ and β phases, rationalizing the direct $\alpha \rightarrow \gamma$ transition observed upon cooling, as well as the synthetic accessibility of β at room temperature. Configurational and vibrational sources of entropy are also separately examined and quantified. Our theoretical work provides clear thermodynamic understanding which can guide further experimental efforts in stabilizing the superionic conducting α and β Li_3PS_4.

Dynamics Design of Solid Electrolytes for Solid State Batteries Xin Li; Harvard University, United States

Solid state battery is a mechanically more coupled device than the commercial liquid electrolyte Li-ion batteries. Mechanical constriction effect strongly modulates the electrochemical stability at all interfaces in a solid-state battery. This effect introduces some unique dynamical evolution of interface reactions upon battery cycling, understanding of which is challenging but also giving us an opportunity to design the battery performance beyond commercial Li-ion batteries. The talk discusses the design of "dynamic stability" at the electrolyte-electrode interfaces for a stable long cycling of Li metal anode solid state batteries, where Li dendrite penetration and cathode interface decomposition can be suppressed through this dynamic process. High-throughput ab initio computation, machine learning, and microstructure morphology control are used to design electrolyte compositions with enhanced dynamic stability. In the end, an anharmonic cation-anion coupling dynamics for enhanced Li-ion conductivity in sulfide solid electrolyte is also discussed.

4:00 PM EN06.07.05
Tuning Ionic Conductivity and Stability of Superionic Solid-State Electrolyte Tung Dang and Santosh KC; San Jose State University, United States

All-solid-state Li-ion batteries gained huge attention because they exhibit higher power density, wider electrochemical stability windows, and overall safety of solid-state electrolytes (SSE) compared to conventional liquid electrolyte-based batteries. Unfortunately, most of the SSE materials have not matched the ionic conductivity of their liquid counterpart. But, recent research and the synthesis of new materials have shown SSE can conduct ions at an equivalent or even higher rate. However, the electrochemical stability needs to be improved. There is a growing research effort in identifying a solid electrolyte that is both electrochemically stable and has a very high ionic conductivity. The $Li_{10}GeP_2S_{12}$ (LGPS) is one of the superionic conductors, is known for its high ionic conductivity that can be deployed as a solid electrolyte in batteries. However, LGPS is not stable as exposed to air and moisture, posing challenges during its manufacturing, and designing process. Thus, in an attempt to optimize the stability and ionic conductivity, the effect of antimony (Sb), tin (Sn), and oxygen (O) substitution on the conductivity and stability of LGPS is investigated using Density Functional Theory (DFT). The systematic study of compositional variation, phase stability, defects chemistry, and the impact on electronic properties and ionic conductivity is performed. Thus, this study will provide significant insights into ion conduction mechanisms and strategies that can tune the ionic conductivity and stability of LGPS-based electrolytes.

Synthesis and Characterization of Sodium Anti-perovskite Ion Conductors for Solid State Batteries Adolfo Urrutia[1,2,3], Jérémie Auvergniot[3], Jean-Noël Chotard[1,4] and Raphaël Janot[1,2]; [1]Laboratoire de Réactivité et Chimie des Solides (LRCS), France; [2]Centre National de la Recherche Scientifique (CNRS), France; [3]Umicore, Belgium; [4]Université de Picardie Jules Verne, France

In 2020, 23 countries and states have announced bans on fossil fuel vehicles within the next couple of decades.[1] Current lithium-ion technologies present both gravimetric and volumetric energy density limitations.[2] These limitations can be overcome by the use of solid electrolytes and metallic anodes in all solid-state batteries.[2] Inorganic solid electrolytes can be classified into 4 main categories, oxide, sulfide, halide, and anti-perovskites, each with their own pros and cons.

The first anti-perovskites date back to 1915 and are the combination of alkali halides and their hydroxides.[3] Furthermore in the late 1900s, Jansen et al. reported the first ionic conductivities for Na-ion anti-perovskites on the order of 10^{-5} S/cm at 480 K.[4,5] Throughout the last decade, Na-ion anti-perovskites have been studied with reported conductivities between 10^{-2} to 10^{-9} S/cm at room temperature.[6] Through tailoring of the anti-perovskite crystal structure and composition, it is believed that the migration barrier for Na-ion hopping can be reduced, facilitating Na-ion motion through the structure.[7]

Because the perovskite and hence the anti-perovskite structure is so versatile, there are many different material compositions that can be studied. The anti-perovskites with most interest have been those with the simple X_3BA composition. Recently, interest has been drawn to anti-perovskites found in nature, ex: Kogarkoite $Na_3(SO_4)F$.[8]

In this work, we have studied various new and existing compositions of anti-perovskites and measured their ionic conductivities for use in solid state batteries. Some of the compositions studied include the new sulfate hydride Na_3SO4H[9], $Na_2(Ca/Mg)PO_4F$ isostructural to existing Na_2MPO_4F cathode materials, and $Na_3(S/SeO_4)(F/Cl)$. Recently, a new composition has been synthesized with conductivities around 10^{-3} S/cm at RT, a promising value for use as solid ionic conductors.

Ionic Glass Electrolytes—The Role of Medium Range Order in Mechanics and Ion Conduction Andrew S. Westover[1], Sergiy Kalnaus[1], Nancy Dudney[1], Mordechai Kornbluth[2], Takeshi Egami[3,1] and Andrew Kercher[1]; [1]Oak Ridge National Laboratory, United States; [2]Robert Bosch LLC., United States; [3]The University of Tennessee, Knoxville, United States

One of the most intriguing classes of solid-state electrolytes is the family of ionic glasses. Ionic glasses are glasses that are primarily bound together with ionic bonds such as amorphous Li_3PO_4 and amorphous Li_4SiO_4 of which LiPON is the most well-known. Here we provide an in-depth structural characterization of the amorphous ionic glasses LiPON and LiSiPON with high Li content. Based on ab-initio molecular dynamics simulations, the structure of these materials is identified as an inverted glass structure with either isolated polyanion tetrahedra or polyanion dimers suspended in a Li^+ matrix. Based on neutron scattering data, this type of inverted structure leads to a significant amount of medium-range ordering as demonstrated by neutron total scattering. Further analysis highlights correlations between the degree of medium range order and the ionic conductivity and mechanical ductility. The combination of tunable ionic conductivity and ductility, has significant implications for solid electrolyte design that can enable next generation high-energy high-power solid state-batteries.

Functionalized and Surface Coated Fillers as Innovative Strategies for Realizing Li/Na Metal Solid-State Polymer Batteries Shanmukaraj Devaraj and Michel Armand; CIC Energigune, Spain

Solid-state batteries using alkali metal anodes are the future for next generation of automotive batteries. The development of Li and Na metal solid-state batteries requires efficient electrolytes to improve the performance of the cells in terms of ionic conductivity, electrochemical stability, interfacial compatibility and last but not the least, the mechanical stability for resilience towards dendrite formation that is a prime inhibiting factor for Li metal batteries.

To realize these targets two innovative approaches will be presented. Firstly, Solid Polymer Electrolytes (SPEs) with new functionalized ethyl cellulose

bearing a lithium/sodium fluorosulfonylimide group (Ethyl cellulose-LiFSI/NaFSI) is proposed as quasi single ion (Li^+/Na^+) conducting polymer electrolyte for all-solid-state lithium and sodium batteries. The functionalization enables a multifunctional strategy taking up the role of Li/Na salt, improving transference number as well as providing mechanical and electrochemical stability. The complex of Li(FSI-ethyl cellulose)/PEO exhibits a Li-ion transference number of $t_{Li}+ = 0.9$, and a Na ion transference number of $t_{Na}+ = 0.6$ for Na(FSI-ethyl cellulose),which are much higher than those reported for ambipolar LiFSI or NaFSI/PEO SPEs under the same measurement conditions. The generated SPEs showed a high electrochemical and mechanical stability as well as a practical ionic conductivity value of ~10^{-4} Scm^{-1} at 80 °C. All solid-state lithium, sodium and Li/Sulfur cells cycled with quasi single ion conducting hybrid SPE exhibit reversible cycling and good performance at 70 °C, making them promising, environmentally benign and cost-effective candidates for use in advanced energy storage systems.
In the second approach we have shown the surface modification of Ga-substituted $Li_7La_3Zr_2O_{12}$ (LLZO) with grafted polymers to be an essential strategy for the preparation of ceramic-rich electrolytes. Ceramic-rich polymer membranes with surface-modified LLZO show marked improvements in the quality of the membranes along with improvement of performance, in terms of electrolyte physical and electrochemical properties, as well as coulombic efficiency, interfacial compatibility, and cyclability of Li metal solid-state cells.

High-Performance Single-Ion Polymer Conductors for Solid-State Lithium Metal Batteries Kaihua Wen, Shundong Guan, Ce-Wen Nan and Liangliang Li; Tsinghua University, China

Solid-state lithium (Li) metal batteries (SSLMBs) have attracted much research interest due to safety and high energy density. It is necessary to develop solid electrolytes with large ionic conductivity, high Li-ion transference number, and good compatibility with electrodes for SSLMBs. One drawback of the traditional dual-ion polymer conductors is the low Li-ion transference number, which causes unwanted polarization in SSLMBs. In this work, we developed a single-ion polymer conductor (SIPC) with carbonyl and cyano groups. When the ion–dipole interactions between Li ions and carbonyl/cyano groups were precisely tuned, the SIPC possessed an excellent selectivity for Li-ion conduction (the Li-ion transference number was more than 0.9), a high room-temperature ionic conductivity of about 10^{-4} S cm^{-1}, a wide electrochemical stability window (>4.5 V, vs Li/Li^+), and a good electrochemical stability with Li metal during long-term cycling at 26 and 60 °C. With the optimized SIPC, $LiFePO_4$-based SSLMBs showed good rate and cycle performance in a wide temperature range from -20 to 90 °C. Using the same method, we also prepared sodium- and potassium-based SIPCs with high ionic conductivity and high cationic transference numbers. Thus, tuning the ion–dipole interactions in SIPCs is an effective way to enhance the electrochemical properties of solid polymer electrolytes.

10:45 AM EN06.08.02
Light-Induced Lattice Dynamics in Solid-State Electrolyte LLTO Jackson D. McClellan[1,2], Alfred Zong[2], Hanzhe Liu[3], Kim Pham[3], Scott K. Cushing[3] and Michael Zuerch[2]; [1]The Ohio State University, United States; [2]University of California, Berkeley, United States; [3]California Institute of Technology, United States

Conventional Li-ion batteries offer less safety and energy density compared to solid-state batteries. However, poor ionic conductivity in many solid-state batteries hinders its practical use in modern energy storage. Characterization of the origin of these effects, which come from the interaction of Li^+ ions with the atomic lattice, is important for the design and improvement of future solid-state batteries. One current electrolyte that is electrochemically stable and has demonstrated a sufficient ionic conductivity at high temperature is lithium lanthanum titanate (LLTO). Because it only demonstrates sufficient conductivity under heat, identifying the properties of this temperature-induced transition of the solid can reveal the direct affects lattice dynamics on conductivity, leading to improved understanding of which structural characteristics are important in solid-state electrolytes for future batteries. Here, we have performed time-resolved x-ray diffraction using the Advanced Photon Source at Argonne National Laboratory to examine the transient lattice change under photoexcitation and heating on LLTO grains in a powder pellet. Due to the high number of photons per pulse of the Advanced Photon Source, we can extract single-shot statistical variance of the change in lattice constant after excitation from 350 nm light and compare this with the averaged change in lattice constant over a series of pump-probe time-resolved scans. The relaxation time of the lattice constant and its relation to the relaxation time of the shot-to-shot variation reveals the lattice relaxation mechanism following the photoexcitation. The 350 nm photoexcitation mimics the extreme heating condition during the charging or discharging of solid-state batteries, and the resulting lattice deformation under these conditions is important to understand as the lattice collects/releases the Li-ions while under high thermal load.

11:00 AM EN06.08.03
Correlated Factors for Li-Ion Migration in Ionic Conductors with the fcc Anion Sublattice Runxin Ouyang[1], Hong Zhu[1] and Zhenming Xu[2]; [1]Shanghai Jiao Tong University, China; [2]Nanjing University of Aeronautics and Astronautics, China

The development of solid-state electrolytes (SSEs) with high lithium ionic conductivities is critical for the realization of all-solid-state Li-ion batteries. Crystal structure distortions, Li polyhedron volumes, and anion charges in SSEs are reported to affect the energy landscapes and it is paramount to investigate their correlations. In this study, we reveal that the distorted tetrahedrally occupied lithium is less energetic favorable than the distorted octahedrally occupied lithium, rationalized from the heatmap of anion charges, lattice volumes and sites distortion. Our works uncover the cooperative effect of lithium site distortions, anion charges and lattice volumes on Li ion migration energy barrier in superionic conductors of $LiMS_2$ (M =Sc, Ti, V, Cr, Mn, Fe, Co, Ni) and Li_2MO_3 (M =Sc, Ti, V, Cr, Mn, Fe, Co, Ni). Manipulating the distortion of tetrahedrally occupied lithium is more impelling than the adjustment of octahedrally occupied lithium distortion to lower Li ion migration barrier. The new descriptor, Li ion sites distortion, can provide new insights into the strategy for screening high conductivity solid-state electrolytes.

11:15 AM EN06.08.04
Effects of F and Cl Doping in Cubic $Li_7La_3Zr_2O_{12}$ Solid Electrolyte: A First Principles Investigation Yu Yang and Hong Zhu; Shanghai Jiao Tong University, China

Anion doping is recently attaining a lot of research interests for the solid-state electrolytes. In this study, we investigated the effects of F and Cl on the phase, electrochemical, and chemical stabilities, ionic conductivity, and diffusion mechanism in cubic $Li_7La_3Zr_2O_{12}$ (c-LLZO), based on density functional theory (DFT) calculations. It is found that a homogeneous diffusion network with low local structural distortion and the high Li jump numbers are beneficial for good ionic conductivity in c-LLZO. The introduction of a certain amount of Li vacancies can enhance both the Li jump numbers and the concerted migration percentage of c-LLZO. Our findings deepen the understanding of diffusion mechanism in c-LLZO and offer a valuable insight for the rational design of solid electrolytes.

Freeze Cast NASICON Solid Electrolytes: Towards High-Performance Sodium Batteries Eldho Edison[1], Elena Tervoort[1], Annapaola Parrilli[2] and Markus Niederberger[1]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Solid-state sodium batteries have received great interest recently as sustainable and viable electrochemical energy storage systems. To bolster the energy density as well as the safety of sodium batteries, it is crucial to develop solid-state electrolytes with high ionic conductivity and electrochemical stability. Among others, NASICON (Na^+ super ionic conductor) materials are promising candidates as solid electrolytes due to their high ionic conductivity and thermal and electrochemical stability. Herein, we employed a freeze-casting technique to develop porous NASICON solid electrolytes based on sodium aluminum titanium phosphate and sodium zirconium silicophosphate materials with high ionic conductivities. By controlling the slurry composition and sintering conditions, we optimized the porous solid electrolyte. We investigated the uniform distribution of parallel channels in the bulk of the freeze-cast solid electrolyte via X-ray tomography technique. Additionally, the effect of wetting agents including ionic liquid (sodium trifluoromethanesulfonimide in 1-butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl)imide) and carbonate electrolytes (sodium perchlorate in propylene carbonate) on the electrochemical performance was explored. Furthermore, a prototype solid-state cell was assembled with the infiltration of sodium vanadium phosphate cathode material into the porous solid electrolyte. The resulting cell delivered a good capacity of nearly 100 mAh $g^{-1}_{cathode}$ and good cycle life with an energy density of nearly 330 Wh $kg^{-1}_{cathode.}$ The improved electrochemical performance could be attributed to the low tortuosity pathways which are uniformly distributed parallel to the thickness of the solid electrolyte, facilitating uniform and efficient sodium ion conduction. The study offers new insights into the optimization of ion conduction in solid electrolytes for sodium batteries.

11:45 AM EN06.08.06
Effect of Composition and Processing on the Multifunctional Properties of Single-Phase Structural Electrolytes Maghen Saltzman[1,2], Payton Parker[1] and Caiwei Shen[1]; [1]University of Massachusetts, Dartmouth, United States; [2]California Polytechnic State University, Pomona, United States

As the world becomes increasingly electrically dependent, energy storage is a factor which seriously limits progress. Unfortunately, popular methods of energy storage, such as lithium-ion batteries contribute significantly to unrecyclable waste once their short life cycles are over. Supercapacitors are an attractive alternative method of energy storage with significantly higher cyclability and power density than batteries. Moreover, multifunctional structural supercapacitors have been developed to further reduce the overall weight and size of products. Previous reports utilize bi-continuous phase materials as the electrolytes for structural supercapacitors, which show significant trade-off between the electrical and mechanical properties. Our research group has recently developed a single-phase solid polymer electrolyte that outperforms previous designs. The current work focuses on studying the effect of composition and processing on the multifunctional properties of such electrolytes. We analyze the thermal, electrochemical, and mechanical properties of the polymer electrolytes composed of polyethylene terphthalate (PET) and lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) at different compositions after various processing conditions to determine its suitability for use in the structural supercapacitors.

Different from the conventional solution casting method to prepare polymer electrolyte, our electrolytes were prepared by mixing and melting PET and LiTFSI together. The LiTFSI salt was fully dissolved in PET to form a single-phase solid solution. Samples with designed sizes were fabricated through injection molding. Some samples were exposed to a controlled humidity environment to improve their electrochemical performance. The thermal properties of samples with 0 to 50 wt% of LiTFSI were characterized by differential scanning calorimetry (DSC). The ionic conductivities of various dry and humidified samples were measured by using electrochemical impedance spectroscopy (EIS). The mechanical properties of similar samples were evaluated through 3-point bending tests.

It was determined that increasing the weight ratio of LiTFSI in our polymer electrolyte was related to a decrease in heat flow, decrease in melting point from 247 °C to 227 °C, slight increase in glass transition temperature, and decrease in crystallinity from 26% to approximately 0%. In fact, the polymer-electrolyte became essentially amorphous with more than 35 wt% LiTFSI. EIS tests showed that the ionic conductivity reached a peak value at a composition of 20 wt% LiTFSI for dry samples. The samples showed higher ionic conductivity when hydrated, and a peak ionic conductivity of about 34 μS/cm occurred at a 2 wt% absorption of water from the humid air. Finally, the 3-point bending tests demonstrated that increasing the water content of samples dramatically increased the ability to resist breaking from bending.

In conclusion, the results show that the phase and crystallinity of the single-phase structural electrolyte can be controlled through material composition and thermal processing. The mechanical toughness and ionic conductivity of the multifunctional electrolyte can be simultaneously improved through controlled hydration treatment. The optimization of material composition, thermal processing, and hydration treatment will lead to structural electrolytes with significantly improved overall multifunctionality.

Developing Materials for Energy Technologies with Decreased Critical Materials Ryan T. Ott; Ames National Laboratory (USDOE), United States

The transition to clean energy technologies creates increasing demand for materials with enhanced performance in harsh environments. These materials often rely on critical materials such as rare earth elements (REE), which enable increased functionality. To address the supply and demand imbalances of these critical materials, we are working to accelerate the development of new materials with decreased critical material content. Specifically, we use high-throughput synthesis and characterization techniques to develop permanent magnet alloys with more abundant materials like Ce and La substituted for critical REE (e.g., Nd, Pr, Dy). This work includes integrating rapid synthesis and testing of alloy libraries over large composition ranges with bulk synthesis of down-selected compositions to accelerate the development of new alloys. We are also addressing critical materials challenges by developing new Al alloys that create market demand for overly produced REE (e.g., Ce), while eliminating the need for critical Li and Sc alloying additions. Using combinatorial additive manufacturing (AM) techniques, we have developed new Al-Ce alloys for advanced manufacturing techniques (e.g., AM and extrusion) that show enhanced performance in harsh conditions. The alloys exhibit excellent processing flexibility, enhanced corrosion resistance and thermal stability. The alloys can both reduce critical material usage in key energy technologies and help address supply-demand imbalances in REE.

2:00 PM *EN07.01.02
Strategy of Critical Materials on the Li-Ion Battery Industry of Korea Min-Ha Lee; Korea Institute of Industrial Technology, Korea (the Republic of)

Demand for Li-ion secondary battery (LiB) drastically increases by the explosion of Electric vehicle (EV) market. The major supplier of LiB is limited in China, South Korea and Japan account 91.8% for over the world in 2022. Supply chain of LiB to EV manufacturer tackled by physical limitation of producing capacity, supply instability of core minerals and geopolitical control of trade.
In these reasons, securing a superior position in the global market with high technology and mass production capacity is critical point of industry.
We introduce how Korean government and companies set up strategy to resolve critical issues in energy industry for securing critical materials (CRMs), especially LiB.
Recently announced ‘Secondary Battery Industry Innovation Strategy’ by Korean government will explain and emphasize example of securing supply chain of CRMs in LiB by (1) formation of Korea team to secure core minerals domestic resource and (2) develop new recycling technology from company in South Korea. Because importance of establishment a sustainable battery circulation system (closed-loop) for recycling waste lithium ion batteries is urgently need to guarantee alternative resources supplying CRMs in Lib industry.
In the last part, we define and discuss the concept of materials flow/business flow applied to CRMs in LiB energy industries. Different aspects of supply risk beyond scarcity will be brought into the discussion through examples of regulation and of geopolitical risk.
We conclude with careful speculation about the roles of resilience and adaptation in future risks analysis, drawing on the perspective global market trends.

2:30 PM *EN07.01.05
Defects-Engineered Bismuth Telluride Alloys Towards Waste Heat Recovery Kyung Tae Kim; Korea Institute for Materials Science, Korea (the Republic of)

Among various types of thermoelectric materials, bismuth telluride (Bi_2Te_3) based alloys have been considered as a key material for waste heat recovery as well as active control in temperature. Recently, Intensive effort to engineer the microstructures of bismuth telluride have been made to overcome the current limitation on its thermoelectric energy conversion performance levels (ZT) in viewpoint of defects. In this presentation, we report two plausible powder metallurgy routes to achieve microstructures which exhibit defect-engineered interfaces in p-and n-type bismuth telluride alloys, respectively. For designing favorable defects of p- and n-BiSbTe alloys, the defect formation energy has thermodynamically been calcaulated by First-principle calcuation based on density functional theory under a certain sintering condition. First, considering the wavelengths of carriers and phonons, we introduce geometrical point defect assembly structures in a nano-scale of about 5-10nm are created and dispersed in the p-type BiSbTe crystalline grain. This nanostructure contributes to a reduction in the lattice thermal conductivity and increase in carrier density. Second, novel synthetic process of n-type BiSbTe alloys with antisite defect such as Te@Sb or Te@Bi rather than BiTeSe has been developed by at the same time utilizing the concept of creating dislocation network arrays. As results of these, the fabricated bismuth telluride alloys show peak ZT values of 1.3 for p-type and 1.2 for n-type, respectively which are 1.6 times higher than those of both pristine BiSbTe alloys fabricated by the same method without defect engineering. And characteristically, the defect-engineered bismuth tellurides show simultaneous control which lowers thermal conductivity despite significantly increased electrical conductivity. We think this defect engineering-based fabrication process using conventional powder metallurgy provide a new avenue for improving and modulating the efficiency of thermal-to-electrical conversion in bismuth telluride. Thus, the newly developed materials can be utilized for waste heat recovery of shipbuilding but also can be applied for thermal energy harvester in ICT field.

Electrocatalysis by Single-Atoms—A Modeling Perspective Gianfranco Pacchioni; Univ Milano-Bicocca, Italy

One of the objectives of electronic structure theory is to predict chemical and catalytic activities. This is a challenging target due to the large number of variables that determine the performance of a heterogeneous catalyst. The complexity of the problem has reduced considerably with the advent of single atom catalysts (SAC), new systems consisting of a single transition metal stabilized on a solid matrix. SACs offer great potential advantages compared to more conventional supported metal nanoparticles in terms of selectivity and of material needs in order to prepare the catalysts. A lot of attention has been given in particular to graphene-based SACs for electrocatalytic reactions such as the oxygen reduction (ORR), the oxygen evolution (OER) and the hydrogen evolution (HER) reactions. In this context we assist to a rapidly growing number of theoretical studies based on density functional theory (DFT) and of proposals of universal descriptors that should provide a guide to the experimentalist for the synthesis of new catalysts. In this talk we critically analyze some of the current problems connected with the prediction of the activity of SACs based on DFT: accuracy of the calculations, neglect of important contributions in the models used, physical meaning of the proposed descriptors, inaccurate data sets used to train machine learning algorithms, not to mention some severe problems of reproducibility. It follows that the "rational design" of a catalyst based on some of the proposed universal descriptors or of the DFT screening of large number of structures should be considered with great caution [1-3].

11:00 AM EN07.02.02
Wet-chemical Synthesis of Tin Oxide and Titania Supported Iridium Oxide Nanoparticles with Ultralow Iridium Density as Novel Catalysts for PEM Electrolysis Melisande Kost[1], Peter Zehetmaier[2], Markus Doeblinger[1], Dina Fattakhova-Rohlfing[2,3] and Thomas Bein[1]; [1]LMU Munich, Germany; [2]Forschungszentrum Jülich GmbH, Germany; [3]Universität Duisburg-Essen, Germany

The proton exchange membrane (PEM) is a promising and intensively researched technology for large-scale production of hydrogen from sustainable sources. However, the economic viability of the PEM process remains limited by the high capital cost of the individual components, particularly the rare and valuable iridium used as a catalyst for the oxygen evolution reaction (OER). An established approach to reduce Ir loading in PEM is to disperse the catalytically active material on corrosion-stable supports with formation of a catalyst with low volumetric Ir density, which increases the noble metal mass-based activity. The material and morphology of the support, as well as the coating process, have a strong influence on catalyst performance and are investigated here to optimize catalyst performance and further reduce iridium content
Here, a novel and scalable catalyst synthesis is presented in which corrosion-resistant crystalline SnO_2 and TiO_2 nanoparticles are coated with an ultrathin layer of amorphous iridium hydroxide using a simple low-temperature wet chemical synthesis. In a further step, the amorphous $IrO(OH)_x$ layer is oxidized in a molten salt-assisted process. This process enables controllable phase transformation and crystallization to form a layer of interconnected, partially crystalline IrO_x nanoparticles with a size of ≈1.5 - 2 nm on the surface of the supporting nanoparticles, which form a percolation pathway. To elucidate the impact of different core-shell designs, transmission electron microscopy (TEM) imaging with a strong focus on iridium coating and crystallinity was performed. The final compounds contain highly active iridium oxide with overall very low Ir weight fractions of only 16% compared to a modern reference catalyst with 75 wt% Ir. Measurements on a rotating disk electrode (RDE) showed that SnO_2-supported IrO_x exhibits higher electrochemical activity and stability than TiO_2-supported IrO_2 at low loading. Further investigation of the membrane electrode assembly (MEA) in a single-cell electrolyzer indicates the possibility of future large-scale application in PEM at industrially relevant current densities.

11:15 AM EN07.02.03
Component & Size-Tunable Metal Nanoparticle via Ultrafast Non-Equilibrium Synthesis—Design of Electrocatalysts for High-Performance Energy Conversion Systems Ji-Yoon Song and Hee-Tae Jung; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

Metal nanoparticles (MNPs) are one of the most attractive materials in diverse applications due to their high electronic and catalytic activity. It has been reported that MNP engineering such as alloying, controlling particle size and formation density can derive unexpected effects leading to high catalytic performance. Unfortunately, in previous methods, alloying is possible only with thermodynamically miscible combinations of metals, and phase separation occurs as the number of the metals is increased due to the increased instability. Furthermore, the unavoidable aggregation of MNPs from particle migration and coalescence and Ostwald ripening during synthesis process result in ununiform NP size and density on the supports which cause low performance and reproducibility. Thus, the development of a universal and effective method for MNP engineering is highly demanded.
In this presentation, we demonstrate a general strategy to overcome the abovementioned obstacles by adopting the carbothermal shock (CTS) method for electrocatalytic energy conversion systems. Immiscible metal alloying and multi-metallic NPs (>4 elements) can be fabricated with high uniformity within 1 second through ultrafast heating/cooling process. Based on the CTS method, the modulation of support materials is simultaneously conducted to develop a full electrode system for high energy conversion efficiency. As the result, we present diverse electrocatalyst designs (i.e. Ru-Cu alloy on 3D carbon foam, Pd on boron nitride nanotube and Cu on cellulose) for electrocatalytic energy conversion systems to move up Net-Zero-World ecosystem; such as carbon dioxide (CO_2) reduction to ethylene (C_2H_4) and nitrogen (N_2) reduction to ammonia (NH_3).

11:30 AM EN07.02.04
Nanoporous PtIr Nanosheets as Bifunctional Electrocatalysts for Regenerative Proton Exchange Membrane (PEM) Fuel cells Ramchandra Gawas[1], Swarnendu Chatterjee[1], Xiong Peng[2] and Joshua Snyder[1]; [1]Drexel University, United States; [2]Lawrence Berkeley National Laboratory, United States

The hydrogen economy is critical for deep decarbonization of the energy sector owing to high energy density of H_2 as a fuel, clean operation, and flexible implementation in terms of scale (W to GWs), source and end-use. To this date, proton exchange membrane water electrolyzers (PEMWEs) and fuel cells (PEMFCs) remain as emergent technologies for H_2 production and utilization due to the development in polymer electrolyte membranes, high current density operations, etc. These devices however operate in highly acidic conditions requiring significant amounts of platinum group metals (PGM)-based materials. Thus, widespread adoption of PEM devices depends on advancements in material development as well as device integration to lower total

system costs and improve efficiencies.
Our group has developed a novel approach to make nanoporous nanosheets of Ir (np-Ir NS). These np-Ir NS show superior catalytic activity and durability as anodic oxygen evolution reaction (OER) electrocatalysts in comparison to commercial IrO_2 nanoparticle catalysts. The unique morphology of nanoporous nanosheets allows support-free integration into catalyst layers and a form factor that results in significantly lower ohmic losses at high current density.[1]
In this work, we implement the previously developed, top-down approach to synthesize nanoporous nanosheets of PtIr (np-IrPt NS). These alloyed np-IrPt NS show excellent electrocatalytic properties for hydrogen oxidation reaction (HOR) and oxygen evolution reaction (OER), comparable with state-of-the-art PGM catalysts. Bifunctional catalytic properties make np-IrPt NS ideal candidates for regenerative fuel cell applications. We will also discuss the integration of np-IrPt NS into regenerative proton exchange membrane fuel cell (R-PEMFC) devices.

Synthesis of Palladium–Based Nanoparticles with Tuneable Sizes for Catalytic Applications Anastasia Kappelou[1,2], Laura Torrente Murciano[1], Nicoleta Muresan[2] and David Thompsett[2]; [1]University of Cambridge, United Kingdom; [2]Johnson Matthey, United Kingdom

This work demonstrates the continuous synthesis of palladium-based nanoparticles with controllable sizes and a narrow size distribution using continuous flow microreactors for catalytic applications. This new method enables for the first time, the elucidation of size-activity relationships, decoupling size and supports effects. In addition, the easy scale-up of the method can lead to a new way of designing and manufacturing catalysts.

Metallic palladium and palladium-based nanoparticles have been extensively studied in a wide range of catalytic applications, including their use in air pollution remediation catalysts in the automotive industry.[1,2] However, the relationships between their catalytic activity and size and composition remains unknown due to the dynamic structure of the nanoparticles under catalytic conditions. In this study, the 3D configuration of microreactors enables continuous colloidal synthesis of palladium-based nanoparticles using hydrolysis and reduction methods. The combination of laminar flow in the microreactors (characterised by low Reynolds numbers) and the promotion of transitional flows (i.e. Langragian turbulence) through 3D configurations leads to a narrow residence time which is translated into narrow size distributions even in the absence of steric capping ligands.[3]

This study investigates the effect of different palladium precursors on the rate of reaction and stability during the synthesis. Palladium oxide (PdO) nanoparticles with sizes below 5 nm are formed through hydrolysis under basic conditions and supported on ceria supports via electrostatic interactions. Metallic palladium nanoparticles are synthesised either by consecutive reduction of the PdO or the direct reduction of the metal precursors using strong a reducing agent. The results reveal the higher instability of the Pd nanoparticles with respect to PdO counterparts in the absence of capping ligands, being greatly affected by the initial speciation of the precursors. Mechanistic understanding as well as the size-activity relationship for the model CO oxidation reaction will also be presented.

Peptide Surfactants at Air-Aqueous Interfaces for Lanthanide Recovery Kathleen Stebe; University of Pennsylvania, United States

We envision a new, green, froth flotation method to separate Rare Earth Elements (REEs) using peptide surfactants to complex selectively to REE cations and drive their adsorption to rising air bubbles sparged through the solution. The REEs are then collected in the enriched foam formed from these bubbles at the top of the solution. The unique feature of this envisioned separation are the surface active peptides designed to bind selectively with particular REEs. We are working to develop these molecules and to understand the molecular details of their complexation with REEs and their adsorption in the complex environment of a fluid interface. This research is performed by a team of researchers at the University of Pennsylvania, City College of New York, the University of Illinois at Chicago, and Northwestern University under the support of the grant DOE BES DE-SC0022240.
Our peptide surfactants are based on lanthanide binding tags (LBTs), peptide sequences with hydrophilic residues arranged as a binding loop that forms a coordinating sphere of ligands around the REE cation. The peptide sequences in LBTs are derived from calcium binding loops in natural calcium binding proteins and have been optimized to bind particular REEs. In the literature, LBTs have been optimized by screening methods to coordinate with high affinity to particular lanthanides (e.g. terbium and europium), which strongly luminesce when coordinated in the loop. LBTs are widely exploited as probes; LBTs grafted into proteins serve as fluorescence reporters of protein structure. We append hydrophobic peptide sequences to the LBTs to make them amphiphilic. We have demonstrated that the LBT-derived peptide surfactants complex REEs in the bulk aqueous phase, are surface active, and adsorb to an air/water interface in un-complexed and complexed forms. We have quantified the binding affinity and aggregation in water, and peptide surfactants' ability to adsorb and complex with REE cations at the interface using technologies at NSF's ChemMatCARS facility at the Advanced Photon Source of Argonne National Laboratory. These studies are supported by molecular modeling of the peptide surfactants in the region of the air-water interface. Current efforts focus on exploring how changes in the amino acid sequence of the peptide loops alter their selectivity and interaction in the bulk and the interface.

Separating f-Elements and Harnessing Their Unique Properties When Globalization Breeds Conformity Joshua Woods[1], Sabari Ghosh[1], Jia-Ahn Pan[1], Emory Chan[1], Michael Connolly[1] and Rebecca Abergel[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley/Lawrence Berkeley National Laboratory, United States

With a large number of lanthanides deemed critical materials, f-elements play a major role in many human-driven activities, such as in nuclear energy, clean energy technologies and catalysis. Separation of f-elements from each other can be arduous due to their similar physical and chemical properties, and significant efforts are currently being pursued to develop more efficient partitioning processes. These processes are not only important in the context of the nuclear fuel cycle but also to ensure adequate supply of those metals that are among the most critical materials for clean energy technologies, and for which future supply disruptions can be avoided with new strategies for recovery and recycling. As a result of these needs, novel approaches to detect, separate and recover f-block elements are direly needed. Harnessing the unique capabilities of f-block metal cations so that one may selective tune the resulting properties involves exercising control over the first coordination sphere of the metal ions. Using high-affinity, chelating ligands is one pathway for controlling Ln local coordination geometry, and currently the highest affinity *f*-block binding is achieved by organic, bio-inspired ligands. We will discuss some innovative ligand synthetic pathways linking specific metal binding units to polyamine, macrocyclic, and polymeric peptoid and protein scaffolds, which, combined with advanced structural characterization techniques are used to achieve unprecedented f-element separation under a wide range of conditions. In a time that favors harmonization, creative scientific solutions to global challenges often necessitate input from a wide variety of backgrounds. The results presented here stem from a team that boasts diversity in scientific discipline, cultural background, and seniority level. Applying our diversity and taking advantage of each f-element's uniqueness, we seek to facilitate new technologies that can be accessed by all.

2:30 PM EN07.03.03
Theoretical Studies on the Solvation Structure of Lanthanide Cations in Hydrated Layered Birnessite Woo Cheol Jeon[1], Siqi Zou[2], Chong Liu[2] and George C. Schatz[1]; [1]Northwestern University, United States; [2]The University of Chicago, United States

Rare earth elements (REs) refer to 17 elements including lanthanides, yttrium and scandium, and among the REs, lanthanides have been of particular interest. They can be used in the industrial applications such as fine chemistry, atomic clocks, phosphors, optical fibers, and high-performance alloys. Each of them has its own unique and diverse electronic properties, which means that having effective ways to separate mixture is important. Two distinctive characteristics and available for separations: ionic radius and Lewis acidity, with the former decreasing and the latter increasing as atomic number increases. These characteristics can induce significant differences in coordination and binding affinities when they are ionized and bind to solvent molecules. Furthermore, their coordination can be altered when they are solvated and confined to solid ionic channels. However, experimental characterization methods still have limitations in characterizing the coordination environment of lanthanide cations. Here, we theoretically investigate the structures and energetics of lanthanide cations confined in hydrated layered birnessite. Density functional theory calculations are implemented with a combination of explicit and implicit solvation. Each system with different types and concentrations of lanthanide cations is modeled and optimized to investigate the changes in coordination in different hydration environments. And the structures are characterized by the coordination number of each atom pair and X-ray diffraction which can be compared to experimental data. In addition, the configurations of hydrated structures and hydration energies of cations in the ionic channel are compared with those in bulk water solution to explain the feasibility of cation transportation into the ionic channel. Based on these results, we propose that cation coordination is mainly influenced by the altered oxidation state of the host material and the presence of water molecules.

2:45 PM EN07.03.04
Bio-Inspired Polymeric Ion Capture for Critical Materials Harvesting Erik D. Spoerke[1], George D. Bachand[1,2], Susan Rempe[1,2], Stephen Percival[1], Leo J. Small[1], Amanda Peretti[1], Pengyu Ren[3] and Elizabeth Wait[3]; [1]Sandia National Laboratories, United States; [2]Center for Integrated Nanotechnologies, United States; [3]The University of Texas at Austin, United States

There is a clear and growing need to develop new, environmentally friendly, cost-effective methods for harvesting of critical materials for energy applications including rare earth metals (REMs; lanthanides plus yttrium and scandium) and other metals vital to rapidly growing technologies, such as batteries. These critical materials, however, are often found in dilute concentrations or in complex mixtures, making them difficult and expensive to harvest and separate. We are exploring a bio-inspired approach to capturing critical metals, following examples set by biological entities, such as methyltrophic bacteria, which are capable of highly efficient and effective capture and concentration of REMs. Here, we describe our combined computational and experimental efforts to understand the key interactions between solvated ions, water, and functional ligands that are responsible for biology's remarkable ion harvesting capacity. We then use this understanding to inform the design of synthetic systems aimed at effective harvesting of energy-critical materials. We describe the efficacy (and limitations) of engineered peptide, polymer, and nanomaterial systems capable of efficient, reversible capture of target mineral elements. Following inspiration from biology promises to reveal key insights needed to unlock new routes to cost-effective harvesting of materials critical to emerging energy applications.
Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

3:00 PM BREAK

3:30 PM *EN07.03.05
Adsorption And Intercalation of Rare Earth Elements In Micas: What Can We Learn About Separation of Rare Earth Elements Sardar B. Alam[1], Dapeng Jing[2], Eshita Samajpati[3], Alberto Perez-Huerta[3], Paul p. Spry[2], Shawn M. Kathmann[4] and Tanya Prozorov[1]; [1]US DOE Ames National Laboratory, United States; [2]Iowa State University of Science and Technology, United States; [3]The University of Alabama, United States; [4]Pacific Northwest National Laboratory, United States

Rare earth elements (REEs) are essential to the economic growth and national security of the United States. Increasingly, the supply chain of these critical minerals becomes vulnerable to disruptions. To exploit secondary sources of REEs effectively, there is an urgent need to learn about the localized environment of REEs in these sources, thereby enabling enhanced recovery and separation approaches optimized across a broad variety of REE and sources, with greater efficiency and selectivity. Regolith-hosted ionic-adsorption clay minerals preferentially adsorb heavy REEs (HREEs) released through the weathering and dissolution of granites and igneous rocks by rainwater. This REE-containing water then flows through the clays, resulting in a natural separation process. The most soluble and lightest elements (LREEs) pass through clays, while the least soluble and heaviest remain adsorbed, resulting in the formation of heavy REE-enriched minerals with minable concentrations from 50 to 1500 ppm.

In contrast, in micas, the REE observed retention trend is reversed, with the light REEs adsorbed at larger amounts and intercalating deeper into the mineral structure, compared to HREEs. By determining the speciation, spatio-chemical environment and quantum mechanical interactions and polarity of rare earths in micas, we are working to obtain the information on key issues affecting REE adsorption, including structural, electrostatic and hydration effects, coordination and oxidation state of the RE ions in these natural layered minerals.

4:00 PM EN07.03.06
Mechanically Strengthened High Magnetic-Performance Sm-Co Sintered Magnets Through Microstructure Engineering Baozhi Cui, Xubo Liu, Ikenna C. Nlebedim and Jun Cui; Ames Lab, United States

As a critical functional material, Sm-Co sintered magnets have been used for energy, information, defense, manufacturing, and health technologies.

However, the utilization of these magnets is restricted by their brittleness.
Sm-Co sintered magnets with improved mechanical properties and well-maintained magnetic properties have been designed and fabricated *via* additive-modified microstructure engineering. A small amount of Sm_2O_3 fine particulates (e.g., 0-3 wt%) has been incorporated into the $Sm_2(CoFeCuZr)_{17}$ sintered magnet to refine the grain size by up to approximately 50% and narrow the grain size distribution. Doping 3 wt% Sm_2O_3 increases the flexural strength by 62% while maintaining magnetic performance.
Both grain-refined unimodal microstructure and heterogeneous laminated coarse/fine grain microstructure were strategically designed and formed. Numerical micromechanics simulation indicates that the fracture is dominated by intragranular mode. The mechanical strength is mainly enhanced by additive-induced grain refinement.
These mechanically strengthened high magnetic-performance magnets will be more cost-effective, efficient, and robust for various functional applications.

4:15 PM EN07.03.07
Development of Layered Oxides for Electrochemically Driven Li Extraction from Dilute Li Sources Grant Hill and Chong Liu; University of Chicago, United States

Due to the rising demand of Li-ion battery powered vehicles, the lithium supply chain is projected to experience strain in the coming decades. This strain can be mitigated by developing new Li extraction methods that can access unconventional Li sources such as seawater. Electrochemical Li extraction has demonstrated high selectivity and recovery rates from dilute Li sources; the insertion host material selection plays a key role in the overall performance. However, few materials have been explored nor have materials been tailored for Li extraction from these multi-cation solutions. With this in mind, we developed a core-shell structured $(NaLi)_{1-x}CoO_2$ by non-Faradaic ion-exchange using parent $LiCoO_2$ with Na ions. Using electrochemical intercalation, this material successfully extracted Li from 1:20,000 Li: Na aqueous solution to 7.6:1 Li: Na, which is a Li selectivity of 1.5 x 10^5 over Na. Based on the same principles, we expanded the capacity and lifetime for layered cobalt oxides using electrochemically assisted ion-exchange. Parent $Na_{1-x}CoO_2$ was used to extract dilute Li and maintain high selectivity for multiple Li extraction sequences. After significant structural changes from the first Li extraction, high Li recovery performance can be maintained over multiple extraction sequences. Additionally, we also report C-rate dependence during the deintercalation recovery step, indicating the importance of method development for optimizing material performance. This work highlights the need for further understanding of layered oxides for Li extraction and the potential of system design for improved Li recovery capacity and lifetime.

4:30 PM EN07.03.08
The Role of Solid Solutions in Iron Phosphate-based Electrodes for Selective Electrochemical Lithium Extraction Gangbin Yan and Chong Liu; University of Chicago, United States

The lithium supply issue mainly lies in the inability of current mining methods to access lithium sources with dilute concentrations and complex chemistry. Electrochemical intercalation can enable lithium extraction from dilute water sources. However, the co-intercalation of lithium and the main competitor, sodium ions, occurs during extraction. The response of host materials to this process is not fully understood. This aspect limits the rational material design for improving lithium extraction.

In this talk, using one-dimensional (1D) olivine iron phosphate ($FePO_4$) as a model host, I will introduce the co-intercalation behavior of lithium and sodium ions and the control of lithium selectivity through intercalation kinetic manipulations. By combining computational and experimental investigations, we noticed that lithium- and sodium-rich phases tend to separate in the host. Exploiting this mechanism, I will discuss how the sodium-ion intercalation energy barrier can be increased by using partially filled 1D lithium channels generated via non-equilibrium solid-solution lithium seeding or remnant lithium in the solid solution phases. Furthermore, the lithium selectivity enhancement during co-intercalation shows a strong correlation with the fractions of solid-solution phases with high lithium content (i.e., Li_xFePO_4 with $0.5 \leq x < 1$). Finally, I will describe how the host material's particle morphology, size, and defect content could affect the solid-solution formation pathway, which further influences Li selectivity.

8:15 AM *EN07.04.01
Molecular-Level Understanding of Mineral-Water Interfaces for Improved Beneficiation of Rare Earth Ores Vyacheslav Bryantsev; ORNL, United States

The criticality of rare-earth element (REE) resources requires responsible and efficient extraction of these elements from mined ores. These elements are often present in mineral deposits at levels well below those economically exploitable, occurring as complex mixtures of rare earth intermixed with commercially valueless, or gangue, minerals. As such, they must undergo extensive processing to ultimately isolate the rare earth in elementally pure forms for use in their respective applications. However, physical processes such as gravity separation and chemical approaches such as froth flotation by which REEs are extracted from their minerals have remained relatively unchanged over the last century, highlighting the need for more efficient strategies for extracting REEs from mined ores. Inspired by natural biomineralization, we seek to discover fundamental principles of molecular recognition at mineral-water interfaces and apply them for selective separation of rare earth from complex mixtures. In this talk, I will give several examples of how we develop an in-depth understanding of key underlying molecular interactions at the surface of REE-bearing bastnaesite, xenotime, and monazite minerals. Such advances are possible by employing a multimodal approach combining density functional theory calculations, calorimetry measurements, and multiple surface-sensitive spectroscopic techniques, including vibrational sum frequency generation, attenuated total reflectance Fourier transform infrared, Raman, and X-ray photoelectron spectroscopies. We anticipate that our extensive, molecular-level understanding of water and collector molecules adsorption on the REE mineral surfaces will provide insights into the design of more efficacious collector ligands for rare-earth separation from complex mixtures and lean sources.

8:45 AM *EN07.04.02
Modelling the Uptake, Transport and Separation of Multiply Charged Ions Through MoS_2 Membranes George C. Schatz; Northwestern University, United States

This talk will present recent studies of the Schatz group in collaboration with the Chong Liu and her group concerning the uptake and transport of multiply charged ions (Cu^{2+}, Pb^{2+}, lanthanides) through membranes that consist of stacked MoS_2 layers. Two levels of theory have been considered: electronic structure calculations using VASP, and molecular dynamics using empirical potentials. The electronic structure calculations involve studies of ion hydration both in the bulk and inside the membrane with models that contain 10-60 explicit water molecules, along with implicit water. These calculations are able to capture important features of the experiments concerning ion-solvent coordination number, membrane interlayer separation, relative binding energy of ions in the membrane, and how hydration varies with location of the ion and whether the MoS_2 is or isn't functionalized with acetate. This leads to a realistic picture of the uptake experiments. Our MD studies of ion transport and separation are able to provide qualitative understanding of the dependence of ion dehydration that takes place as the ion enters the membrane, and dependence of diffusion on strength of interaction of the ion with the membrane, but the empirical potentials are apparently not accurate enough to capture subtle effects that reflect chemical interactions of the ions with the membrane, especially concerning variation of the interlayer separation while the ion diffuses, and the transport of mixtures of different ions.

9:15 AM EN07.04.03
Surface X-Ray Studies of Rare Earth Group Ion Transport Pathway on Functionalized Monolayer MoS_2 Maoyu Wang and Hua Zhou; Argonne National Laboratory, United States

Rare earth elements (REs) have been identified as critical elements with short-term supply risks. They are essential in modern technologies and devices such as permanent magnets, optical fiber, and medical imaging agents. [1,2] REs exhibit very similar chemical properties but varied electronic properties, and their application requires high purity of every single element. Therefore, achieving effective and efficient separation among REs from one another has been the challenge since their discovery and this task is especially critical now to enable recycling to secure the REs supply. Currently, the solvent extraction used in industrial productions induces a negative impact on the environment due to the drawbacks of energy and chemical intensiveness. [3-5] Based on the two important properties of REs: ionic radius (decreasing with an atomic number) and Lewis acidity (increasing with atomic number), [2] we proposed to create two-dimensional (2D) solid ionic channels with stacked 2D materials (such as MoS2) that are able to modulate the dehydration, transport, and hydration of REs. To achieve selective transport of REs by rational design, a better understanding of the binding and conduction of REs ions through the 2D channels is required. Hence, we established an understanding of binding thermodynamics on the single monolayer MoS2 with the functionalized surface as a model system to determine how lanthanide RE ions contact and interact with pristine and surface functionalized monolayer 2D materials. We combined surface X-ray diffraction (crystal truncation rod) and gracing incidence X-ray absorption spectra to provide a precise local coordination configuration. This allows us to create an accurate molecular-level structural model for the electronic structure computation and modeling, which would be better to reconstruct the ion transport pathway and realize the selectivity control among REs. The outcomes will have immediate impact to enabling new energy efficient separation methods, especially transport-based separation technologies (membrane separation), to be applied to REs extraction, separation, and recycling.

9:30 AM EN07.04.04
Computational Optimization of Nickel Metal Recovery from Li-ion Cathodes for a Circular Economy in Energy Storage Julia Yang[1,1], Amanda Ooi[2], Kyle Bystrom[1], Ah-Hyung Alissa Park[2,2,2] and Boris Kozinsky[1,3,1]; [1]Harvard University, United States; [2]Columbia University, United States; [3]Robert Bosch LLC Research and Technology Center, United States

In order to achieve the clean energy transition for our sustainable future, energy-relevant materials including critical minerals are required in unprecedented quantities. Thus, it is urgently needed to develop metal recovery methods for unconventional resources such as increasingly Nickel (Ni)-rich Lithium (Li)-ion battery (LiB) spent cathodes (i.e., NMC (containing Ni, Manganese (Mn), and Cobalt (Co)) or NCA (containing Ni, Mn, and Aluminum). Ethaline, a green, tunable, and non-toxic deep eutectic solvent (DES) with a 2:1 molar ratio of ethylene glycol and choline chloride, has been shown to recover critical metals such as Ni from black mass, albeit at the expense of its thermal decomposition and generation of toxic byproducts.

In this work, we use first-principles calculations and electrodeposition to demonstrate that ethaline can in fact be used as a stable solvent to recover Ni from NMC111. We quantify the extent of Ni recovery using ICP-OES/MS and characterize the purity and composition of electrodeposited Ni with SEM/EDX, FTIR, and XPS. To understand the apparent sluggish transport of divalent Ni in ethaline, we use on-the-fly active learning (using FLARE: Fast Learning of Atomistic Rare Events [1]) and machine learning methods to approximate the potential energy surface and recommend ways to tune ethaline to optimize divalent Ni transport and subsequently, more efficient Ni recovery.

Rare Earth Ions at Aqueous Soft Interfaces Amanda J. Carr, Seung Eun Lee, Srikanth Nayak, Raju R. Kumal and Ahmet Uysal; Argonne National Laboratory, United States

The increasing demand in electronic display, battery, catalysis, and magnet technologies requires better refinery and recycling processes for rare earths and other critical materials. Some of the common separation technologies include liquid liquid extraction (LLE), membranes, sorbents, and capacitive deionization. In all of these separation processes, rare earth ions adsorb on or transfer through an interface. Therefore, understanding the molecular-scale details of trivalent ion adsorption at these interfaces is crucial to developing high capacity, high throughput, and highly efficient separation technologies. LLE is one of the go-to methods in heavy element separations. In LLE, metal ions are transferred from an aqueous phase into an organic phase with the help of amphiphilic extractant molecules. The aqueous phase speciation, interfacial interactions, and the organic phase structures create a complex free-energy landscape that require a detailed investigation. We pay special attention to interfaces. We combine multiple surface sensitive techniques to investigate extractant-metal interactions and interfacial water structures. I will emphasize the connections and correlations between the interfacial structures and the rare earth extraction trends.
Graphene based membrane and sorbent materials have been extensively studied in recent years, due to their mechanical stability, unique structural and functional properties, tunability, and high surface area. Graphene based materials, alone or as additives, can be very useful under harsh conditions of heavy element separations, where the stability of polymer based materials fail. In spite of their popularity, molecular scale details of ion adsorption at graphene and graphene oxide interfaces are poorly understood. Especially, understanding the interplay between the ion hydration and adsorption is very challenging at these interfaces. We utilize *in situ* synchrotron X-ray scattering and vibrational sum frequency generation (VSFG) spectroscopy techniques to study trivalent ion adsorption at graphene and graphene oxide surfaces. Our initial studies focus on the two end points of the broad graphene based materials spectrum. High quality pristine graphene and graphene oxide.

10:45 AM *EN07.04.06
Recycling of Critical Materials to Meet Clean Energy Goals Yoshiko Fujita; Critical Materials Institute, Idaho National Laboratory, United States

The goal of the U.S. Department of Energy's Critical Materials Institute (CMI) is to increase the resilience of supply chains for critical materials essential to the clean energy transition and decarbonization. These materials (e.g., rare earth elements, lithium, cobalt, nickel, graphite) are contained in components and devices indispensable to electric vehicles and renewable energy adoption, such as magnets and motors, hard disk drives, and batteries. In addition to developing technologies to enhance primary production and developing substitute materials and processes less reliant on critical materials, expanding and improving the recycling and recovery of materials from end-of-life products will be necessary. Current recycling methods such as pyrometallurgy can recover most of the metal value in end-of-life products, but rare earth element (REE) and lithium recovery are challenging. Moreover, pyrometallurgy and other conventional end-of-life recovery approaches often have significant energy and environmental costs. CMI has focused on developing more environmentally sustainable approaches for critical material recycling, often coupled with co-recovery of high value materials such as copper and gold that can improve economic returns. These lower impact processes may include unconventional methods such as microbiology and electrochemistry in the recovery strategy, as well as novel chemistries. Researchers must consider upstream and downstream operations, and in some cases develop complete flowsheets to maximize recovery value. Iterative economic and environmental assessments during development mitigate the risk of funding approaches with limited commercial utility. This presentation will cover a selection of critical material recycling approaches developed within CMI, an Energy Innovation Hub funded by the Advanced Manufacturing Office of the U.S. Department of Energy.

11:15 AM EN07.04.07
Ultrafast Lithium Recovery by Microwave Assisted Lithium-Ion Battery Cathode Recycling Using Deep Eutectic Solvents Sohini Bhattacharyya, Salma H. Alhashim and Pulickel Ajayan; Rice University, United States

Lithium-ion batteries (LiBs) are crucial in the move towards a net-zero carbon economy. With the spurt in the electrical vehicles sales, LiB sales are touted to triple from 250 million units in 1999 to 700 million 2030. This in-turn has culminated in the double-edged problem of LiB waste management on one hand and supply of critical materials (e.g., cobalt, nickel, graphite, lithium, and manganese) on the other. These essential materials have limited reserves, many of which lie in conflicted regions and war zones. Considering the current trends in mobile and stationary LiBs usage, the demand for graphite, lithium, and cobalt is expected to increase by almost 500% by 2050, whereas a shortage of nickel is estimated to arise within the next 5-6 years. Thus, the recycling of LiB systems is essential to reduce environmental hazards while establishing a circular green economy, diminishing the need for extensive mining. Among the prevalent methods for recycling LiB cathodes, hydrometallurgy, involving the use of a lixiviant to dissolve the precious elements from the cathodes, is simple, requires less energy and shows high efficiencies. However, conventional methods of hydrometallurgy use concentrated acids and harsh solvents, e.g., peroxides which that end up adversely affecting the environment. Although green solvents like organic acids or deep eutectic solvents (DESs) have been explored as lixiviants for hydrometallurgical LiB cathode recycling, they require much higher temperatures and longer times as compared to concentrated inorganic acids, making them economically unsustainable.[1] DESs, comprising a hydrogen bond donor and acceptor, are environmentally benign, biodegradable and low cost. They have exceptional metal dissolution properties that has been used in metal electrodeposition, extraction, and recovery, and are also promising lixiviants for the hydrometallurgical leaching of LiB cathodes[2] and do not need any additional reducing agents. In this work, we report the ultrafast recovery of Li from LiB cathodes in a Choline chloride (ChCl):Ethylene glycol (EG) based DES. We observe Li leaching efficiencies as high as ~80% within 5 mins and ~95% in 15 mins from commonly used cathode materials, e.g., NMC ($LiNi_{0.33}Mn_{0.33}Co_{0.33}O_2$) and NCA ($LiNi_{0.80}Co_{0.15}Al_{0.05}O_2$). The leaching efficiency remains almost unaffected by lowering the temperature significantly or by increasing the solid-to-liquid ratio. A combination of experimental results and DFT calculations have been used to investigate the leaching mechanism, where EG acts as a hydrogen bond donor, while Cl^- from ChCl assists in solvation of the cations. While Co and Ni form terachlorometalate complexes, Li remains in close contact with Cl^- ions in a van der Waals type interaction, which is energetically and kinetically more favorable, leading to its faster leaching. The increased concentration of ChCl in the DES improves the leaching efficiency due to the higher availability of Cl^- ions. The Li thus leached is recovered by precipitation in the form of Li_2CO_3. This work delineates an economically viable and environmentally benign pathway for LiB cathode recycling, while also providing insights into its leaching mechanism, which will be instrumental in the future design of such lixiviants.

Stimuli-Responsive Ligand Systems for Rare Earth Element Separation Ilja Popovs; Oak Ridge National Laboratory, United States

Rare earth element separation is one of the most challenging demixing problems of the modern age. The difficulty of separating lanthanides into groups stems from their chemical similarity in the most prevalent +3 oxidation state and only marginal change in ionic radii of the cations across the series. Even more challenging is the adjacent lanthanide separation, which in conventional solvent extraction process requires hundreds of stages to isolate individual REE in high purity. Additionally, overall process consumes large volumes of chemicals and produces waste. We have designed an electrochemically-driven separation of REEs using smart ligand. Depending on the redox state of the ligand, it can be soluble in either organic or aqueous phase, thus imparting the solution with selectivity towards heavy lanthanides. By applying electrical current or through addition of reducing or oxidizing reagent, we can control partitioning of both the ligand and the lanthanide of interest in the phase of choice. Dual ligand system allows efficient separation of near adjacent lanthanides with high efficiency. Mechanistic considerations, ligand design strategy and REE separation performance of this novel system will be presented.

11:45 AM EN07.04.09
Investigating Molecular Systems Based on Rare-Earth Metals via SX-STM Sarah Wieghold[1], Nozomi Shirato[1], Kyaw Zin Latt[1], Volker Rose[1], Eric Masson[2] and Saw Wai Hla[1,2]; [1]Argonne National Laboratory, United States; [2]Ohio University, United States

Rare-earth metals exhibit promising optical, magnetic, and catalytic properties and are used in a wide variety of energy conversion applications and emerging quantum technologies. Recently, molecular systems such as coordination complexes and supramolecular networks have attracted attention due to their potential to precisely control the location and local environment of the rare-earth atoms by incorporating them into a molecular scaffold. These molecular approaches provide an engineering control in which the metal ion, bond length, angle and functionality of the organic linker can be varied depending on the application.

In this contribution, we present a synchrotron x-ray scanning tunneling microscopy (SX-STM) approach to investigate molecular systems based on various rare-earth atoms and organic linker moieties at the nanoscale. We use STM to study the inter- and intramolecular interactions of supported molecular systems at the nanoscale. Further, we use x-ray absorption near edge spectroscopy (XANES) via SX-STM to probe the local oxidation state and change in the total electron yield (TEY) depending on the rare-earth concentration. This work provides fundamental understanding of local chemical environment of rare-earth ions caged inside the molecular scaffolds and will be useful for designing novel rare-earth molecular systems for potential applications.

Grain Boundary Rich Noble Metal Nanoparticle Assemblies—Synthesis, Characterization and Reactivity Long Luo; Wayne State University, United States

Grain boundaries (GBs) have been previously used extensively to control mechanical strength, plasticity, and conductivity, and recently, the interest in GBs has extended to their catalytic properties. Here, we present a comprehensive study on the synthesis, characterization, and reactivity of grain-boundary (GB)-rich noble metal nanoparticle (NP) assemblies. A facile and scalable synthesis of Pt, Pd, Au, Ag, and Rh NP assemblies is developed, in which NPs are predominantly connected via Σ3 (111) twin GBs, forming a network. Driven by water electrolysis, the random collisions and oriented attachment of colloidal NPs in solution lead to the formation of Σ3 (111) twin boundaries and some highly mismatched GBs. This synthetic method also provides convenient control over the GB density without altering the crystallite size or GB type by varying the NP collision frequency. The structural characterization reveals the presence of localized tensile strain at the GB sites. The ultrahigh activity of GB-rich Pt NP assembly toward catalytic hydrogen oxidation in air is demonstrated, enabling room-temperature catalytic hydrogen sensing for the first time. Finally, density functional theory calculations reveal that the strained Σ3(111) twin boundary facilitates oxygen dissociation, drastically enhancing the hydrogen oxidation rate via the dissociative pathway. This reported large-scale synthesis of the Σ3 (111) twin GB-rich structures enables the development of a broad range of high-performance GB-rich catalysts.

Relationships Between Structural Inhomogeneities at Atomic-Scale and Functional Properties Hyoju Park, Micah Prange, Peter V. Sushko and Dongsheng Li; Pacific Northwest National Laboratory, United States

Catalytic activity is highly influenced by the bonding of reactants to solid surfaces to modulate the energetic barriers that must be overcome. The strengths of these bonds can be modified by the choice of material composition and control of the atomic arrangements. For example, researchers have found that deformation in the crystal lattice (strain) significantly affects catalytic activity. In turn, the strain distribution can be tailored by defects, grain boundaries, and the interaction of the catalyst with underlying support.
In this work, we employ high-resolution transmission electron microscopy (TEM) to investigate the atomic structures of heterogeneous catalysts (e.g., Pt supported on TiO_2 nanoparticles), focusing on the detailed characterization of their structure, including bonding states, strain distribution, defects, and grain boundaries, especially at the contact areas of nanoparticle assemblies and the interfaces of catalyst with underlying support. In addition, using in-situ TEM, we explore kinetics and dynamics of catalytic reactions upon exposure to various conditions at the surfaces of catalysts and the interfaces of catalyst and support materials by observing the evolution of the surface structures of nanoparticles and the active epitaxial sites at the interfaces. The experimental results based on the structural analysis and catalytic activity tests corroborated with *ab initio* simulations based on the density functional theory to explore the structure-function relationships and establish factors responsible for the enhanced catalytic activity. This provides an insight that allows utilizing the structural inhomogeneities and designing surface structures and compositions for tailored functionality of catalytic materials.

2:15 PM EN07.05.03
Effect of Contacts in Assemblies of Nanoparticles on Hydrogen Adsorption and Kinetics Nanjun Chen[1], Hyoju Park[1], Xin Geng[2], Micah Prange[1], Long Luo[2], Dongsheng Li[1] and Peter V. Sushko[1]; [1]Pacific Northwest National Laboratory, United States; [2]Wayne State University, United States

Numerous studies have demonstrated a strong coupling between the lattice strain and catalytic activity of platinum group elements. Understanding the strain–activity relationships require creating new types of strained nanoscale materials. Here, we investigate strain distribution in assemblies formed by attachment of metastable Pt and Pd nanoparticles. Through the formation of coherent and incoherent interfaces at the particle-particle contacts, these systems give rise to unusual coordination environments and strain states that may affect their catalytic activity. Transmission electron microscopy observations suggests that octahedral nanoparticles form preferentially face-to-face, corner-to-corner, and corner-to-face contacts. We use classical molecular dynamics to simulate the nanoparticles attachment process leading to the formation of particle-particle contacts and to create plausible atomistic models of these contacts depending on the relative orientation of the nanoparticle. Characteristics of the atomic sites in the vicinity of the contacts regions, including coordination number and local interatomic distances, allow us to relate the structure of the particle-particle contacts and the corresponding strain distributions to their ability to bind and accumulate hydrogen species. These predictions are then validated against *ab initio* simulations and further linked to the local electronic properties of the interfacial atoms. This study deepens our mechanistic understanding of the role of nanoparticle contacts in hydrogen adsorption and provides suggestion on a viable path towards rational design of hierarchical structures with a high affinity to hydrogen.

2:30 PM EN07.05.04
Artificial Intelligence Multiscale Modeling for Highly Ordered Pt@PtCo Core-Shell Catalysts as Durable Electro-Catalysts in the PEM Fuel Cell Jong Min Lee[1], Song Jin[2,3], Mun Seon Kang[1], Minseon Park[4], Sung Mook Choi[1] and Min Ho Seo[5]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Korea Institute of Materials Science (KIMS), Korea (the Republic of); [3]Gwangju Institute of Science and Technology (GIST), Korea (the Republic of); [4]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [5]Pukyong National University, Korea (the Republic of)

Development of highly active electrocatalysts that are cost competitive takes the center stage in research fields for next-generation electrochemical energy conversion and storage systems like fuel cell and metal-air battery. Regarding the systems for commercialization, there are various challengeable issues, which should overcome sluggish kinetics and stability on the electrocatalyst for the aimed reactions such as oxygen reduction reaction (ORR) occurred in the high over-potential and harsh conditions. Although there was huge technological advancement as minimizing the usage of a noble metal or developing non-precious owing to many attempts to reach the purpose in the past decade, it still needs further improvement in order to gain acceptance in the market. To find new material or optimize it, the efficient way would be initialized from the knowledge of the underlying physical and chemical mechanisms in a material system. For this reason, therefore, fundamental studies using quantum mechanics (QM) along with experimental confirmation have been commonly conducted to explain the activity and stability of oxygen reactions. These approaches are very successful and provide fundamental insight to scientists and researchers. Nevertheless, calculative simulations are still the restrictions to obtaining trustable data and predicting correct consequences, especially on large-scale modeling. This talk will present recent efforts for accurate modeling with experimental data. We predicted and validated the ORR activity and stability for PtCo alloy and Pt@Co core-shell structure in density functional theory (DFT). The force field, which is an efficient way of describing the dynamics with large-scale simulations, was developed to simulate large-scale models via machine-learning Force Fields. This synergetic approach using both computational models and experiments with physicochemical analyses would accelerate to find new materials and optimize catalyst performance. This work was supported by the NRF of Korea Grant and by the Technology Innovation Program of MOTIE [NRF- 2022R1A2C2093090 & 20019175]

Understanding Competitive Electrochemical Reactions on Strained Surfaces Kelsey A. Stoerzinger[1,2]; [1]Oregon State University, United States; [2]Pacific Northwest National Laboratory, United States

In heterogeneous electrocatalysis, reactants adsorb on a materials surface, and subsequently transfer electrons to or from the solid in conjunction with ionic motion, forming and breaking chemical bonds. This complex interface—between a solid surface and a reactive gas and/or liquid—can change dramatically with the electrochemical potential that drives such reactions. For example, materials can change oxidation state (where changes in the surface oxidation state are associated with adsorbates, and bulk changes require diffusion of oxygen through the material itself) or change their structure/phase. Such changes in a catalyst are intimately linked to their functionality and activity for desired electrochemical reactions.

We have been investigating how metal electrocatalysts react with species from aqueous solution by electrochemical approaches with complementary spectroscopy. We are particularly motivated by complex reaction environments where multiple species – such as reducible reactants and protons – compete for sites on the surface, influencing the activity for reduction reactions. This competition and resultant activity depends on the applied voltage, but also characteristics of the electrocatalyst itself, such as strain and the presence of defects. We will share how such changes in a material's bulk influence competitive processes on the surface and the formation of hydride phases under electrochemical conditions.

3:45 PM EN07.05.06

Catalytic Performance Promotion of Pd Cluster Towards H_2O_2 Production by Potential-Driven Coordination Adjustment Zhiping Deng and Xiaolei Wang; University of Alberta, Canada

Electrochemical synthesis of hydrogen peroxide has been emerging as an appealing process for the onsite production of this chemically valuable oxidant, while its commercial application is still hindered by the development of efficient electrocatalyst. Herein, we design an efficient electrocatalyst for the electrochemical synthesis of H_2O_2 consisting of Pd cluster loading on hollow mesoporous carbon spheres (HMCS). Pd coordination environment is well designed with S in the first coordination sphere and O in the second coordination sphere. The as-prepared material exhibits superior performance with high H_2O_2 selectivity (maximum value: 99%) over a wide potential range of 0 to 0.6 V. Moreover, a high kinetics mass activity (4.059 A mg^{-1} at 0.45V) of Pd_x/HMCS is achieved, which is almost three times larger than the state-of-the-art Pd-Hg alloy catalyst. What's more, in neutral electrolyte, Pd_x/HMCS also a positive onset potential of 0.647 V and high H_2O_2 selectivity of 84-93% within a wide potential range. The excellent performance can be attributed to the unique Pd cluster structure and optimized Pd coordination environment, especially the oxygen modification on HMCS support. In-situ Raman results reveal that under potentials, oxygen atoms transfer from the second coordination sphere (oxygen containing functional groups on HMCS) to the first coordination sphere (Pd-O bond). Density functional theory (DFT) calculations confirm that such oxygen coverage helps optimize the *OOH binding energy on Pd surface, resulting in significantly enhanced catalytic performance towards H_2O_2 production. This work reveals the structure difference between in-situ and ex-situ situations, proposes a new mechanism for the improved performance, and provides new insights into the future catalyst design.

4:00 PM EN07.05.07

The Study of Surface Stability of Pt_3Co Alloys Under Oxygen Pressure Using AP-XPS and AP-STM Jeongjin Kim[1], Jeong Young Park[2], Hiroshi Kondoh[3], Toyoshima Ryo[3] and Bongjin S. Mun[4]; [1]Brookhaven National Laboratory, United States; [2]KAIST, Korea (the Republic of); [3]Keio University, Japan; [4]Gwngju Institute of Science and Technology, Korea (the Republic of)

The Pt_3Co alloys has been the choice of catalyst for the proton-exchange membrane fuel cell due to significantly higher oxygen reduction rate (ORR) than pure Pt catalyst. While the Pt_3Co catalyst received much attentions for its excellent performance and extensive lifetime in fuel cell applications, the basic questions such as the role of Co in ORR and the chemical active states of Co elements, have not been clearly answered. To address the basic knowledges on these aspects, the study on a model system is highly necessary.

In this presentation, utilizing both ambient pressure X-ray photoelectron spectroscopy and scanning tunneling microscopy, our investigation on the surface chemical states and surface morphology of Pt_3Co (111) single crystal will be presented. Under the elevated oxygen pressure and temperature, the presence of surface segregation of transition metals is clearly observed. However, the surface morphology and chemial states in Pt_3Co are slightly different from those of Pt_3Ni alloy. To identify the chemically active site on surface, the reactivity of the nanostructured oxides and Pt is tested under CO oxidation condition, revealing important information on the role of interfacial oxygen on the nanostructured metal oxides.

4:15 PM EN07.05.08

Synthesis and Characterization of Pt and Pd Nano-Shells to Optimize the Performance and Reduce the Cost of Expensive Catalysts Alexandre Foucher and Frances Ross; Massachusetts Institute of Technology, United States

The transition to sustainable and efficient industrial processes requires the development of novel nano-catalysts to enhance the production of chemicals and energy. Unfortunately, many catalysts used for important processes are composed of the most expensive transition metals. For instance, Pt is an ideal catalyst for the production of H_2 or for fuel cells, while Pd is an essential catalyst for CO oxidation in catalytic converters or for the hydrogenation of alkynes. To reduce the use of these two metals and ultimately achieve sustainable and cost-efficient catalysis, we synthesized monodisperse core-shell Cu-Pt and Cu-Pd particles with a solvothermal method. The Cu core was then removed through thermal oxidation, which caused the migration of Cu oxide through the Kirkendall effect, and left empty shells of Pt and Pd. The thickness and size of the shells could be controlled. *In situ* transmission electron microscopy at high temperatures and under a gaseous atmosphere demonstrated the stability of the samples. The core-shell configuration allows an increased surface area of exposed Pt and Pd to catalyze gases or liquids. Oxygen reduction reaction (ORR) measurements on the Pt nano-shells and CO oxidation analysis on Pd nano-shells showed enhanced activity and stability. Thus, the design of these nano-shells with enhanced functionality can help to achieve sustainable supply of expensive materials for the chemical industry.

4:30 PM EN07.05.10

Superior Performance and Stability of Anion Exchange Membrane Water Electrolysis—Non-Precious Electrocatalysts for the Oxygen Evolution

Reaction Ju-chan Yang[1], Jaehoon Jeong[1], Ji-hoon Lee[1] and Sung Mook Choi[1,2]; [1]Korea Institute of Materials Science, Korea (the Republic of); [2]University of Science & Technology, Korea (the Republic of)

The application of electrocatalysts with high activity to a practical water electrolysis cell is a crucial challenge for the production of pure hydrogen and commercialization of the water electrolyzer. Herein, the Cu–Co oxide electrocatalysts were synthesized for the OER through pH-controlled co-precipitation to apply as the anode electrode of AEMWE. We developed nano-sized $Cu_{0.5}Co_{2.5}O_4$ with abundant oxygen vacancies very easily and creatively by using the difference in precipitation rate with the pH of Cu and Co. It was confirmed that $Cu_{0.5}Co_{2.5}O_4$, which has been optimized by pH control, has many oxygen vacancies and a large amount of Co3+, which is an active site for the OER. Because of this, it exhibits superior catalytic activity and long-term stability in the half-cell tests. Recent reports on electrocatalysts for water electrolysis have only focused on catalytic activity in half-cell tests. An important point for the commercialization of water electrolysis is that they should show excellent performance even when the catalyst is applied to an electrolyzer. This study not only compared the catalytic activity of the synthesized $Cu_{0.5}Co_{2.5}O_4$ catalyst but it also directly applied a full cell for the AEMWE system to confirm the performance of practical hydrogen production. The performance of the AEMWE cell was higher than that of any AEMWE cells reported in the literature, even compared to the AEMWE using IrO_2 as an anode.

5:00 PM EN07.06.01
Fabrication of ZnV2O4 Nanoparticles Embedded in Carbon Nanofibers as a Cathode Material for High-Performance Aqueous Zn-Ion Batteries
Jiwon Jung, Jeong-Ho Park, Na-Yeong Kim, Ilgyu Kim and Min Kyeong Gi; University of Ulsan, Korea (the Republic of)

Recently, lithium-ion batteries have led the related market. However, the price of Li is expected to increase continuously, leading to unbalance of demand and supply for LIBs used for electric vehicles (EVs) and energy storage systems (ESS). For replacing LIBs, electrically rechargeable aqueous zinc-ion batteries (ZIBs) have been spotlighted due to Zn's attractive properties, such as being environmentally friendly, low price, and high stability. Nevertheless, the low capacity of ZIBs is attributed to low-capacity cathode material, restricting their practical utilization. To increase the capacity of ZIBs, ZnV_2O_4 containing the Zn element has recently been considered. However, the ZnV_2O_4 cathode developed so far shows various problems of low electronic conductivity and low surface area limiting reaction sites. Here, we suggest ZnV_2O_4 nanoparticles embedded in carbon nanofibers (ZVO@CNFs) as a promising cathode material for ZIBs. The ZVO@CNFs were synthesized using the electrospinning process and heat treatments, including stabilization and carbonization. The fabricated ZVO@CNFs were investigated by SEM, TEM, XRD and XPS to confirm how can the ZVO nanoparticles form inside. In addition, Raman analysis was conducted to know the composition of ZVO@CNFs and crystal lattice information. The ZIB cell with the ZVO@CNFs was evaluated for its feasibility. Charge and discharge tests and rate tests were conducted for the ZIB cell with ZVO@CNFs, which delivered a specific capacity of approximately 300 mAh/g at a current density of 500 mA/g, and excellent stability for 250 cycles. CV(Cyclic Voltammetry) was conducted to determine the voltage window, reversibility, and impurities in the system where the redox reaction occurs.

5:00 PM EN07.06.15
Hydrothermally Synthesized Cobalt-Iron-Based Nanocomposite Doped Sulfur and Phosphorous for Energy Storage Application Shiva Bhardwaj[1,2], Rishabh Srivastava[1,2], Teddy Mageto[1,2] and Ram Gupta[1,2]; [1]Pittsburg State University, United States; [2]National Institute for Material Advancement, United States

The continuous use of fossil fuels for energy production leads to their depletion at a faster rate. The amount of energy produced using fossil fuels generates carbon dioxide(CO_2), leading to global warming. However, using these fossil fuels to create devices that store energy might decrease our dependency on fossil fuels and produces less CO_2. Various devices can store energy, like batteries, supercapacitors (SC), and fuel cells. Among these devices, SC outperforms others with several advantages, including high-power density, fast charge discharge, and low-cost production. This work introduces cobalt-iron-based nanocomposites prepared using a hydrothermal synthesis route followed by sulfurization and phosphorization. The crystallinity of nanocomposites has been confirmed using X-ray diffraction, where crystalline nature improves from as-prepared to sulfurized to phosphorized. The as-synthesized CoFe-nanocomposite exhibits a specific capacitance (C_{sp}) of 120 F/g at 1 A/g, along with a power density of 3752 W/kg and a maximum energy density of 4.3 Wh/kg. The results improved after sulfurization showing 183 F/g at 1 A/g with 3892 W/kg, 7.9 Wh/kg of power, and energy density. Furthermore, the phosphorized nanocomposite shows the best performance by exhibiting 252 F/g at 1 A/g and the highest power and energy density of 4183 W/kg, 10.1 Wh/kg. This shows that the results get improved more than twice. The electrochemical impedance spectroscopy study shows the lowest charge transfer resistance for the phosphorized nanocomposite. The 95% capacitance retention after 5000 cycles shows cyclic stability of phosphorized CoFe. Our research thus offers cost-effective and highly efficient energy storage devices.

5:00 PM EN07.06.02
Enhancing Selectivity Towards CO over Co/CeO_2 Catalyst for CO_2 Hydrogenation by Calcination Rena Oh[1], Xiaoyang Huang[2], Yanping Zheng[2], Ki Tae Nam[1], Gyeong-Su park[1] and Seong Keun Kim[1]; [1]Seoul National University, Korea (the Republic of); [2]Xiamen University, China

Seeking energy sources to supplant fossil fuel is a confronted task to mitigate atmospheric CO_2 concentration and suppress global warming problem. Electricity-based fuel (E-fuel), synthesized from green H_2 and CO_2, is one of solutions. Due to a thermodynamic unfavourability of C-C bond formation through direct CO_2 hydrogenation, synthetic fuels are usually generated by CO hydrogenation, i.e., Fischer Tropsch synthesis, which requires selective CO production by electro-catalytic CO_2 reduction or thermos-catalytic CO_2 hydrogenation. Here, we demonstrated a simple preparation method of Co/CeO_2 catalyst to increase the selectivity towards CO during CO_2 hydrogenation. Generally, Co-based catalysts of metallic Co nanoparticles with metal oxide support material are well-known for its selective production towards CH_4. However, we found that by using CeO_2 support calcined at an unusually high temperature, the CO selectivity significantly increased over Co/CeO_2 catalyst under atmospheric pressure at a wide range of reaction temperature. We investigated the microstructure of catalysts and identified the formation of reduced CeO_{2-x} surface layer in the CO-selective catalyst, corroborated by *in-situ* X-ray photoelectron spectroscopy and high-resolution transmission electron microscopy with electron energy loss spectroscopy. Based on the catalyst structure, we suggested that CO-production is correlated to an enhanced reduction of CeO_2 support and the reduced CeO_{2-x} may be preserved during CO_2 hydrogenation without sacrificial oxidation instead of metallic Co due to a weak metal-support interaction. In addition, the CO-selectivity further enhanced upon the additional pretreatment over the reduced catalyst, which is attributed to the formation of carbon structures encapsulating the Co surface.

5:00 PM EN07.06.03
Mechanism Investigation of Enhanced Electrochemical H_2O_2 Production Performance on Oxygen-rich Hollow Porous Carbon Spheres Zhiping Deng and Xiaolei Wang; University of Alberta, Canada

Electrochemical oxygen reduction is a promising approach for the sustainable decentralized production of H_2O_2, but its viable commercialization is hindered by the insufficient development of efficient electrocatalysts. Here, we demonstrate a promising carbon-based catalyst, consisting of oxygen-rich hollow mesoporous carbon spheres (HMCS), for selective oxygen reduction to H_2O_2. The as-prepared HMCS exhibits high onset potential (0.82 V) and half-wave potential (0.76 V), delivering a significant positive shift compared with its oxygen-scarce counterparts and commercial Vulcan carbon. Moreover, excellent H_2O_2 selectivity (above 95%) and electrochemical stability (7% attenuation after 10 hours operation) make this material a state-of-the-art catalyst for electrochemical H_2O_2 production. The outstanding performance arises from a combination of several aspects, such as porous structure-facilitation of mass transport, large surface area, and proper distribution of oxygen-containing functional groups modification on the surface. Furthermore, the proposed ORR mechanism on HMCS surface reveals that -OH functional groups help promote the first electron transfer process while other oxygen modification facilitates the second electron transfer. Furthermore, we investigate the porosity engineering effect on catalytic performance inconsistency through a material platform consisting of a series of HMCS samples. The performance comparison of HMCS samples in RRDE and Zn-air battery together with the simulation of diffusion behavior reveals that in low current density conditions large surface area is preferred but the mass transport governs the performance in high current density region. On account of the favorable porous structure, HMCS-8 nm delivers the most excellent practical performance (166 mW cm^{-2}) and performs well in the bifunctional Zn-air battery for the wastewater purification (70% RhB degraded after 2 min and 99% after 32 min).

5:00 PM EN07.06.04
***In Situ* Formed Nickel Silicide as a Recombination Layer for Perovskite/TOPCon Tandem Solar Cells** Dowon Pyun, Jiryang Kim, Dongjin Choi, Seok-Hyun Jeong, Changhyun Lee, Jiyeon Hyun, Ha Eun Lee, Sang-Won Lee, Hoyoung Song, Solhee Lee, Yoonmook Kang, Donghwan Kim and Hae-Seok Lee; Korea University, Korea (the Republic of)

Up to date, perovskite/silicon 2-terminal tandem solar cells have shown continuous improvement of efficiency. The majority of highly efficient tandem solar cells are employing transparent conductive oxide (TCO) as an interlayer to connect top and bottom subcells. However, TCO requires additional deposition process, such as sputtering, which can negatively affect the performance of bottom subcell especially in open circuit voltage. Furthermore, high cost and scarcity of indium in TCO could hinder commercialization of tandem solar cells in near future. In this work, nickel silicide was proposed as a new concept of in-situ recombination layer which can replace TCO. NiO_X was directly deposited on n^+ poly-Si and anealed at high temperature. During annealing, Ni atoms in NiO_X diffused into n^+ poly-Si, which results in formation of nickel silicide. Contact properties of NiO_X/n^+ poly-Si with 2 different interlayers (NiSi, ITO) were measured and compared with energy band diagram. Ohmic contact was confirmed with nickel silicide, while schottky contact with ITO. Furthermore, diffusion of Ni leads NiO_X film to be Ni-deficient, which can improve carrier extraction and also FF. These results imply the potential of nickel silicide as a recombination layer for perovskite/TOPCon tandem solar cells.

5:00 PM EN07.06.05
A Study on PID-p(polarization) Phenomenon in Bifacial p-PERC Solar Module Solhee Lee, HongJun Jang, Yoonmook Kang, Donghwan Kim and Hae-Seok Lee; Korea University, Korea (the Republic of)

Bifacial solar cells have high efficiency by receiving light from both sides, and are in the spotlight as a solar cell that ultimately lowers the levelized cost of electricity (LCOE). Looking at the status of the global solar market, bifacial solar modules accounted for nearly 30% in 2021, and is expected to occupy more than 60% in 2032. Among them, bifacial p-PERC solar cells started to be commercialized in 2017, and mass production lines already exist. However, when a solar module is actually installed outside to generate an output of 600 V or higher, as time goes by as it is exposed to a high temperature and high humidity environment, PID (potential-induced degradation) degradation occurs in some cells within the module. This is a problem already known to occur in crystalline silicon solar cells, and solutions are being actively studied. In the bifacial p-PERC solar cell, it is known that the degradation at the back side is greater than that at the front side. In previous studies, it is known that PID-s (shunting) at the front and PID-p (polarization) degradation occurs at the rear, and the mechanism of rear polarization has not been clarified. In this study, a bifacial p-PERC solar module was fabricated and PID and recovery experiments were conducted, and characteristics were analyzed through light J-V, dark I-V, external quantum efficiency (EQE), and electroluminescence (EL) image measurements.

5:00 PM EN07.06.06
Highly Active and Stable Ir, Ru Metal Catalysts on t-ZrO_{2-x} Supports with Uniform Structure Derived from Metal-Organic Frameworks for Hydrogen Evolution Reaction Jonghwan Park[1,2], Mansu Kim[2], Sohui Kim[1,2], Joseph T. Hupp[2] and Dongmok Whang[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Northwestern University, United States

Electrocatalysts play a key role in green hydrogen production, essential for establishing sustainable society. Platinum group metals(PGM) are well-known for its high catalytic efficiency and stability for electrochemical hydrogen evolution reactions(HER). However, high cost of PGM hinders practical application of electrocatalysts. Supported metal catalysts are regarded as one of the potential solution by reducing the amount of metal content while maintaining the activity of catalysts. Nitrogen doped carbon and oxides are used as supports for catalyst metals to enhance stability of the catalyst metals in strong acid or basic conditions, even improving the intrinsic activities of catalysts by tuning the electronic structure of metals. Especially oxygen deficient oxides like t-ZrO_{2-x} are well known for their strong interaction with metals. Due to the abundant oxygen vacancies on the surface of t-ZrO_{2-x} particles, metals can be strongly bonded to t-ZrO_{2-x} particles. Furthermore, various ions and molecules can be absorbed on the surface of t-ZrO_{2-x} particles in aqueous solution where HER is conducted out. Those surface properties of t-ZrO_{2-x} particles can promote HER reactions on metal catalysts. In this study, we made the supported metal catalysts with the structure where M(M= Ir, Ru)-ZrO_{2-x} particles are well dispersed on the porous carbon using metal-organic frameworks(MOF) as a precursor. Uniform structure of M-ZrO_{2-x}/C was derived from chemically homogeneous nature of MOF. During the pyrolysis process of MOF in inert condition, ZrO_2 nods form t-ZrO_{2-x} nanoparticles on the conductive carbon matrix. Porous carbon matrix derived from MOF with high surface area facilitates the mass transport in HER. M-ZrO_{2-x}/C catalyst showed enhanced activity and greatly improved stability compared to commercial catalysts despite of low content of metals. Moreover, we found that surface property of t-ZrO_{2-x} nanoparticles can promote HER on the metal as a cocatalyst depending on the surrounding conditions.

5:00 PM EN07.06.07
A $NiCo_2O_4$ Electrocatalyst with a Thin Graphitic Coating for the Anion Exchange Membrane Water Electrolysis of Wastewater Jae-Yeop Jeong, Jaehoon Jeong and Ju-chan Yang; Korea Institute of Materials Science, Korea (the Republic of)

Water electrolysis has been suggested as one of hydrogen production system, following steam reforming, photoproduction, fossil fuel and gas extraction. Among these methods for production of hydrogen, the most attractive merit of water electrolysis is their high efficiency and the generation of high purity hydrogen without environmental pollution. Anion exchange membrane water electrolysis (AEMWE) is a technology that has recently attracted attention

because it combines the advantages of existing polymer exchange membrane water electrolysis (PEMWE) and alkaline water electrolysis (AWE). Similar to PEMWE, AEMWE can be manufactured in a stack with a solid membrane, so it has high purity of hydrogen with high pressure. And, it is possible to reduce cost by using a non-noble based electrode by operating in an alkaline atmosphere. However, since the performance is lower than other precious electrocatalyst, it is urgent to develop a high efficiency non-precious metal catalyst to overcome this problem.
We demonstrate the simple preparation of a non-precious metal catalyst based on $NiCo_2O_4$ (NCO). Further, we used high-energy ball milling with graphite to modify the NCO catalyst to prepare a material with small particle size, high surface area and high conductivity, which enhanced the electrocatalytic performance of the materials in electrochemical tests and when applied to an anion exchange membrane water electrolyzer. Crucially, comparison of the performance of the pristine NCO catalyst and that modified with graphite (NCO@C) revealed that the latter showed better activity and durability for the hydrogen and oxygen evolution reactions under alkaline conditions. Further, we applied the possibility of using this electrocatalyst in alkaline wastewater and observed similar performance and durability to that in pure electrolyte.

5:00 PM EN07.06.08
Thermal Selenization of Transition Metal-Based Nanomaterials Renata Palowska[1,2], Mikolaj Kozak[1,2], Marta Zych[1,2], Agnieszka Brzozka[1], Lifeng Liu[2] and Grzegorz D. Sulka[1]; [1]Jagiellonian University, Poland; [2]International Iberian Nanotechnology Laboratory, Portugal

Transition metal selenides (TMSs) belong to the group of materials interesting to water electrolysis research, due to their favourable electrocatalytic activity towards either hydrogen (HER) or oxygen (OER) evolution reactions, good conductivity and stability [1]. Additionally, some TMSs have been reported to show catalytic activity towards both HER and OER [2], and might be used in both acidic and alkaline environments [3]. The most commonly used TMS synthesis paths include electrodeposition, hydro/solvothermal methods and chemical vapour deposition (also called thermal selenization) [3]. Among them, thermal selenization seems to be quite useful, as it can be combined with a variety of transition metal precursor preparation methods, allowing for various morphologies and stoichiometries.
In this contribution we show how thermal selenization can be used in tandem with electrodeposition to prepare Co, Ni or Mn-based materials. Transition metal nanostructures were prepared via electrodeposition from either aqueous or ethaline-based solutions. Then, thermal selenization was performed in a tube furnace in temperatures ranging from 400°C to 600°C, under an inert atmosphere, for up to 2 h. Scanning electron microscopy, X-ray powder diffraction and energy-dispersive X-ray spectroscopy measurements were carried out to determine the morphology and phase content of obtained TMS nanomaterials.

Molten Metal Catalyst with Ceramic for CO_2-free Hydrogen Production Young Jae Lee, Waqas Muhammad and Hyungtak Seo; Ajou University, Korea (the Republic of)

Hydrogen energy is sustainable and clean energy, but the process of hydrogen production is not clean. The major hydrogen production route is based on steam methane reforming. This method generates a lot of CO_2 when hydrogen is produced (i.e., 9-15 ton of CO_2 per 1 ton of H_2). As hydrogen is claimed as environmentally benign energy resources or carriers, steam methane reforming is not suitable. Therefore, a new strategy for clean hydrogen production is highly on demand.
Methane pyrolysis can achieve CO_2-free hydrogen production using thermal catalysts. Solid metal catalysts have beneficial advantages for methane pyrolysis at lower operating temperatures. However, the solid metal catalysts in methane pyrolysis have a fatal limitation which suffered from deactivation. When the solid metal catalysts react with methane on active sites, solid carbon as reaction products deposit on it.
Molten catalysts were used to overcome the drawback of the solid metal catalyst. After the reaction, the products (most of the carbon) escaped to the surface by density difference instead of being deposited on active sites. In this work, reported molten Nickel bismuth (NiBi) catalyst with addition of cerium (IV) oxide (CeO_2) aiming promotion effect of conversion rate was prepared as a methane cracking catalyst.
The methane conversion rate was measured by gas chromatography (GC) at various temperatures and methane gas flows. After conversion rate evaluation, the catalyst stability test upto 100 hours was performed. The catalyst activation was maintained for 70 hours. Compared to molten NiBi catalyst, the performance of molten CeO_2-NiBi catalyst showed enhanced methane conversion rate and increased reactivity as time goes on. It means CeO_2 also helps the pyrolysis reaction as the catalyst. These results showed not only molten metal but also other various materials like ceramics can be composed for methane pyrolysis strategies.

Transition Metal-Doped Complex Metal Oxide as Highly Efficient Electrocatalyst for Oxygen Evolution Reaction in Alkaline Media Minsol Kwon, Taehyun Kwon and Dongju Lee; Chungbuk National University, Korea (the Republic of)

As the global energy crisis grows, hydrogen is attracting attention as a sustainable and clean energy to replace fossil fuel. Electrochemical water splitting by renewable energy, such as sunlight and wind, is a pollution-free way to produce large amounts of hydrogen and oxygen. The development of non-noble electrocatalysts with low cost, excellent performance and durability for overall water splitting is very important. Complex transition metal oxide, such as nickel iron oxide, nickel cobalt oxide, and cobalt iron oxide, exhibits relatively good performance in the oxygen evolution reaction. Recently, many studies have been conducted on improving the performance of oxygen evolution reaction due to the fast and brisk transfer of electrons through doping.
In this work, we investigated the effects of transition metal doping on electrocatalytic performance of nickel iron oxide prepared by hydrothermal method. The transition metal-doped nickel iron oxide electrocatalyst showed better performance and stability in the oxygen evolution reaction for overall water splitting due to efficient charge transfer.

Thiometallate Precursors for the Synthesis of Supported Pt and PtNi Nanoparticle Electrocatalysts— Size-Focusing by S Capping Woo Yong Choi; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Thiometallate precursor enabled the monodisperse synthesis of supported Pt nanoparticles and the in situ formation of S, which were caught directly in a collection system by the nanoparticle synthetic processes consisting of impregnation and thermal processes. S is proven to act as a capping agent in generating highly stable nanoparticles with the size ranging from 2 nm to 3 nm and further favors the formation of monodispersed particles by solid-state digestive ripening. The proposed synthetic methodology can be applied to high-quality PtNi alloy nanoparticle systems. The prepared carbon-supported Pt and PtNi nanoparticles were characterized as electrocatalysts for the oxygen reduction reaction and exhibited superior performance and durability to commercial Pt/C.

Fluorine-Decorated Graphene Nanoribbons with Tailoring Chemical Exfoliation State for an Anticorrosive Polymer Electrolyte Membrane Fuel Cell Song Jin[1,2], Jong Min Lee[3], Minseon Park[4], Jeemin Hwang[3], Sung Mook Choi[2] and Min Ho Seo[5]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Materials Science, Korea (the Republic of); [3]Korea Institute of Energy Research, Korea (the Republic of); [4]Pohang University of Science and Technology, Korea (the Republic of); [5]Pukyong National University, Korea (the Republic of)

Pt-supported carbon material-based electrocatalysts are formidably suffering from carbon corrosion when H_2O and O_2 molecules are present at high voltages in polymer electrolyte membrane fuel cells (PEMFCs). In this study, we discovered that the edge site of a fluorine-doped graphene nanoribbon (F-GNR) was slightly adsorbed with H_2O and was unfavorable with O atoms after defining the thermodynamically stable structure of the F-GNR via the DFT calculations. Based on the computational predictions, the physico-electrochemical properties of F-GNRs with tailoring fully or partially exfoliated state were investigated as support materials for electrocatalysts and the additives in the cathode of a PEMFC. In electrochemical evaluations, the Pt/F-GNR with controlled exfoliation states (fully or partially) showed much lower degradation rate in the carbon corrosion condition and were effective in the cathode as additives compared to commercial Pt/C, resulting from the improved carbon corrosion durability owing to the improved structural stability and water management. Notably, the F-GNR with highly stable carbon corrosion contributed to achieving a more durable PEMFC for long-term operation.

Doped Transition Metal Based Electrocatalyst for Water Splitting Seunghun Lee[1], Yangdo Kim[1], SeoHyun Park[2] and Yoo Sei Park[2]; [1]Pusan University, Korea (the Republic of); [2]Chungbuk University, Korea (the Republic of)

Electrochemical water splitting is attracting attention as a next-generation renewable energy technology that uses renewable electricity from solar or wind energy to produce hydrogen. So, developing cost-effective and highly active electrocatalysts for enhancing the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) is a significant challenge for overall water splitting. Currently, benchmark catalysts for oxygen evolution rely on noble metal oxides such as iridium oxide (IrO2) and ruthenium oxide (RuO2), and the most effective catalyst for hydrogen evolution is a platinum (Pt)-based noble metal catalyst. However, these precious metal materials are not widely applied due to their high price and scarcity. The development of highly active, highly functional electrocatalysts for electrochemical water splitting offers several advantages in simplifying device manufacturing and reducing costs. Various transition metal-based electrocatalysts (i.e., oxides, phosphides, sulfides and hydroxides..) were developed to overcome the disadvantages of precious metal-based catalysts, showing high catalytic activity against total water electrolysis. In particular, transition metal-based hydroxides are considered promising electrocatalysts due to their high catalytic activity and excellent durability. This study manufactured a transition metal-based catalyst improved through doping as a catalyst for total water electrolysis and analyzed its characteristics as a water electrolyte electrode catalyst through surface, composition, and electrochemical analysis.

5:00 PM EN07.06.16

Metal Organic Framework Catalyst of Mesoporous K-doped $NiCo_2O_4$ for Improved Oxygen Evolution Nam-Woon Kim[1], Jihun Oh[2] and Hyunung Yu[3]; [1]Samsung Electro-Mechanics, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [3]KRISS, Korea (the Republic of)

The water splitting reaction is a key process for the conversion and storage of clean and renewable energy, but requires a highly efficient non-precious metal electrocatalyst to reduce wide overpotentials for oxygen evolution reaction (OER) or hydrogen evolution reaction (HER). In particular, many efforts have been applied to explore high-efficiency OER catalyst because the OER has a higher kinetic barrier than the HER. Here, we have developed a novel K-doped $NiCo_2O_4$ (NCO) catalyst derived from the metal organic framework structure of Prussian Blue analogue (PBA) to demonstrate a high-performance OER electrode. The material is prepared with a simple hydrothermal synthesis method using the potassium (K) precursor present in the PBA. The K-doping in the NCO catalyst shows a high conductivity not only to increase the number of active oxygen vacancies but also change their intrinsic properties such as binding energy. The cyclic voltammetry (CV) scan of the K-doped NCO catalyst showed a low overpotential value of 0.292 V at a current density of 10 mA cm^{-2} and a Tafel value of 49.9 mV dec^{-1}, outperforming a commercial OER catalyst (Iridium). The synthesized K-doped NCO can be utilized as high performance electrode materials for metal-oxide batteries and supercapacitors.

Suitability of Tungsten Nitride (WN) as a Sustainable Hard Coating Material for Nuclear Applications Sri Bharani Ghantasala and Sumitra Sharma; National Institute of Technology Silchar, India

The recent technological advancements led to the development of fourth generation nuclear reactors with an improved thermal efficiency. This ensures an effective and efficient power generation through the nuclear power plants operating at higher temperatures. Consequently, the components of the nuclear reactors generally made up of nickel (Ni) based super-alloys are exposed to extreme temperatures, severe wear and corrosion resulting in increased maintenance and replacement costs. Moreover, Ni is considered to be critical raw material (CRM) as per the 2010 and 2014, EU reports [1]. In this regard, the nuclear industry traditionally uses chromium (Cr) film synthesized using electro-deposition that provides decent corrosion and wear resistance. However, the recent regulation norms on the Cr restricted the usage due to its harmful nature and adverse health effects [2]. So, it is highly important to explore new materials in order to protect the nuclear components from extreme wear and corrosion at high temperatures. The viability of transition metal nitrides (TMNs) as protective hard coating materials has thrown much attention in the current research to address the increasing industrial demand. The reason for this could be their significant structural, morphological, thermal and mechanical properties. Out of various TMNs, tungsten nitride (WN) possesses a peculiar property of solid lubricity that makes it highly wear and scratch-resistant. Furthermore, this material can withstand upto very high temperature and it is chemically inert. On account of this, WN is known to be one of the best refractory and corrosion resistant material [3]. However, tungsten (W) is also considered to be a CRM as per the 2010, 2014 and 2017, EU reports. In this context, it is required to fabricate highly durable and reliable WN films to ensure the sustainable utilization of the W metal in nuclear applications. To achieve this, the current study adopts magnetron sputtering, a physical vapor deposition (PVD) technique, to deposit high-quality uniform WN films with excellent morphological and substantial adhesive properties. The WN films were produced at argon (Ar) flow rate of 30 sccm and a varying nitrogen (N_2) flow percentages of 5 %, 15 % and 25 % of total gaseous mixture (i.e. Ar + N_2) at a deposition power of 30 W and 300 ^{o}C substrate temperature (for initial 15 min of the deposition) using magnetron sputtering. The X-ray diffraction (XRD) technique confirmed the presence of the FCC β-W_2N phase of WN at a N_2 flow of 5 %. It was also confirmed by the formation of W $4f_{7/2}$ and W $4f_{5/2}$ doublet peaks at the binding energies of 30.6 and 32.8 eV, respectively, depicted through W 4f core level spectra of X-ray photoelectron spectroscopy (XPS). On increasing the N_2 flow percentage, the β-W_2N is converted to mixed phases of β-W_2N and δ-WN (hexagonal) and further increment leads to the formation of amorphous phases of WN. In addition to this, field emission - scanning electron microscopy (FE-SEM) and atomic force microscopy (AFM) portrayed the formation of dense microstructures with a root mean square (RMS) surface roughness of 1.15 nm at a N_2 flow of 5 %. The mechanical properties of the WN films such as hardness and elastic modulus are found to be 32.66 GPa and 163.64 GPa, respectively characterized via nano-indentation test. Furthermore, the nano scratch test performed on the WN film resulted in a considerable wear rate and a friction coefficient of 0.33. These experimental outcomes would be sufficient enough to propose WN as a suitable material for sustainable protective hard coatings in nuclear reactors.

Critical Materials: Atomic Level Investigations and Manipulation of Individual Rare Earth Complexes on Materials Surfaces Saw W. Hla; Argonne National Laboratory/Ohio University, United States

Complexes containing rare-earth ions [1] attract great attention for their technological applications ranging from spintronic devices to quantum information science. While charged rare-earth coordination complexes are ubiquitous in solution, they are challenging to form on materials surfaces that would allow investigations for potential solid-state applications. In this talk, we will present formation and atomically precise manipulation of rare-earth complexes on a gold surface [2]. Atomic scale characterizations of individual rare-earth complexes are performed with the most advanced instrumentation including low temperature scanning tunneling microscope manipulation, and synchrotron X-ray scanning tunneling microscopy. Although they are composed of multiple units held together by electrostatic interactions, the entire complex can be rotated as a single unit on a one-complex-at-a-time basis when electrical energy is supplied from a scanning tunneling microscope tip. Here, 100% control of their rotational directions is achieved using a negative electric field. Moreover, we form rare-earth ionic clusters composed of a precise number of 2, 4 and 6 units on a gold crystal surface. Unlike other non-ionic molecular clusters, the observed rare-earth clusters are very stable. Furthermore, they are conformationally chiral and their high mobility on the surface suggests that they are in a two-dimensional liquid state. Taken in concert, these experiments provide unparalleled atomic level information of the rare-earth ion environment within the complexes and will enable to develop rational blueprints for the design and synthesis of new structures with improved functions for potential applications in rare-earth separation, tribology, nanotechnology, and quantum information science.

Heterogeneous Catalysis for Sustainable Chemical and Energy Technologies: an Atomistic View Swetlana Schauermann; Kiel University, Germany

The molecular transformation of carbon dioxide to value-added chemicals and synthetic fuels is one of the most promising approaches towards sustainable chemical and energy technologies starting from economical and renewable feedstock. Heterogeneous catalysis is of the most effective technologies capable of activation and chemical transformation of CO_2 to a broad class of compounds such as alcohols, different types of oxygenates, alkenes. An atomistic-level understanding of heterogeneously catalysed processes of CO_2 activation and chemical transformations is an important prerequisite for the rational design of new effective catalysts. Towards this goal, we follow a rigorous surface science approach to obtained a detailed understanding of the reaction mechanisms, kinetics and thermodynamics of processes involved in chemical conversion of carbon dioxide on well-defined model oxide-based surfaces. We employ a unique combination of the state-of-the-art experimental tools including multi-molecular beam techniques, infrared and polarization-modulation infrared reflection-absorption spectroscopy, scanning tunnelling microscopy, single crystal adsorption calorimetry to address these major issues and derive precise structure-reactivity relationships.

In my talk, I will focus on the interaction of CO_2 and H_2O with different types of well-defined oxides – CoO, Co_3O_4 and Fe_3O_4 – prepared by epitaxial growth on metal single crystals under ultra-high vacuum conditions. Specifically, it will be shown that CO_2 can be effectively activated on these oxide surfaces and react with H originating from the co-adsorbed hydroxyl groups formed upon adsorption and dissociation of water. The mechanistic picture of the latter process will be discussed in more detail for water interaction with model Fe_3O_4(111)/Pt(111) oxide.[1] Combining single crystal adsorption calorimetry, infrared spectroscopy on the isotopically labelled iron oxide and theoretical studies, we show that water dissociates readily on iron oxide surfaces forming a dimer-like hydroxyl-water complex and prove that the generally accepted model of water dissociation to two individual OH groups is incorrect.

In the second part, I will introduce a concept of ligand-directed heterogeneous catalysis and provide an example on how purposeful functionalization of a catalytic surface with co-adsorbed organic molecules can dramatically enhance chemoselectivity in hydrogenation of multi-unsaturated hydrocarbons. Specifically, I will present a mechanistic study on formation and dynamic changes of a ligand-based heterogeneous Pd catalyst for chemoselective hydrogenation of α,β-unsaturated aldehyde acrolein.[2] Deposition of allyl cyanide as a precursor of a ligand layer renders Pd highly active and nearly 100 % selective toward propenol formation by promoting acrolein adsorption in a desired configuration via the C=O end. Employing a combination of real space microscopic (STM) and *in operando* spectroscopic (IRAS) surface sensitive techniques, we show that an ordered active ligand layer is formed under operational conditions, consisting of stable butylimin species, which turns the surface highly selective toward the desired product. Obtained atomistic-level insights into the formation and dynamic evolution of the active ligand layer under operational conditions provide important input required for controlling chemoselectivity by purposeful surface functionalization.

9:15 AM EN07.07.03
Facets Control Photoelectrochemical Water Oxidation in Strontium Titanate Single Crystals Samutr Assavachin, Anna C. Kundmann, Chengcan Xiao and Frank E. Osterloh; University of California, Davis, United States

Photocatalytic water splitting requires successful electron-hole separation toward its specific redox sites to perform H^+ reduction and H_2O oxidation simultaneously. Exposed facets of a catalyst can act as either a reduction or oxidation site controlling charge separation and photocatalytic activity of the material. This is the basis for the near unity water splitting quantum efficiency of the CoO(OH)/SrTiO3/Rh/Cr2O3/ photocatalyst reported by the Domen group (Takata, T., et al. Nature, 2020, 581, 7809, 411-414). In this work, we demonstrate photoelectrochemistry dependence on exposed facets of hydrogen reduced strontium titanate single crystals ($SrTiO_3$, $E_g = 3.2$ eV) with three different exposed facets [100, or 110, or 111] showing drastic differences for water oxidation photocurrent (0.01, 0.66, 1.53 mA cm^{-2}) at 0.72 V versus RHE applied bias in 0.5M Na_2SO_4 electrolyte at pH = 6.06 under UV illumination (60 mW cm^{-2}). Photocurrent onsets are observed at 0.42, -0.35, -0.38 V versus RHE for the [110], [100], and [111] crystals. Reduced $SrTiO_3$ single crystals were annealed at 1,100^{o}C in forming gas atmosphere (10% H_2 in argon) leading to a broad optical absorption from 400 nm into the IR region from the presence of Ti^{3+} states. Based on the optical absorption at 1,000 nm, the [110], [100], and [111] facets have electron donor concentrations of 4.1x10^{18}, 6.01x10^{18}, and 5.85x10^{18} # cm^{-3} respectively, after the H_2 treatment, much higher than as received crystals which are all approximately ~ 4x10^{17} # cm^{-3}. Controlled photoelectrochemical scans with 20% (v:v) added methanol yield photocurrents of 0.31, 1.31, and 2.90 mA cm^{-2} for the [110], [100], and [111] crystals respectively. Photocurrent onsets are -0.45, -0.38, -0.38 V versus RHE. Compare to OER photocurrent onsets, [111] remained unchanged, [110] was slightly shifted, and [100] experienced the strongest shift towards a reducing potential. This is the same current density trend observed for water oxidation, suggesting that differences in band bending control the photocurrent in these systems rather than the water oxidation kinetics. These findings will be discussed together with surface photovoltage, X-ray photoelectron spectroscopy, and Mott Schottky data for these systems.

Atomically Dispersed Ir Catalysts on Si Photoanode for Efficient Photoelectrochemical Water Splitting Sang Eon Jun and Ho Won Jang; Seoul National University, Korea (the Republic of)

Hydrogen is expected to become sustainable future energy due to zero-emission, non-toxicity, and large energy density. However, it usually exists in covalent compounds tightly bonded with other elements such as oxygen, nitrogen, and organic materials. One of the promising electrochemical methods to obtain pure hydrogen from these compounds is a solar water splitting. As a photoelectrode, Si has been widely investigated owing to its excellent charge carrier mobility, long carrier diffusion length, earth abundance, and wide-range solar spectrum absorption. Nevertheless, the poor catalytic activity, chemical corrosion in aqueous electrolyte, and negative valence band position limit its practical application. Hence, it is necessary to apply the photoelectrochemical catalysts having large amounts of active sites with complete coverage of photoelectrodes.
Single atom catalysts (SACs) have been recently investigated in electrochemical (EC) reaction to not only maximize the atomic efficiency of platinum group element (PGE) catalysts but also introduce unconventional geometric and electronic structures. The modification of the chemical state of single atoms induced by electronic interactions with the support matrix plays an essential role in improving catalytic activity and stability. However, stabilizing atomically dispersed PGE single atoms on Si photoanodes for photoelectrochemical-oxygen evolution reaction is still challenging due to the scarcity of anchoring sites.
Here, we demonstrate the decoration of Ir SAs on Si photoanodes and reveal the role of SAs on the separation and transfer of photogenerated charge carriers. NiO/Ni thin film, an active and highly stable catalyst, enables to embed the Ir SAs in its lattices by locally modifying the electronic structure. The existence of atomically dispersed atoms, electronic structure, and environmental coordination were identified by high-resolution transmission electron microscope (TEM), X-ray absorption near edge structure (XANES), and X-ray absorption fine structure (EXAFS) analysis. In addition, the roles of the isolated Ir SAs, enabling effective photogenerated charge transport by suppressing the charge recombination and lowering the thermodynamic energy barrier in the rate-determining step, were revealed by intensity-modulated photocurrent spectroscopy (IMPS) and DFT calculations. As a result, the Ir SAs/NiO/Ni/ZrO2/n-Si photoanode shows a benchmarking photoelectrochemical performance with a high photocurrent density of 27.7 mA cm-2 at 1.23 VRHE and 130 h stability. This study proposes the rational design of SAs on Si photoelectrodes and reveals the potential of the PGE SAs to boost photogenerated charge carrier kinetics.

9:45 AM EN07.07.05
Investigating the Electrocatalytic Activity and Stability of Cobalt-based Materials during the Oxygen Reduction Reaction in Acidic Media Ashton Aleman, Gaurav A. Kamat, Aniket Sandip Mule, Melissa E. Kreider, Michaela Burkes Stevens and Thomas Jaramillo; Stanford University, United States

Thermodynamically, cobalt has a large potential window of instability in acidic media that impacts its usage in devices for energy storage. In particular, leaching of cobalt from the Pt-Co/C catalyst cathode in commercial proton-exchange membrane fuel cells (PEMFCs) can limit the fuel cell's overall performance and lifetime. Enabling longer device lifetimes would involve strategies to stabilize cobalt-based materials while maximizing their utility. This presents an opportunity to develop an understanding of cobalt's stability in acidic media under reaction conditions. In this work, we study the material stability and catalytic performance of Co foil during the oxygen reduction reaction (ORR) in 0.1 M $HClO_4$ by performing *in-situ* elemental analysis (with an inductively coupled plasma mass spectrometer, ICP-MS) and additional *ex-situ* characterization. By coupling ICP-MS with electrochemical testing (on-line ICP-MS), we simultaneously monitor Co dissolution and electrochemical ORR activity as functions of electrochemical protocol and electrolyte gas saturation, and then use Atomic Force Microscopy (AFM) to compare the surface morphology and roughness of Co before and after electrochemical testing. In this study, we investigate the impact of catalysis, starting potential, potential range, and time on the material stability and catalytic activity of Co. In the flow cell, ORR onset (-0.2 mA cm^{-2}) occurs nominally at -0.55 V relative to the reversible hydrogen electrode (RHE). To evaluate the role of catalysis, we compare Co dissolution in O_2 vs N_2 saturated electrolyte in which we observe a ~9 fold increase in dissolved Co under O_2 saturation relative to N_2 saturation at 0 V vs RHE despite negligible faradaic current. After ORR onset, Co stabilizes and there is < 25 ng s^{-1} dissolution at -0.8 V vs RHE for both gases, despite the difference in current density between the two gases being -0.5 mA cm^{-2} . These results indicate that the presence of O_2 destabilizes the surface despite the absence of catalysis. Furthermore, when evaluating the role of starting potential, potential range, and time, we observe changes in the catalytic activity, material stability, and surface morphology. These findings showcase the importance of considering different experimental parameters when designing protocols for activation and operation of commercial catalysts. Altogether, this work provides important insights to reduce the dissolution of cobalt metal in acidic media. Such understanding will motivate future studies to improve the stability of cobalt-based materials for a variety of applications, including fuel cells, lithium-ion batteries, and electrolyzers.

Effects of Crystal Lattice Deformation on Catalytic Activities Miao Song, Peng Ren, Zexi Lu, Hyoju Park, Micah Prange, Peter V. Sushko and Dongsheng Li; Pacific Northwest National Laboratory, United States

Deformations of hierarchical structures at the atomic scale, especially long-range ones, can significantly enhance their functional behavior, such as catalytic activity. Metastable states or grain boundaries during the synthesis and processing of nanomaterials can introduce and control deformations (strains) in crystal lattices. We will design the deformations in the crystal lattice to enhance the catalytic functionality of catalysts, such as TiO_2 and platinum-group-based metals, by controlling their synthesis processes of phase transformation and particle aggregation. For example, TiO_2 polymorphs have distinct properties that have been widely employed in various applications. It is well known that these polymorphs can transform into more stable phases, such as from anatase to rutile and from TiO_2-B to anatase. Here, based on results from semi-in-situ transmission electron microscopy, density functional theory, and X-ray photoemission experiments, we discover a physical picture of transitional structures, in which continuous variations in atomic positions form along these two phase-transformation pathways. These gradient structures give rise to continuous band bending, which promotes electron-hole separation and inhibits their recombination across the bulk of the particles, leading to a large functionally active volume fraction and resulting in high photoactivity. We also seek to control deformations in supporting materials and their effect on catalytic materials to uniquely tailor functionalities. These findings suggest that extended gradient structures (lattice deformations) can be designed to advance new functions not achievable using abrupt interfaces.

11:00 AM EN07.07.07
Electronic Structure and Charge Trapping at the Interface of Pt and Strained Anatase Micah Prange[1], Quinn Carvalho[2], Sri K. Padavala[2], Kelsey A. Stoerzinger[2,1], Hyoju Park[1], Dongsheng Li[1] and Peter V. Sushko[1]; [1]PNNL, United States; [2]Oregon State University, United States

Since the rate of photooxidation reactions at the (001) surface of anatase TiO_2 depends strongly on charge separation efficiency, much effort has been expended elucidating factors that are believed to contribute to the electron-hole separation, including effects of surface structure, reconstruction, and undercoordination, while the effect of underlying bulk anatase has been relatively ignored. Inspired by recent observations of strained regions of anatase-like TiO_2 in heat-treated samples, we explore whether the coupling between lattice strain and electronic properties in these regions can facilitate efficient separation of photoexcited electron-hole pairs, thus increasing their catalytic activity. To this end, using density functional theory, including hybrid exchange-correlation functionals, we quantify the dependence of the near-surface band structure and charge transfer properties on the degree of local deformation near strained anatase (001) surfaces and their interfaces with Pt. We show that hole, electron, and triplet exciton biding energies in the surface and subsurface layers of anatase depend on the degree of strain in the anatase lattice. We calculate the energetic positions of the Pt d band centers and edges relative to the surface states, and we evaluate the possibility of spontaneous hole and electron transfer to Pt particles supported by anatase in experimentally observed strain states. Our results are consistent with experimentally observed enhancement of water splitting at the surface of thermally treated anatase, which points to a significant effect of the heat-induced deformations on post excitation charge carrier dynamics and photoredox catalysis.

Toward Elucidating the Role of Noble Metal Co-catalysts in Photocatalytic Oxidation of Methane to Methanol Gang Wan, Chenlu Xie, Eddie Sun and Arun Majumdar; Stanford University, United States

The availability of methane as the principal component in the natural gas resources and a potent greenhouse gas calls for the development of efficient mitigation strategies for its conversion to value-added chemicals and fuels, such as methanol. Methanol is a key vector to fuel a future. And a direct methane-to-methanol conversion holds the promise as a drop-in replacement for the methane reforming, which is highly energy-intensive process. Activation of C-H bond in methane is the key step in the direct methane-to-methanol conversion, which has been demonstrated to benefit from the use of free radicals. Photochemical methane activation offers intriguing and vital opportunities by generating free radicals directly from water and oxygen and thus is promising for large scale fuel production. Such photocatalytic process involves the use of inorganic semiconductor catalysts and noble metals nanoparticles co-catalysts. Despite intensive studies, the photocatalytic methane oxidation faces the challenge of a limited selectivity toward methanol, and the catalytic functions of different noble metal co-catalysts remain largely unexplored.

In this talk, on the basis of catalysts design, in-situ X-ray absorption spectroscopy, electron paramagnetic resonance and kinetic studies, we will discuss the relationship between the role of co-catalysts, the controlled generation and diffusion of free radicals, and the selectivity toward various liquid products. Such molecular-level insights are expected to facilitate the selective functionalization of light alkanes and offer informative design principles for photocatalysts.

Nanocrystalline Non-stoichiometric CeO_x on Pt Heterogeneous Catalysts for Selective Oxidation of Methanol to Methyl Formate Gyu Rac Lee, Kyoungjae Song, Jeong Young Park and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Due to the increasing energy and environmental crisis, the utilization of C1 chemistry has gained much attention as a reliable pathway for “green chemistry” over several decades. Among various intermediates in C1 chemistry, methyl formate is one of the key components to produce more than 50 chemical products in the field of industry. In general, most methyl formate is produced by the carbonylation and dehydrogenation reaction of methanol. Since these reactions proceed at elevated temperatures, the selectivity for methyl formate generation is inevitably low, producing unintended by-products such as carbon dioxide. In this regard, the catalytic methanol oxidation reaction (MOR) capable of forming methyl formate even at room temperature can be considered an efficient alternative route. However, because MOR can generate both carbon dioxide and methyl formate via full oxidation and partial oxidation respectively, it is essential to maximize the partial oxidation selectivity of MOR for achieving the desired component.

Recently, the formation of heterogeneous catalysts with platinum group metals (PGMs) and reducible metal oxides has been attempted because they provide enhanced reaction rate and partial oxidation selectivity in MOR, which is derived from the strong metal-support interactions (SMSI). The charge transfer between PGM and metal oxide occurs by forming the interfaces and this electronic interaction at the interface is the origin of the SMSI. Especially, several studies already revealed that the metal-oxide interface plays an important role to accelerate MOR performance and partial oxidation selectivity is correlated with the concentration of the interface. However, it is still unclear how the oxidation state or chemical composition of constituent materials in heterogeneous catalysts correlates with partial oxidation selectivity and methyl formate generation.

Here, to explore the effect of the oxidation states of support oxides on partial oxidation selectivity in MOR, we fabricate heterogeneous catalysts composed of nanocrystalline non-stoichiometric CeO_x nanowires and Pt film (CeO_x/Pt). The oxidation state of CeO_x nanowires was controlled with varying annealing atmospheres (vacuum, Ar, Air, O_2). Although there was no noticeable difference in the crystallinity of CeO_x nanowires depending on the annealing conditions, it was confirmed that the ratio of O/Ce and the amount of Ce (III) changed after the annealing process depending on the processing conditions. To evaluate the turnover frequency (TOF) and the selectivity to methyl formate generation toward MOR, a batch reactor experiment was carried out. We verified that all the CeO_x/Pt regardless of annealing conditions exhibit higher TOF and methyl formate selectivity compared to a Pt film used as a reference. Interestingly, although there is no TOF difference among the samples, CeO_x/Pt with vacuum treatment achieved almost 70% of significantly enhanced selectivity to methyl formate compared to the others. Further analysis revealed that a high fraction of the Ce (III) in CeO_x/Pt obtained with vacuum treatment boosted the catalytic selectivity. Our findings provide a new pathway to design heterogeneous catalysts with exceptional selectivity for achieving desired product by engineering the chemical composition in the metal oxide.

Cu Single-atom Catalyst on Metal Oxide Support for Efficient and Selective Photocatalytic Nitrate–Ammonia Conversion Hyun Sik Moon and Kijung Yong; POSTECH, Korea (the Republic of)

Photocatalytic nitrate (NO_3^-) reduction to ammonia (PcNRA) is considered a promising NH_3 production route to alternate N_2 reduction from an energy point of view. NO_3^- is highly soluble in water, which precludes the limitation of reactant solubility, and the N=O bond can be dissociated at a relatively low energy of 204 kJ mol^{-1} compared to the N≡N bond. There are two possible pathways for photocatalytic NO_3^- reaction: N_2 formation via five-electron reduction (0.74 V vs. NHE) and NH_3 formation via eight-electron reduction (0.69 V vs. NHE). The former reaction is both kinetically and thermodynamically favored, and therefore most previous studies on photocatalytic NO_3^- reduction have primarily produced N_2 in a water treatment manner. Thanks to the intensive effort, PcNRA has recently achieved excellent selectivity towards NH_3 synthesis, but its catalytic activity falls short of practical standards. In this work, we present a single-atom Cu-doped TiO_2 nanosheet (Cu-TNS) photocatalyst for selective as well as highly efficient PcNRA. The incorporation of single-atom Cu into the TiO_2 matrix preferentially occurs at Ti vacancies and this site-specific Cu introduction induces spontaneous defect formation such as oxygen vacancy and lattice distortion. The single Cu site accumulates photogenerated electrons, significantly suppressing charge carrier recombination and allowing more electrons to participate in NO_3^- reduction, while the unique properties of the Cu species ensure the high selectivity for NH_3 formation. Moreover, the spontaneous defect formation accelerates NO_3^- adsorption, effectively eliminating the reactant activation barrier. Consequently, the simultaneous presence of Cu single atom, oxygen vacancy, and lattice strain in Cu-TNS synergistically stimulates PcNRA, leading to 62-fold enhancement in ammonia production compared to the pristine sample, and an apparent quantum yield of 11.7% at 330 nm under optimised conditions.

Expanding the Materials Search Space for Multivalent Cathodes Ann C. Rutt[1] and Kristin A. Persson[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Multivalent batteries are an energy storage technology with the potential to surpass lithium-ion batteries, however their performance has been limited by the low voltages and poor solid-state ionic mobility of available cathodes. Developing high-performance multivalent batteries also provides an opportunity to consider sustainability factors to avoid the growing concerns over resource constraints from projected increases in Li-ion battery production. A computational screening approach to identify high-performance multivalent intercalation cathodes among materials that do not contain the working ion of interest has been developed which greatly expands the search space that can be considered for materials discovery. This approach has been applied to magnesium cathodes as a proof of concept and lessons learned from the resulting data are discussed in further detail.

2:00 PM EN07.08.02
NaF-Rich Solid Electrolyte Interphase for Dendrite-Free Sodium Metal Batteries Mengyang Xu, Yang Li, Muhammad Ihsan-Ul-Haq, Nauman Mubarak, Zhenjing Liu, Junxiong Wu, Jang-Kyo Kim and Zhengtang Luo; Hong Kong University of Science and Technology, Hong Kong

Efficient energy storage systems are essential to the widespread application of renewable energy, as well as fulfilling the rapidly growing demand of mobile devices and electric vehicles. Sodium metal batteries (SMBs) have attracted much attention as a sustainable technology owing to the high theoretical energy density and abundance of Na. However, the practical realization is hindered by several critical challenges arising from high reactivity of metallic Na with organic electrolyte and its uneven deposition. A NaF-rich SEI layer on Na metal surface has been explored to demonstrate its beneficial effect on electrochemical performance of SMBs. Unlike previous strategies based on expensive and unstable fluorinated electrolytes to form NaF-rich SEI layers, this work employs PTFE micro powders that react with molten Na, whose process is much simpler at a lower cost. The spontaneous reaction with Na metal converts C-F to NaF which suppresses the formation of dendrites as proven by combined depth-profiling X-ray photoelectron spectroscopy (XPS) and time-of flight secondary ion mass spectrometry (ToF-SIMS) and theoretical DFT calculations. The full battery prepared with a $Na_3V_2(PO_4)_3$ cathode delivers 99% retention of Coulombic efficiency after 400 and 600 cycles at 1C in ether- and carbonate-based electrolytes, respectively. The SEI layer design strategy presented here can shed new insights into the development of high-performance dendrite-free Na metal and solid-state batteries.

Ultrasonic Spray Deposition and its Uses in Manufacturing New Bespoke Graded Electrodes for Energy Storage Devices Matthew Tudball, Thomas S. Miller and Paul Shearing; University College London (UCL), United Kingdom

Li-ion batteries are become an increasing necessity in daily life, however with lithium and cobalt prices ever increasing, new types of batteries that utilise more abundant materials are becoming more essential.

Lithium sulphur batteries boast a much higher theoretical specific capacity than traditional Li-ion batteries (1672 mAh/g)[1] while removing the need for expensive and difficult to source materials such as cobalt and nickel. The current major issues of LiS batteries include, their short cycle life, due to sulphur loss through the polysulfide shuttle and subsequent parasitic reactions, as well as their poor rate capability, due to the low conductivity of sulphur and Li_2S as well as the pore blocking (surface deposition) of these species at high charge and discharge rates. It is thought that tuning the carbon support of the cathode can create electrodes with higher conductivity and a suitable pore network can allow for higher rate capable LiS batteries which increases their functionality and versatility.[2]
The ultrasonic spray technique allows for layer by layer deposition of material and can therefore be used to form through-thickness gradient structures. This has benefits over traditional film deposition methods such as doctor blading where the full film is deposited at once. By altering the ink composition throughout the spray the structure of the film can be changed, this is particularly important with electrochemical devices where movement of a species into the film is necessary.

This work involves the spray deposition of graded films for use in Li-ion and LiS batteries. LiS cathodes are fabricated with a conductive additive gradient, employing higher conductivity carbon near the current collector and a more porous carbon at the surface of the film. This is particularly useful for improving the rate capability of the cells, which is often hampered by the pore blocking effect of non-conductive sulphur species. By creating through-thickness pore channels, electrolyte wetting can be improved which can lead to improved homogeneity of solid S_8 and Li_2S deposition. This gradient structure has been tested previously with lithium iron phosphate cathodes and was shown to improve capacity at high C-rates.[3]

Recent literature has shown that the addition of metal nanoparticles in the sulphur cathode can help to catalyse the electrodeposition of solid S_8 and Li_2S. Applying this metal in a gradient can help to prevent build-up of solid non-conductive material at the surface of the electrode, which helps improve rate capability, lengthen lifetime of the cell and improve sulphur utilisation.[4]

This gradient spray technology is not specific to LiS batteries and has potential uses in a wide range of thin film manufacture, from other battery types to super-capacitors and fuel cells, allowing for manufacture of bespoke designed films for a range of applications.

3:45 PM EN07.08.05
Manipulating the Diffusion Energy Barrier at the Lithium Metal Electrolyte Interface for Dendrite-free Long-life Batteries Zhongjiu Yang[1,2], Jyotshna Pokharel[2] and Yue Zhou[1,2]; [1]University of Texas at Dallas, United States; [2]South Dakota State University, United States

The high theoretical capacity and low reduction potential make lithium metal one of the promising candidates for anode materials. However, there are some challenges such as the growth of the lithium dendrites and associated electrolyte decomposition which lead to limited cycling performance and safety concerns. One of the effective strategies to counter these challenges is to construct a protective artificial solid electrolyte interphase. A straightforward method with scale potentials to manufacture lithium nitrate-rich SEI to minimize the diffusion energy barrier of lithium-ion across it is discussed. Different from polycrystalline lithium nitrate SEI manufactured from conventional experiments, our lithium-rich SEI is phase-pure/single crystalline interphase which has high mechanical strength and low lithium-ion diffusion barrier. The combination of integrating phase field simulations with experiments is applied to elucidate the correlation among lithium-ion transference number, diffusion behavior, concentration gradient, and the stability of the lithium metal electrode. By applying this unique lithium nitrate-rich SEI into both symmetric cells and full lithium-metal batteries, excellent charge/discharge cycling performance is achieved. We realize long stable plating/stripping cycling up to 3500 hours at 0.5mA cm^{-2} for the symmetric cell and cycling up to 500 cycles at 160 mAg^{-1} (1C rate) for the full cell. These studies develop a new understanding of the designing and engineering of an ideal artificial SEI for stable and high-performance lithium metal batteries.

4:00 PM EN07.08.06
Applying Life Cycle Analysis (LCA) for Materials Selection in Li-O_2 Batteries Melodie Chen-Glasser, Amy E. Landis and Steven C. DeCaluwe; Colorado School of Mines, United States

Li-O_2 batteries are often discussed as solution to overcome the limited range of electrified vehicles. Their theoretical high energy density is promising; however, the technical challenges of parasitic reactions and high charging voltage have led to exploration of a wide range of catalysts, solvents, and cathode structures. The wide variety of materials and different reporting metrics used in Li-O_2 battery research makes it difficult estimate their environmental impact. As the ultimate goal of battery development is to reduce environmental impacts by eliminating fossil fuel consumption, their experimental design should be guided by LCA. This paper will examine a range of commonly used materials for Li-O_2 batteries and determines the variation in their environmental impacts, allowing researchers to pre-select their materials by their sustainability. In addition, five new LCA are performed on experimental Li-O_2 batteries, demonstrating how LCA can be used as a metric to drive experimental research.

4:15 PM EN07.08.08
Reducing Voltage Hysteresis in Li-rich Sulfide Cathodes by Tuning the Metal-ligand Covalency Xiaotong Li, Eshaan Patheria and Kimberly See; California Institute of Technology, United States

Multielectron redox can be achieved by leveraging the redox activity of lattice anions (anion redox) in addition to the transition metal, to significantly increase the capacity of cathode materials. Li-rich sulfides are promising cathode candidates for anion redox since they operate at voltages within the electrolyte stability window and sustain high capacity. A promising system for the study of anion redox is based on Li_2TiS_3 (d^0 Ti^{4+} is redox inactive), whose redox activity can be “activated” by substituting redox-active transition metals. There have been systematic studies on the capacities with different substitution ratios. Besides the capacity, another essential challenge of anion redox is the large voltage hysteresis between the charge and discharge processes. In this work, we seek to explore the influence of metal-ligand bond covalency (overlap between the metal *d* and sulfur *p* states) on the voltage hysteresis during anion redox. By substituting redox-active transition metals (e.g. Fe^{2+}, Mn^{2+}, Co^{2+}) in Li_2TiS_3, we aim to systematically adjust the position of transition metal *d*-states relative to the S *p*-states. The electrochemical activities were characterized for Mn^{2+} and Co^{2+}-substituted Li_2TiS_3 ($Li_{1.33-2y/3}Ti_{0.67-y/3}M_yS_2$, M = Mn and Co, $y = 0 - 0.5$). After Mn substitution, the redox process is “activated” and the capacity increases until $y = 0.3$. More interestingly, the voltage hysteresis is reduced from 500 meV in Li_2TiS_3 to 150 meV in $y = 0.3$ sample for the first cycle. Overall, this system offers fundamental insights to deepen our understanding of structure-property relationships that govern reversible anion redox.

SESSION EN07.09: Poster Session II: Critical Materials for Energy

5:00 PM EN07.09.01
Synergistic Effects of LSPR and Z scheme Heterojunction on $W_{18}O_{49}$/Au/g-C_3N_4 for Efficient Photocatalytic Hydrogen Production Covering UV-Vis-NIR Inju Hong and Kijung Yong; POSTECH, Korea (the Republic of)

Recently, Z-scheme heterojunction that enables high spatial charge separation, wide-spectrum solar light harvesting, and simultaneously enhances powerful redox capacity, has attracted considerable attention for photocatalytic hydrogen (H2) production. However, it remains challenging to design strategies to accelerate charge transfer in heterojunctions. Solid-state electron mediators can be a solution to this problem. Inserting solid-state electron mediators at the Z scheme heterojunction interfaces not only facilitate charge transfer in the Z-scheme system, but also prevent undesired backward reactions. Among the various solid-state electron mediators studied so far, Au, in particular, is efficient in promoting charge transfer dynamics, and its localized surface resonance (LSPR) effect is advantageous for light harvesting in the visible light region. In addition to metal Au, defects in non-metallic and nonstoichiometric semiconductors have the same properties because they are likely to generate high-density free carriers, leading to induce the occurrence of LSPR. For this reason, $W_{18}O_{49}$ (WO_{3-x}) has an LSPR effect due to its abundant oxygen vacancies, which can result in absorption into near-infrared regions (NIR) containing more than half of the solar energy emitted to the earth.
Here, we introduced Au nanoparticle mediators at the interface of the Z-scheme $W_{18}O_{49}$/g-C_3N_4 heterostructures, in which Au nanoparticles not only served as a charge mediator for Z-scheme but also brought about the LSPR effects. In addition, the light absorption region over a wide spectrum was extended using NIR reactive $W_{18}O_{49}$. The photocatalytic hydrogen production rate of $W_{18}O_{49}$/Au/g-C_3N_4 was 3465 μmol/g*h, which is 1.9 times higher than that of $W_{18}O_{49}$/g-C_3N_4 (1785 μmol/g*h) and 2.8 times higher than that of single g-C_3N_4 (1242 μmol/g*h) under 1 sun irradiation. The improved photocatalytic H_2 production activity of $W_{18}O_{49}$/Au/g-C_3N_4 is attributable to synergistic effect of LSPR and Z scheme heterojunction.
First, Z-scheme charge transfer is incorporated by the Au NP mediator, which enhances charge separation and increases redox potentials. Second, the plasmonic Au NPs can sensitize $W_{18}O_{49}$/Au/g-C_3N_4 to visible light using hot electron injection arising from LSPR-related effects, e. g. resonant photo-induced coherent oscillation of free charges. Third, the abundant oxygen vacancies of the nonstoichiometric semiconductor $W_{18}O_{49}$ (WO_{3-x}) generated a high density of free carriers, providing a high possibility to induce the occurrence of LSPR. In addition, the LSPR of $W_{18}O_{49}$ extends the photoreaction region of $W_{18}O_{49}$/Au/g-C_3N_4 to NIR irradiation, leading to remarkable solar H_2 production. After consecutive solar hydrogen production experiments, both photocatalytic activity and catalytic structure remained unchanged, emphasizing the superior stability and reusability of this photocatalyst.
For these reasons, $W_{18}O_{49}$/Au/g-C_3N_4 is a good photocatalyst showing the high photoactivity of H_2 production extended to the visible and NIR region, and we propose the importance of integration of Z-scheme heterostructures and mediators based on LSPR effects.

5:00 PM EN07.09.02
Direct Growth of Ni(Fe,Mo)P Nanowires for Enhanced Alkaline Water Splitting with Facile Method Hyogyun Roh and Kijung Yong; Pohang University of Science and Technology, Korea (the Republic of)

Hydrogen as a renewable energy becomes more attention to solve the CO_2 emission. However, electrochemical H_2 production with zero CO_2 emission is still too expensive owing to high price of noble metal based electrocatalysts. Although cheap transition metal based electrocatalysts have impressively improved in recent researches, their low conductivity and poor activity on electrolysis limit the replacing noble metal. The self-supporting synthesis of various nanostructured electrode is a novel approach for developing cheap transition metal electrocatalyst with improved surface reaction area and long-term stability. In this research, NiFeP, NiMoP, NiCoP, and NiVP nanowires are fabricated by earth abundant transition metal through a two steps process: cation exchange from Zn oxide to metal oxide and surface phosphorization. The prepared samples are electrochemically tested as hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) catalysts in alkaline (1 M KOH) solution. The OER activities of all NiMP (M = Fe, Mo, Co, V) nanowires show enhanced activity compared to NiP. Especially, NiFeP exhibits the best OER performance with an overpotential of 279 mV (η_{100}) and a Tafel slope of 34 mV dec^{-1}, and this activity was higher activity than that of the IrO_2. The high electrocatalytic activity originated from the low kinetic energy barrier and the large surface active sites. In the HER activity, NiMoP shows improved performance with an overpotential of 68 mV (η_{10}) and a Tafel slope of 87 mV dec^{-1}. Although overpotential was higher than that of Pt in low current density, NiMoP exhibits outperformed activity at high current density. The combining of NiMoP and NiFeP as overall water splitting system requires potential of 1.57 V to generate 10 mA cm^{-2} current density.

5:00 PM EN07.09.03
Iron and Nitrogen Co-doped Agricultural Waste-derived Activated Carbons as Cathode Material for Microbial Fuel Cells Chia-Chieh Hsu and Han-Yi Chen; National Tsing Hua University, Taiwan

Microbial fuel cells (MFCs) are one of the attractive and sustainable energy sources in development while society pays more attention to environmental issues. MFCs are a bio-electrochemical system with the direct conversion from organic matter to electricity via microbes, which can be applied to wastewater treatment, electronic devices, and bio-sensors. However, MFCs tend to have low power output due to the poor oxygen reduction reaction (ORR) on the cathode, which significantly limits the power density. Therefore, platinum has been widely used as a catalyst to improve ORR activity, and this also leads to high cost, poor durability and stability. To deal with the problems, non-noble metal catalysts with high ORR activity and stability are crucial to replace Pt-based catalysts for commercialization in MFCs.
In this study, we developed iron and nitrogen co-doped agricultural waste-derived activated carbons (FeNAC) as cathode material in MFCs. The raw materials and precursors are inexpensive, and the synthesized FeNAC exhibit high surface area and favorable active sites for better electrocatalytic activity on the cathode. The results showed outstanding electrochemical performance, demonstrating that FeNAC is a promising material for MFC.

5:00 PM EN07.09.04
Ultrahigh-Loading Dry-Process for Solvent-Free Lithium-Ion Battery Electrode Fabrication Minje Ryu; Yonsei University, Seoul, Korea (the Republic of)

The current LIB electrode fabrication process relies heavily on the wet coating process, which uses the environmentally harmful and toxic N-methyl-2-pyrrolidone (NMP) solvent. Aside from being non-ecofriendly, this expensive organic solvent substantially increases the cost of battery production, as it needs to be dried and recycled throughout the manufacturing process. Furthermore, NMP is flammable and known to cause male infertility; thus, prolonged exposure can pose health risks to workers and present fire hazards. For this reason, achieving a completely solvent-free process for electrode fabrication is currently a unified goal for many battery researchers and manufacturers. Here, we report an industrially viable and facile dry process for LIB electrodes, namely, the dry press-coating process using multiwalled carbon nanotubes (MWNTs) and polyvinylidene fluoride (PVDF) as a dry powder composite and etched Al foil as a current collector. The MWNT-PVDF dry powder composite uniquely forms a robust 3D conductive scaffold that houses the active materials upon pressing, and the submicron pore-covered etched Al current collector provides remarkable adhesion to the interlayer. Notably, the mechanical strength and performance of the fabricated $LiNi_{0.7}Co_{0.1}Mn_{0.2}O_2$ (NCM712) dry press-coated electrodes (DPCEs) far exceed those of conventional slurry-coated electrodes (SCEs) and give rise to ultrahigh loading (71 mg cm^{-2}, 13.2 mAh cm^{-2}) with impressive specific energy and volumetric energy density of 372 Wh kg^{-1} and 763 Wh L^{-1}, respectively.

5:00 PM EN07.09.05
Facile Synthesis of Hollow-Structured Fe, F Dual-Doped CoS_2 Electrocatalyst for Oxygen Evolution Reaction Hyejin Kim, Kyeongseok Min, Jaeseo Lee and Sung-Hyeon Baeck; Inha university, Korea (the Republic of)

Due to the serious environmental problems caused by excessive consumption of fossil fuels, developing renewable energy sources and sustainable storage process have attracted significant attention from many researchers. The hydrogen is considered as one of the leading options for alternative energy carrier owing to its high gravimetric energy density. Water electrolysis is an efficient way to produce ultra-high purity hydrogen without environmental pollution. However, sluggish reaction dynamics and high overpotential of oxygen evolution reaction (OER) at anode greatly hinders the overall efficiency of water electrolysis. Although precious metal-based materials, such as IrO_2 and RuO_2, are considered as state-of-the-art OER electrocatalysts, their high cost, scarcity and low stability during long-term operation have limited their large-scale applications. Therefore, enormous efforts have been performed for development of highly efficient and stable noble metal-free electrocatalysts. Recently, metal-organic frameworks (MOFs), a class of inorganic-organic hybrid crystalline materials fabricated via the self-assembly of metal cations and organic building blocks, have aroused considerable interest owing to their high porosity, multifunctional properties, large specific surface area. Prussian-blue-analogues (PBAs) with the formula $M^{II}_3[M^{III}(CN)_6]_2$ (M = Fe, Co, Ni, etc) are a class of MOFs with coordinated metal sites linked by the cyano groups. PBA materials can be simply converted to transition-metal based chalcogenides, which are widely explored as efficient OER electrocatalysts. Therefore, they can be utilized as an appropriate precursor for transition metal-based electrocatalysts.
In this study, Fe, F dual-doped CoS_2 nanospheres with abundant active sites using bimetallic CoFe-PBA were fabricated for OER via facile self-templating co-precipitation strategy and subsequent annealing processes with sulfur and fluorine source. First, the monometallic Co-glycerate nanospheres were employed as a self-sacrificial template because of its facile synthetic procedure and low cost. After that, the Co-glycerate was converted to CoFe PBA via simultaneous dissolution and precipitation process at room temperature for 24 h. The self-templating strategy provides a simple synthetic route to prepare hollow-structured bimetallic nanospheres without additional steps of template elimination. The CoFe PBA hollow nanospheres were calcined with sulfur powder to prepare Fe-CoS_2. Subsequently, the prepared samples were pyrolyzed with NH_4F in Ar flow to obtain F, Fe dual-doped CoS_2 hollow nanospheres (Fe-CoS_2-F). The high electronegativity of F (4.0) compared with those of Fe (1.83), Co (1.88), and S (2.58) can partially withdraw electrons from other elements, thereby modulating the surface electronic properties and adsorption energy of oxygen-containing reaction intermediates. Furthermore, simultaneous cation and anion dual-doping can maximize the surface polarity, promoting the infiltration of aqueous electrolytes during OER procedure. As expected, the as-prepared Fe, F dual-doped CoS_2 nanospheres exhibited superior electrochemical performance toward OER with an overpotential of 298 mV to achieve the current density of 10mA cm^{-2}, and a Tafel slope of 46 mV dec^{-1} in 1.0 M KOH, which was much better than the commercial RuO_2 catalysts.

5:00 PM EN07.09.06
ZIF-67 Derived Co_3O_4/CoFe-LDH with Strongly Coupled Interfacial Junction as an Enhanced Electrocatalyst for Oxygen Evolution Reaction Jaeseo Lee, Sojeong Min, Minjung Kim and Sung-Hyeon Baeck; Inha University, Korea (the Republic of)

Development of renewable and clean energy production has become an urgent issue owing to the increasing concerns about depletion of fossil fuels and environmental crisis. Producing hydrogen using water electrolysis is regarded as promising strategy for solving the problem owing to its environmental friendliness and high energy density of H_2. However, the sluggish kinetics and large overpotential of oxygen evolution reaction (OER) at the anode remains a bottleneck in water electrolysis. Until now, noble metal-based oxides, such as Ir/Ru based oxides, are generally used as state-of-the-art electrocatalysts for OER. Unfortunately, their scarcity, high cost and low durability during long-term operation have seriously hindered the large-scale applications of water electrolysis system. Accordingly, development of earth-abundant electrocatalysts with high activity and stability is essential to substitute the expensive electrocatalysts for water electrolysis. Spinel-structured cobalt oxide (Co_3O_4), which is constructed by combination of Co^{2+} and Co^{3+}, is one of the promising electrocatalysts for OER due to rich redox properties and high corrosion resistance. Also, the bimetallic layered double hydroxide (LDH) structure is generally known as highly efficient electrocatalyst owing to its large surface area and flexible open structure.
Based on the above considerations, we synthesized the core-shell structured Co_3O_4/CoFe-LDH composite with abundant oxygen vacancies via co-precipitation, heat treatment, and subsequent sonochemistry method. First, ZIF-67 was prepared by the co-precipitation reaction of Co^{2+} with 2-methylimidazole in methanol solution. Second, the ZIF-67 was annealed and oxidized at high temperature to prepare dodecahedral-shaped Co_3O_4 (Co_3O_4@C). After that, the Co_3O_4 was partially reduced under H_2/Ar flow to induce oxygen vacancies into Co_3O_4 (V_o-Co_3O_4@C). Finally, the Co^{2+} and Fe^{3+} ions (molar ratio of 2:1) dissolved in DI water, and as-prepared V_o-Co_3O_4@C was added into the solution. After stirred for about 30 min to promote adsorption of metal ions on the surface of V_o-Co_3O_4@C, 1M KOH was injected into the above mixture, and ultrasonicated for 30 min. In this step, the adsorbed metal ions react with OH^- ions, resulting in formation of CoFe LDH on the surface of V_o-Co_3O_4 (CoFe-LDH/V_o-Co_3O_4@C). Owing to the electrostatic interaction between oxygen defect sites and metal ions, the CoFe-LDH/V_o-Co_3O_4@C has strongly coupled interfacial junction. Construction of interfacial junction of different phase is effective way to boost charge transfer efficiency. Additionally, it also can prevent the detachment of CoFe-LDH, thereby enhancing the long-term stability of electrocatalyst during OER process. As a result, the CoFe-LDH/V_o-Co_3O_4@C exhibited significantly improved electrocatalytic OER activity with low overpotential and Tafel slope, which are even superior to state-of-the-art RuO_2 electrocatalyst. Moreover, the prepared electrocatalyst showed stable operation over 100 h at a current density of 10 mA cm^{-2} in alkaline solution. We believe that this research will provide a new insight into the preparation of transition metal-based composite materials for energy storage and conversion system.

5:00 PM EN07.09.07
Facile Synthesis of Co, N Dual-Doped Ni_2P Grown on Nickel Foam as Active Electrocatalyst for Oxygen Evolution Reaction Minjung Kim, Hyejin Kim, Kyeongseok Min and Sung-Hyeon Baeck; Inha University, Korea (the Republic of)

Due to the increasingly severe energy depletion and environmental pollution, a lot of studies on efficient and renewable energy have been actively conducted. Recently, Hydrogen is regarded as the most prospective energy source to replace the traditional fossil fuels. Overall water electrolysis, which consists of hydrogen evolution reaction (HER) on the cathode and oxygen evolution reaction (OER) on the anode, is a noticeable technology for producing high-purity hydrogen. The OER has complicated reaction mechanism involving four electron transfer, thereby resulting in high overpotential. To overcome this issue, noble metal-based materials, such as IrO_2 and RuO_2, are generally employed as electrocatalysts owing to their high activity. However, the high cost and poor stability of precious metal-based electrocatalyst have limited widespread application of water electrolysis. Therefore, non-noble metal-based

electrocatalysts with high OER performance have been explored.
Specifically, Ni-, Co-, Fe-, Mn-based electrocatalysts, including their phosphides, sulfides, oxides, chalcogenides, have studied due to their adjustable electronic structure and earth abundance. Among them, transition metal phosphides (TMPs), which have high electrical conductivity, high electrochemical stability, and rich active sites, have been reported as efficient OER electrocatalysts. Furthermore, in order to increase intrinsic OER performance, heteroatom doping strategy has been carried out to modify their electronic configuration structure. The introduction of dual dopants, which have different polarity and electronegativity, can not only modify the electronic state of host species but change the adsorption free energy of reaction intermediates during the OER process.
On the basis of above explanation, Co, N dual-doped Ni_2P grown on nickel foam was synthesized by only two step hydrothermal reaction and subsequent heat treatment. First, a piece of nickel foam (1 cm x 3 cm) (NF) was sonicated with 1.0 M HCl for 15 min to remove the oxide layers and rinsed with DI water and ethanol. Afterward, HCl, $K_3[Co(CN)_6]$, and $Na_3C_6H_5O_7$●$2H_2O$ were put into a Teflon-lined autoclave (130 mL) with NF, and kept at 95 °C for 24 h to synthesize nickel cobalt Prussian blue analogue on NF (NiCo-PBA/NF). Owing to the surface etching of NF by HCl solution, the released Ni^{2+} species immediately react with the $K_3[Co(CN)_6]$, resulting in formation of bimetallic PBA. Finally, the NiCo-PBA/NF was annealed with NaH_2PO_2 at 430 °C for 2 h under NH_3/Ar atmosphere. During the process, the NiCo-PBA was phosphidized owing to PH_3 gases generated by thermal decomposition of NaH_2PO_2. Simultaneously, the nitrogen dopants can be introduced into Co-doped Ni_2P structure under the NH_3 flows and elevated temperature. As a results, the Co, N dual-doped Ni_2P exhibited a notable enhancement of catalytic activity toward the OER compared with Co-Ni_2P, N-Ni_2P, and pure Ni_2P counterparts. Furthermore, the Co, N-Ni_2P/NF showed lower overpotential and superior long-term durability than state-of-the-art RuO_2 electrocatalyst. Undoubtedly, this work will offer a new synthetic insight on the rational design of defect-rich transition metal-based materials with improved catalytic performance for energy storage and conversion system.

5:00 PM EN07.09.08
Simulation of Deformation Mechanisms in Coated and Uncoated Platinum Nanoparticles Muztoba Rabbani[1], Ingrid M. Padilla Espinosa[1], Ruikang Ding[2], Tevis Jacobs[2] and Ashlie Martini[1]; [1]University of California Merced, United States; [2]University of Pittsburgh, United States

Single-digit-nanometer particles are the building blocks for emerging energy technologies, but the complex interrelationships between their size, shape, and mechanical properties are still not fully understood. Particularly, for the smallest nanoparticles, the traditional "smaller is stronger" trend may not apply, and deformation can occur through both atom diffusion and dislocations. Decreasing particle size leads to a greater percent of surface atoms with lower activation energy for diffusion and therefore more diffusion-mediated deformation. Surface energy can be modified by coating nanoparticles, so coatings are expected to affect the relative contributions of diffusion vs. dislocations to deformation. In this study, we used classical molecular dynamics simulation to study the deformation mechanisms of platinum nanoparticles of various shapes and sizes, with and without a surface coating of another metal or oxide. Compression tests were performed on both coated and uncoated nanoparticles to investigate the link between surface energy and deformation mechanisms. Our study contributes to the understanding of nanoparticle deformation which is crucial for designing nanoparticle-based energy systems.

Facile Synthesis of CeO_2 Decorated Co_4N Nanoparticles as Highly Active and Durable Electrocatalyst for Oxygen Evolution Reaction Kyeongseok Min, Jaeseo Lee, Sojeong Min and Sung-Hyeon Baeck; Inha University, Korea (the Republic of)

Growing concerns about depletion of fossil fuels and global warming demand the exploration of eco-friendly and efficient energy sources. Recently, hydrogen gas has been considered as a promising candidate for future energy source owing to its environmental friendliness and high energy density. Electrochemical water splitting, involving cathodic hydrogen evolution reaction (HER) and anodic oxygen evolution reaction (OER), is an ideal technology for hydrogen production without any other impurities such as carbon dioxide. Unfortunately, the overall efficiency of water electrolysis is seriously limited by the sluggish kinetics and large overpotential of OER due to the energetically unfavorable four-electron reaction pathway. Therefore, the development of efficient and durable OER electrocatalyst is essential to decrease the reaction energy barrier for OER and enhance the performance of the overall water electrolysis.
Among the noble metal-free materials such as transition metal oxides, sulfides, phosphides, nitrides *etc*., the transition metal nitrides (TMNs) showed promising electrocatalytic activity toward the OER. The TMNs have anti-corrosion stability in alkaline solution and high electrical conductivity due to their metallic feature. Furthermore, the nitrogen atoms in TMNs induce expansion of metal lattice and modify transition metal d-band structure, thereby shifting their d-band center into the optimal energy state for OER. Despite the noticeable progress in TMNs-based electrocatalysts, their unsatisfactory OER performance need to be further improved because of inferior redox reaction kinetics of TMNs.
To boost electrocatalytic OER activity of TMNs, construction of heterostructure with other species which has rich redox properties can be adopted as efficient strategy. The formation of well-defined heterostructure not only offer abundant electrochemical active sites but optimize the electronic properties of catalysts owing to strong interfacial coupling effect between the two components, thus leading to enhanced oxygen evolution performance. Recently, cerium oxide (CeO_2) has been employed as an activating agent for promoting electrocatalytic oxygen evolution, which is attributed to its rich redox property owing to versatile oxidation state between Ce^{3+} and Ce^{4+}. Furthermore, the CeO_2 has abundant empty d orbitals and oxygen vacancy defects, leading to strong electron interaction and introduction of efficient active sites for OER in alkaline solution.
Herein, inspired by above mentioned considerations, we proposed a facile method to prepare heterostructured Co_4N/CeO_2 nanoparticles using bimetallic CoCe-BTC (benzene-1,3,5 tricarboxylate) MOF (metal organic framework). As a self-template and precursor of Co_4N/CeO_2, bimetallic BTC MOF has substantial merits such as chemical and structural tunability, low cost, high surface area and porosity. The CoCe-BTC was converted into heterostructured Co_4N/CeO_2 via simple annealing and selective nitration process. Benefiting from electrical conductive metallic feature of Co_4N and multivalent nature of CeO_2, the synthesized Co_4N/CeO_2 electrocatalyst exhibited exceptional OER performance with a low overpotential of 297 mV to acquire a current density of 10 mA cm^{-2}, small Tafel slope of 88 mV dec^{-1}, and excellent long-term durability over 100 h in alkaline electrolyte. This research will pave the way for development of heterostructured noble metal-free electrocatalyst for various energy storage and conversion system.

5:00 PM EN07.09.10
Hollow Structured N, S Co-Doped Carbon Nanotubes Encapsulating Co/CoS_2 Nanoparticles as Highly Efficient Electrocatalyst for Zinc-Air Battery Sojeong Min, Minjung Kim, Hyejin Kim and Sung-Hyeon Baeck; Inha University, Korea (the Republic of)

The development of sustainable energy conversion and storage systems is crucial owing to the depletion of fossil fuels and energy crisis. Recently, rechargeable Zn-air batteries (ZABs) are regarded as promising energy devices due to their high specific energy density (1084 Wh kg^{-1}), reliable safety and cost effectiveness. However, the ORR and OER involving a four-electron reaction process at cathode always suffer from sluggish kinetic behaviors during the charge and discharge process. Although noble metal-based materials (Pt/C for ORR and RuO_2 for OER) are commonly used as the most excellent catalysts for ORR and OER, their high cost, monofunctionality and low electrochemical durability limit the practical application of ZABs. Consequently, it is essential to develop non-noble metal-based electrocatalysts with superior durability and high electrochemical activity for utilization of ZABs. Transition metal-based materials (alloys/ sulfides/ oxides/ nitrides/ phosphides) have attracted considerable attention as electrocatalysts for rechargeable ZABs benefiting from their low cost, high electrochemical activity, and stable operation. Among the various candidates, transition metal sulfides have superior electrical conductivity compared with other chalcogenides, which is mainly attributed to the shallower valence band generated by S 3p orbital, resulting in

formation of narrower band gap. Moreover, the formation of heterojunction between *n*-type metal sulfides and metals, which is known as Mott-Schottky contact, can further improve the charge transfer efficiency of electrocatalysts.
Inspired by above considerations, hollow structured microsphere with N, S co-doped carbon nanotube shell encapsulating Co/CoS_2 nanoparticles (Co/CoS_2/NSCNT) was prepared via facile polymerization and subsequent pyrolysis steps. First, we synthesized polystyrene (PS) spheres by polymerization, which were used as self-sacrificial template to generate uniform hollow structures. And then, Co^{2+} ions and 2-methylimidazole were mixed in PS solution and ZIF-67 was coated on the surface of PS spheres. Subsequently, the obtained core-shell structured PS@ZIF-67 was pyrolyzed with dicyandiamide at 750°C for 1.5 h under Ar flow. During pyrolysis, PS spheres were completely removed and surface of the spheres became rougher with the growth of N-doped carbon nanotubes owing to the catalytic effect of Co nanoparticle, resulting in the formation of hollow structured Co/NCNT. The well-defined hollow structure can not only reduce ion diffusion length but also increase active surface area. Finally, Co/NCNT was annealed with sulfur at 550°C for 2h under Ar atmosphere to simultaneously conduct partial sulfidation of metal species and sulfur doping into carbon matrix (denoted as Co/CoS_2/NSCNT). Generally, the CNT provide an efficient electron pathway for active species and protect the encapsulated nanoparticles from aggregation and dissolution during the electrochemical reaction. Furthermore, introducing heteroatoms (e.g. N, S, and P) into the carbon materials can affect the electron neutrality of the sp^2 carbon lattice and lead to partial polarization of adjacent carbon, thereby promoting the adsorption of reaction intermediates. As expected, the prepared Co/CoS_2/NSCNT exhibited the excellent ORR activity with half-wave potential of 0.890 V (vs. RHE), outperforming that for the state-of-the-art Pt/C (0.855 V (vs. RHE)). Additionally, it also showed outstanding OER kinetics and low overpotential of 363 mV at a current density of 10 mA cm^{-2}, which was superior to the other prepared electrocatalysts.

5:00 PM EN07.09.12
Feasible Fabrication of Carbon Nanotube-Poly(Acrylic Acid) Network Encapsulating Silicon Microparticle for Lithium-Ion Batteries Gwanghyun Lee and Jong Hyeok Park; Yonsei University, Korea (the Republic of)

Recently, the electrification of personal mobility is accelerating the development of Li-ion batteries. With the demands for a lightweight battery, silicon (Si) is considered a strong candidate to achieve high energy density due to its high theoretical capacity (>3600 mAh g^{-1}). However, the unstable capacity retention of Si anodes is a critical issue for industrial applications. Si particles experience harsh volume changes due to the alloying with the Li ions. This results in the pulverization of Si particles followed by the excessive growth of the solid-electrolyte interphase (SEI) layer. Here, we propose the conductive hybrid network encapsulating Si particles fabricated with a facile slurry-casting method. The functionalized carbon nanotubes (FCNTs) were easily dispersed into water and formed entangled network structures. In addition, poly(acrylic acid) (PAA) enhanced the mechanical properties of the FCNT network and enabled flexible behaviors. This hybrid network uniformly coated Si surfaces and allowed stable connections between the particles providing electron pathways. After the cycle, the pulverized Si particles maintained their morphology with the mechanical supports of the FCNT/PAA network inhibiting the irregular formation of the SEI layer while Si anode with conventional carbon black showed severe destruction of the structure. The electrode with FCNT/PAA network exhibited stable cycle performance during 200cycles and excellent rate capability even at 10C which indicates safe and fast electron transport toward Si particles.

5:00 PM EN07.09.13
Photo-Electrocatalysis (PEC) Enhancement of Anatase TiO_2 Thin Films with [001] Texture for Both Oxygen Evolution Reaction (OER) and Energy-Efficient Applications Luis Esquivel, Andrew Ichimura and Jingjing Qiu; San Francisco State University, United States

The production of hydrogen from water has the potential to be part of the portfolio of renewable energy sources that will help to reduce our dependence on fossil fuels. Splitting water requires catalysts to help drive the hydrogen and oxygen evolving reactions. Photo electrocatalysis (PEC) is a method to split water that employs a light-absorbing semiconductor to produce charge carriers and a catalyst to lower the overpotential of the hydrogen and oxygen evolving reactions (HER and OER, respectively). Typical catalysts for PEC water splitting include nobel metals such as Pt and Pd (HER) and IrO_2 (OER), which are expensive and rare. In order to realize the potential of PEC, less expensive, nontoxic, and earth-abundant materials must be studied to replace these noble metals, especially for the kinetically slow OER.
Anatase titanium dioxide is a well-known functional material with applications in the fields of environment and energy. The band gap value in semiconductors determine the energy requirements for electron transfer and light absorption. Anatase has a band gap of 3.2 eV and valence and conduction band energy levels that are suitable for PEC water splitting and especially the OER reaction. Experimental studies demonstrate that (001) facets are highly oxidizing surface and the [001] orientation imparts a negative flatband potential that makes it ideal for OER and charge transfer. In this work, we combine these two structural characteristics into the semiconductor TiO_2 layer to improve the PEC performance.
Anatase TiO_2 thin films with (001) facets and [001] orientation were synthesized following previous work (Ichimura, et al. 2012) modified for FTO substrate. . First a blocking layer of amorphous titania (a-TiO_2) was first deposited onto clean FTO substrate. Then, anatase with [001] texture was grown hydrothermally from TiF_4 solution. The films were then annealed at 500 C and then any pinholes were sealed by electrochemically by depositing a-TiO2 from a $TiCl_3$ solution. Finally, the NiO/Ni$(OH)_2$ catalyst layer was formed by electrodeposition and monitored by chronoamperometry/chronocoulometry. The resulting thin films are characterized with gracing incidence X-ray diffraction (GI-XRD), atomic force microscopy (AFM), and scanning electron microscopy (SEM). These measurements confirm the [001] orientation and (001) faceting at the surface of the thin films. the photoelectrochemical measurements of the thin films were conducted by means of cyclic voltammetry in 0.1 M KOH solution using a 150 W xenon arc lamp as a light source. The PEC OER of anatase thin films before and after Ni2+ deposition was observed under dark and light conditions. Before illumination, only the Ti^{3+}/Ti^{4+} redox couple can be observed with an onset potential of -0.7 V (vs Ag/AgCl) and negligible OER at anodic potentials. Under irradiation, the TiO_2 thin film without Ni^{2+} catalyst exhibits a small photocurrent that saturates at low potentials through the anodic scan. With the NiO(OH)/Ni$(OH)_2$ catalyst present, the photocurrent continues to increase throughout the anodic region. Our preliminary results show a current density of ~1.5 mA cm^{-2} at 0.8 V. This study may lead to improvements in the PEC activity of anatase TiO_2 thin films based on optimizing the film structure for both reactivity and charge transport.

A Recyclable Solid Electrolyte for Li-Ion Batteries Composed of Supramolecular Nanostructures Yukio Cho, Cole D. Fincher, Yet-Ming Chiang and Julia Ortony; Massachusetts Institute of Technology, United States

The recyclability of Li-ion batteries is a critical goal but is technically challenging and often impractical due to the complex structure of mixed materials and the irreversible process of production. We investigated the use of organic small molecule self-assembled nanoribbons as an electrolyte material because they offer precise spatial arrangement, high surface areas, tunable surface chemistry, and most notably here, reversible structural formation. In this study, we synthesized nanoribbons by self-assembly of aramid-containing amphiphiles that overcome structural stability problems, and we systematically modified the surface chemistry to promote Li-ion conductivity. We investigated the performance and transport mechanism of these supramolecular nanomaterials as a solid electrolyte for Li-ion batteries. Furthermore, we show direct recyclability of the end-of-life cell.

Ionothermal Upcycling of Spent NMC 111 to Nickel-rich NMC Cathodes in Reciprocal Ternary Molten Salts Tao Wang[1,2], Huimin Luo[1] and Sheng Dai[1,2]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

The wide use of lithium-ion batteries (LIBs) in portable devices and electric vehicles has changed people's lifestyles, while end-of-life (EOL) LIBs are causing severe environmental risks due to their hazardous components. Thus, properly handling EOL LIBs has become an urgent and promising task. Though the current recycling technology can recover valued metals through the breakdown of cathodes, the added value from the compound structure of cathode materials is lost. Direct recycling stands out as an emerging technology to retrain the added value of the compound structure by healing the compositional and structural defects in spent cathode materials. However, the recovered state of EOL LIB may be outdated, because the recycling of EOL LIBs generally happens years later after production. In this work, beyond direct recycling, direct upcycling of spent cathodes to the next-generation cathodes is realized to maximize the value of EOL LIBs.[1] The directly upcycling of spent NMC 111 to Ni-rich NMCs was achieved in "reciprocal ternary molten salts" (RTMS) by simultaneously realizing the addition of Ni and the relithiation of Li. After flux upcycling in RTMS, the obtained Ni-rich NMCs exhibited very similar performance to that of the pristine NMC 622 including an α-$NaFeO_2$-type layered structure, restored Li content, and excellent electrochemical performance.

Scheme 1. Illustration of the upcycling of D-NMC 111 to Up-NMC 622 in RTMS.

Electrochemical Resource Recovery Using Battery Electrode Materials Seoni Kim; Ewha Womans University, Korea (the Republic of)

Demand for lithium is dramatically increasing due to the rapid growth of secondary battery usage. Lithium is mainly produced via evaporation and precipitation from brine lakes, which requires a long period of time for lithium production. Also, this process can only be applied to limited water sources that contain low amounts of certain ions, and several environmental concerns are arising regarding the evaporation and precipitation method.

Recently developed electrochemical lithium recovery systems, whose operation principle mimics that of lithium-ion batteries, might relieve these concerns. The cathodes (e.g., $LiMn_2O_4$, $LiFePO_4$) for lithium-ion batteries have the suitable channel size for selective Li^+ insertion, which enables selective recovery of lithium from source waters with a wide range of lithium ions (Li^+) concentrations. However, there had been a lack of understanding of the physicochemical behaviors of the Li^+-selective electrode in realistic operation conditions. In addition, the stability and cost of the counter electrodes of this system have been serious issues that impede the practical application of this system.

This talk will cover the physicochemical behavior of the Li^+ selective electrode during the electrochemical lithium recovery process regarding the Li^+ concentration in source water and the operation rate will be covered. On the basis of the understanding based on the characterization of the electrodes using X-ray techniques, increasing the density of the electrode/electrolyte interface is suggested as a realistic and general route to enhance the overall lithium recovery performance and is experimentally corroborated in a wide range of operating environments. Also, new electrode designs for the electrochemical lithium recovery system to improve performance and durability are suggested.

Circular Economy Strategies for Clean Hydrogen Technologies Taylor Uekert, Hope Wikoff and Alex Badgett; National Renewable Energy Laboratory, United States

Clean hydrogen produced from water electrolysis and powered by renewable electricity is expected to play a critical role in achieving decarbonization goals. Recovery and recycling of the valuable materials contained within electrolyzers and fuel cells will be essential to maintain a resilient supply chain and mitigate environmental impacts. However, research into circular economy strategies for clean hydrogen production lags behind other renewable energy technologies such as lithium-ion batteries or photovoltaics. This quantitative analysis maps electrolyzer and fuel cell components to emerging recycling techniques such as pyrometallurgy and acid- or organic solvent-based recovery. The recycling options are then assessed and compared across environmental impacts, costs, and technical capabilities (e.g., recovery yields). This critical analysis lays crucial groundwork for the development of a circular economy for hydrogen technologies.

9:30 AM EN07.10.07

High Throughput Screening of Cladded Steel Pipelines for Hydrogen Fuel Vijay Shankar Sridharan[1], Varun Chaudhary[1], Siwei Du[2] and Dong Zhili[1]; [1]Nanyang Technological University, Singapore; [2]Advanced Remanufacturing and Technology Centre, Singapore

Many nations have aimed for net zero emissions by 2050. Existing gas pipelines and containers can be upgraded for transport and storage of hydrogen as part of a sustainable energy transition. However, pipeline-hydrogen interaction and its safety need to be established for further use within the operational conditions. In this study, hydrogen embrittlement behavior of alloy gladed API X 60 steel was studied using high throughput methodologies. API X-60 steel is widely used in the oil and gas pipeline for transportation over long networks. The compositionally graded alloy deposition was performed through additive manufacturing technique direct laser deposition. A combination of 316L and In625 powders were used to compositionally deposit in different gradients to identify the optimal composition in terms of depositions that are crack free and at the same time has maximum resistance towards hydrogen embrittlement. The high-resolution Scanning Kelvin Probe Force Microscopy (SKPFM) is used to map the diffusion profiles of hydrogen at cross section of samples after hydrogen charging. The results from SKPFM, electron microscopy, and variation in mechanical behavior before and after HER was correlated and presented as a function of alloying composition. The variations in the resistance to hydrogen embrittlement and hardness, measured using high throughput characterization techniques, were rationalized by recourse to different phases present in the microstructures. Our study showed that the composition gradient coatings through additive manufacturing has improved the resistance to corrosion and hydrogen embrittlement of API X-60 steel.

Multiscale Hydrogen Chemistry of Direct Iron Reduction in Decarbonizing Steelmaking Xueli Zheng, Lauren Y. Moghimi, Subhechchha Paul, Yi Cui and Leora E. Dresselhaus-Marais; Stanford University, United States

Steelmaking contributes to 8% of the total annual CO_2 emissions globally. One attractive approach to decarbonizing steelmaking is to shift from the conventional coal-based reduction of iron ores in blast furnaces to hydrogen-based direct reduction of iron, preventing CO_2 emissions from coal. Despite its opportunity, hydrogen-based steelmaking has been slow to scale up because iron ore reduction with hydrogen is slow and energy-intensive (i.e. endothermic). While extremely important, the reaction kinetics and mass transfer in hydrogen-based steelmaking are poorly understood. Herein, we measure the kinetics of magnetite (Fe_3O_4) reduction with H_2, comparing industrial Fe_3O_4 to the lab-synthesized nanoscale Fe_3O_4 samples. Using *in situ* synchrotron X-ray diffraction and Rietveld analysis, we obtain the phase fraction of Fe_3O_4, wustite (FeO), and metallic Fe as reduction propagates on the full temperature dependence from 300 ^oC to 800 ^oC. We further map out the reaction kinetics and reveal the associated structural/morphology changes. Using *in situ* small-angle X-ray scattering, we demonstrate how the kinetics evolve simultaneously with mesoscopic structural changes. Ptychographic X-ray computed tomography reveals how evolved nano-/microstructure influence reduction reaction kinetics in H_2-based steelmaking. Our work provides insights on microstructure design to accelerate reduction reaction kinetics, further paving the way for commercializing sustainable steelmaking.

10:30 AM EN07.10.09
A Multi-Scale View of Scalability Challenges in H_2-Based Ironmaking Leora E. Dresselhaus-Marais; Stanford University, United States

Modern metals manufacturing relies on centuries-old techniques that we must now revisit in light of global challenges in environmental and resource sustainability. While steel is ubiquitous, its refinement currently contributes 8% of the global CO_2 footprint, 64% of which originates from ironmaking. Updating ironmaking processes requires careful studies of the fundamental science that complicates scalability and direct integration of those approaches with scale models. I will present my group's work using *in-situ* X-ray and electron probes (diffraction and imaging) to directly resolve the kinetics and multiscale structural dynamics for H_2-based direct iron reduction. By mapping these dynamics from the atomic through µm-scales, we demonstrate we demonstrate the intricate and complex links between mechanics, chemistry, and mass transport give rise to complex chemistry. Our finding shed light on the complex reaction dynamics of this system, paving the way for important insights into the energy-landscape of carbon-free steelmaking that offer an important starting point for process models.

10:45 AM EN07.10.10
The Poisonous Effect of Carbon-Bearing Species on Adsorption of Hydrogen on Pd Alloys Membrane Surfaces Abduljabar Alsayoud[1], Ahmed Abuelyamena[1], Venkateswara Manga[2], Rached Ben Mansour[1] and Mohammed Habib[1]; [1]KFUPM, Saudi Arabia; [2]The University of Arizona, United States

Hydrogen separation through the Pd membrane is one of the most promising technologies for producing pure H_2. This work investigates the effect of gaseous impurities, CO, CO_2 and CH_4 on the adsorption process of hydrogen, i.e. on the physisorption, and the chemisorption of hydrogen on Pd- x (x- Au, Pt) surface using density functional theory (DFT). Specifically, the study aims to sample the energy landscape associated with the hydrogen-adsorption while varying the structural and compositional degrees of freedom. The relative orientations of adsorbing molecules with respect to the surface of the slab, the crystallographic plane of the slab and various configurations of the adsorbed species have been investigated. In the case of compositional degrees of freedom, adsorption as a function of surface coverage, of mainly hydrogen, is studied. The physisorption of H2 on the Pd alloys-surface at different coverages of H-atoms (and without any impurities) has revealed that among the available adsorption sites, the top site with the horizontally oriented gaseous molecule is energetically the most favorable. Among the impurity gaseous species, when investigated for their binding to the Pd-surface and for their effect on the physisorption energies of the H2, CO is found to alter the energetics of the adsorption process, indicating a higher poisoning effect relative to CO2 and CH4. Moreover, the study also showed that at higher coverages of H-atoms, the physisorption energies of H2 decrease.

11:00 AM EN07.10.11
Emission-Free Hydrogen and High-Value Carbon Co-Production from Methane Pyrolysis Marco Gigantino[1], Eddie Sun[1], Alexander Nelson[1], Henry Moise[1], Vasudev Haribal[2], Andrew Tong[2], Jian-Ping Shen[2], Raghubir Gupta[2], Arun Majumdar[1] and Matteo Cargnello[1]; [1]Stanford University, United States; [2]Susteon Inc., United States

Methane pyrolysis is a technology that allows to produce greenhouse-gas-free H_2 along with solid carbon using less energy per mole H_2 than water electrolysis (37 vs. 286 kJ/mol H_2). Catalytic approaches applied to methane pyrolysis are strongly limited by catalyst deactivation from carbon coking. In addition, a system that possesses high and stable H_2 yield while producing high-quality carbon has remained elusive. Here, we report on a novel methane pyrolysis process for the co-production of H_2 and high-value carbon, which contains a large fraction of carbon nanotubes. The process consists of repeated pyrolysis steps followed by in-situ (i.e., within the reactor) regeneration steps of an iron-based catalyst, aimed at dislodging the carbon from the catalyst active surface. In such way, the catalyst can be reused while the carbon can be collected in a semi-continuous fashion. We demonstrated the operation for multiple cycles with high CH_4 conversion, high selectivity for H_2, and carbon dislodging in a fluidized-bed reactor system. Besides methane, we also investigated ethane as a feedstock for this process, since it is another main component of natural gas. Overall, this process demonstrates the production of high-quality carbon and hydrogen without carbon emissions.

11:15 AM EN07.10.12
CO_2 Capture Using Nanomaterials and Low-Energy Requirements Vitaliano Dattilo[1,2], Alexsanthra Rodriguez[1], Dogukan Yazici[1], Michael Bozlar[1,1], Marco Simonetti[2], Forrest Meggers[3] and James Coleman[3]; [1]The University of Texas at Arlington, United States; [2]Politecnico di Torino, Italy; [3]Princeton University, United States

Natural phenomena combined with intense human activities have resulted in a sudden increase in carbon dioxide (CO_2) emissions over the last century, and CO_2 is a major anthropogenic greenhouse gas. The most recent reveal that CO_2 concentration in the atmosphere rose from 378 parts per million (ppm), back in 2005, to 419 ppm in 2022. In order to mitigate CO_2 concentrations in the atmosphere, we propose to focus on different aspects of CO_2 capture and management, from the perspectives of materials science and computational chemistry. The main purpose of this research is to identify adequate materials and optimal processes to accomplish sustainable CO_2 capture and sequestration. In particular, we focus on materials chemistry in order to minimize the energy demands for CO_2 sorption and conversion/sequestration. Using computational techniques including, Density Functional Theory (DFT), as well as Molecular Dynamics (MD) Simulations, we study the electronic properties of the materials (Fermi Level, Density of States, and Charge Density Difference Analysis), as well as their ground states after adsorption and their capacity to capture CO_2. We also analyze the nature of the physical and chemical interactions of the different sorbent materials used. Then, we quantify the energetic requirements for the adsorption and desorption processes. To validate our models, we identify and design sorbents as well as experimental processes to replicate environmental conditions. The results indicate that the proposed sorbents can capture several thousands ppm of CO_2 in 24 hours under stationary diffusion conditions.

Engineering the Solid State Synthesis and Processing of Nickel Boride with Enhanced Functionality Jennifer Hong, Paolo P. Pescarmona and Loredana Protesescu; University of Groningen, Netherlands

Nickel boride Ni_xB_y has shown potential as an efficacious catalyst for a broad range of systems (hydrogenations, hydrogen, and oxygen evolution reactions) under challenging conditions (such as high pH or high temperatures). Given the increased surface area and surface optimization, as commonly displayed by other nanosized materials the nanostructured Ni_xB_y remains underdeveloped despite the potential enhanced performance,. The limited development of nano NixBy is mainly due to the notoriously difficult synthetic process. Recent works have shown that synthetic methods at lower temperatures (<400 ^oC) yield amorphous polydisperse nanocrystals (NCs), while phase purity remains an issue at higher temperatures. Here, a simple, scalable synthesis is demonstrated to obtain a phase-pure nanocrystalline Ni_xB_y. Through the solid-state reaction of either metallic Ni^0 or $NiCl_2$ with $NaBH_4$ at a relatively low temperature (400 ^oC) under atmospheric pressure, crystalline nanosized Ni_2B and Ni_3B could be obtained with high yield in pure phase and with narrow size distribution (15-30 nm). Through extensive mechanistic studies, we show that Ni nanoclusters (*approx.* 1 nm) are intermediate in the boriding process, while the halide precursors lower the decomposition temperature of the $NaBH_4$ (used as a reducing agent and B source). We further explore the size control using reaction mediators, and we probe the differential nucleation and growth of Ni (clusters) or Ni_xB_y NCs while using L (amine, phosphine) and X-type (carboxylate) mediators. The synthesized Ni_3B nanopowder can undergo surface functionalization with inorganic ligands in polar solvents, forming a stable ink. Furthermore, the Ni_3B nanocrystals ink can be ligand-exchanged with organic ligands in a non-polar low-boiling point solvent. This work opens the door for the large-scale production of Ni_xB_y nanocrystals solution-processable inks to make it a commercially viable catalyst and pave the way for other metal borides colloidal nanostructures.

Nanoscale Iron Redistribution During Thermochemical Decomposition of $CaTi_{1-x}Fe_xO_{3-\delta}$ Alters the Electrical Transport Pathway Jason Luong[1], Xin Wang[1], Alicia Tsung[2], Nicholas Humphrey[2], Huiming Guo[1], Benjamin Lam[1], Shaama M. Sharada[2] and William J. Bowman[1]; [1]University of California, Irvine, United States; [2]University of Southern California, United States

Potential applications of the earth-abundant, low-cost, and non-critical perovskite $CaTi_{1-x}Fe_xO_{3-\delta}$ in electrocatalysis, photocatalysis and oxygen transport membranes has motivated intensive research to tune its chemical composition and morphology. However, investigations on the decomposition mechanism(s) of $CaTi_{1-x}Fe_xO_{3-\delta}$ under thermochemically reducing conditions are limited, and direct evidence of the nano- and atomic-level decomposition process are not available in the literature. In this work, the phase evolution of $CaTi_{1-x}Fe_xO_{3-\delta}$ (x=0-0.4) was investigated in a H_2-containing atmosphere after heat treatments up to 600 °C [1]. The results show that $CaTi_{1-x}Fe_xO_{3-\delta}$ maintained a stable perovskite phase at low Fe content while exhibiting a phase decomposition to Fe/Fe-oxide nanoparticles as Fe content increases. In $CaTi_{0.7}Fe_{0.3}O_{3-\delta}$ and $CaTi_{0.6}Fe_{0.4}O_{3-\delta}$ the phase evolution to Fe/Fe-oxide was greatly influenced by the temperature: Only temperatures of 300 °C and greater were shown to facilitate phase evolution. Fully coherent Fe-rich and Fe-depleted perovskite nanodomains were observed directly by atomic resolution scanning transmission electron microscopy (STEM). Prior evidence for such nanodomain formation was not found and it is thought to result from a near-surface Kirkendall-like phenomena caused by Fe migration in the absence of Ca and Ti co-migration. Density functional theory simulations of Fe-doped bulk models reveal that Fe in an octahedral interstitial site is energetically more favorable than in a tetrahedral site. In addition to coherent nanodomains, agglomerated Fe/Fe-oxide nanoparticles formed on the ceramic surface during decomposition, which altered the electrical transport mechanism. From temperature-dependent electrical conductivity measurements it was found that heat treatment and phase decomposition change the transport mechanism from thermally activated p-type electronic conductivity through the perovskite to electronic conduction through the iron oxide formed by thermochemical decomposition. This understanding will be useful to those who are developing or employing this and similar earth-abundant functional perovskites for use under reducing conditions, at elevated temperatures, and when designing materials syntheses and processes.

Synthesis of Cobalt and Nickel based MOF@MOF configuration for Overall Water Splitting Chandan C. Gudal, Jae Wook Lee and Chan-Hwa Chung; Sungkyunkwan University, Korea (the Republic of)

Human activities in developing a better future consider less or no harm to the environment and climate on the planet Earth. Concerning this, fossil fuel usage is the main cause, these combustion releases harmful gases, which further leads to global warming and air pollution. Among the various alternative energy sources, the production of the hydrogen gas used in place of fossil fuels guarantees a secure and clean energy future. Moreover, hydrogen gas is mass-produced using fossil fuels, which leaves a carbon footprint in the environment as well. Water splitting is a method that produces hydrogen gas without leaving any harmful gases listed in greenhouse gases. The use of a highly efficient catalyst to break down the water molecules into hydrogen and oxygen gas will lead to the betterment of the future. The high overpotential and slow kinetics of two-half reactions during water splitting, such as hydrogen evolution reaction (HER) and oxygen evolution reaction (OER), have necessitated the development of new efficient and porous crystalline electrocatalysts. Due to the high cost and scarcity of noble metal-based materials such as Pt and IrO_2/RuO_2, it has become necessary to investigate alternative electrocatalysts derived from inexpensive metals for water splitting.

The combination of inorganic and organic materials co-exist and perform better than individually by enabling high properties like tunable porous crystallinity, surface areas, and functionality. Metal-organic frameworks (MOFs) are a class of porous crystalline polymeric materials that promise properties that are dependent on their structures with their compositions and architectures. However, the functionalization of MOFs with other kinds of MOFs remains challenging and relatively unexplored. The porous structure and metal-ion in the MOFs act itself as building blocks for the self-assembly of homogenous and/or heterogeneous MOFs generating hybrid structures. Therefore, progressive research on MOFs materials has led to a new family of

MOF@MOF composites developed by two or more MOF units.

MOFs based on the coordination of metal ions and organic ligands have rich porous structures, ultrahigh specific surface areas, and an abundance of adjustable sites and are widely used in a variety of domains, including gas storage, sensors, catalysis, energy storage and conversion, gas separation, and drug release. Furthermore, MOF derivatives made by using MOFs as self-precursor/sacrificing templates to make metal sulfides, metal phosphides, metal oxides, carbon materials, and their composites with micro/nanostructures can inherit the unique structural properties of MOF precursors. The exploration of novel MOF@MOF composite electrocatalysts originated from inexpensive metals and room-temperature synthesizable electrocatalysts for water splitting. Herein, the development of room temperature synthesized Co-MOF@Ni-MOF composite was successful. The obtained Co-MOF@Ni-MOF exhibited high catalytic activity towards HER and OER with the requirement of low overpotentials of 170 and 290 mV to reach a current density of 10 mA cm^{-2}, respectively. In addition, this catalyst showed superior stability for HER and OER, better than commercial Pt/C and RuO_2 products. This benefited from advantageous porous crystalline nanoarchitecture, which provided a large surface area and abundant electroactive sites, leading to remarkable electrocatalytic activity and stability in alkaline conditions. The achieved results excitingly suggested a novel catalyst for effectively producing hydrogen gas via the overall water-splitting process.

$Ni_{5-x}Ga_{3+x}$ Catalyst for Selective CO_2 Hydrogenation to MeOH—Investigating the Activity at Ambient Pressure and Low Temperature with Microreactors Filippo Romeggio, Christian D. Damsgaard, Jakob Kibsgaard and Ib Chorkendorff; DTU Physics, Denmark

Methanol obtained from the direct hydrogenation of CO_2 at low pressures and temperatures can be used as a fuel/chemical feedstock and, if paired with renewable energy sources, could strongly contribute to reach a more sustainable society.
We have studied the catalytic performance of the intermetallic compound $Ni_{5-x}Ga_{3+x}$ for methanol production. The catalyst shows outstanding activity and selectivity at low temperatures, outperforming the conventional Cu/ZnO. At higher T, the selectivity promptly shifts towards the production of methane and CO, leading to surface poisoning. Nevertheless, the experiments demonstrate the possibility of full regeneration of the catalyst by hydrogen reduction. Lastly, high stability over time under reaction conditions makes it an interesting candidate for scale-up and future industrial application.
A variety of techniques are used to characterize the surface before and after reaction, including XPS, HR-SEM/STEM, XRD, etc., along with close collaboration with computational theoreticians for DFT calculations. All the experiments are performed in state-of-the-art equipment: microreactors of 256 nL are used for catalytic testing. The inlet flow rate is in the order of magnitude of nanomoles/min, making it possible for all the gases to enter directly the QMS, leading to extremely high product detection sensitivity. This, together with an almost immediate temperature control, makes our system ideal for further fundamental studies about CO_2 hydrogenation.

Low Thermal Conductivity Micro-fabricated GeSn Thermoelectric as a Potential Energy Harvester Sabur A. Ayinde[1,2] and Maksym Myronov[1]; [1]The University of Warwick, United Kingdom; [2]The Federal Polytechnic, Nigeria

Clean energy from renewables remains the key solution to decarbonisation, but the resources to tap into this are not sufficiently available. Thermoelectric (TE) as a clean energy source still suffers from low efficiency, which has been very challenging over the years. Thermal conductivity, as one of major parameters that determines the figure of merit (efficiency of TE) of a material, is required to be around ~1 Wm^{-1}K^{-1} for optimum performance of TE material.
In this work, we experimentally measure the thermal conductivity of high tin content up to 9% relaxed germanium tin ($Ge_{0.91}Sn_{0.09}$) semiconductor grown epitaxially on a silicon (Si) substrate via a germanium (Ge) buffer toward energy harvesting for low energy consuming device. Suspended microwires of a single layer $Ge_{0.91}Sn_{0.09}$ epilayer were fabricated to isolate the single layer thermoelectric material from the underneath layers thereby eliminating the parasitic thermal effect from the substrate (Si) and a buffer layer (Ge).
Thermal conductivity measurements of relaxed $Ge_{0.91}Sn_{0.09}$ epilayer was obtained at temperatures between ~180 and ~550 K. As a result, thermal conductivity of the undoped 82% relaxed $Ge_{0.91}Sn_{0.09}$ epilayer microwire was found to be 2.5 Wm^{-1}K^{-1} at room temperature. It is comparable to the thermal conductivity of ~1.12 Wm^{-1}K^{-1} of the best thermoelectric material $Bi_2Te_{2.7}Se_{0.3}$ for room-temperature applications. It is a major achievement on a pathway for new high performance thermoelectric materials, which could be manufactured on large diameter silicon wafers and from abundant materials like Ge and Sn to reduce cost of thermoelectric devices and bring them into everyday life.

3:15 PM EN07.11.08
90% Silver Reduction in Silicon Heterojunction Cell Metallization with Reactive Silver Inks Steven DiGregorio[1], Michael Martinez-Szewczyk[2], Subbarao Raikar[1], Mariana I. Bertoni[2] and Owen Hildreth[1]; [1]Colorado School of Mines, United States; [2]Arizona State University, United States

Silver is the most expensive non-silicon component in photovoltaic cells. This is particularly salient for Silicon Heterojunction (SHJ) cells which can consume between 200-400 mg of silver in low-temperature silver pastes. Replacing low-temperature silver pastes with reactive silver ink can reduce silver consumption by producing more conductive fingers and lower contact resistances while avoiding high temperatures that can damage SHJ cells. This work investigates ink formulation and optimization for SHJ cells with a focus on PV performance and reduced silver consumption. We test reactive silver inks with different dominant reduction pathways, additives, and printing temperatures and characterize the silver fingers using electrical measurements and top-down and cross-section microscopy. The best performing ink achieved silver fingers with resistivities of 3.1 μΩcm and contact resistivities of 3.2 mΩcm^2 when printed at 61 °C. A 156 mm × 156 mm SHJ cell metallized with this reactive ink showed similar cell performance to low-temperature silver pastes while consuming 80-90% less silver.

Surface Photovoltage Spectroscopy Reveals the Modulating Influence of Water on the GaP-$BiVO_4$ Interface Anna C. Kundmann and Frank E. Osterloh; University of California, Davis, United States

Dual-absorber or "tandem" photocatalysts (PCs) hold promise for generating the large potentials (>1.6 V) needed to drive the overall water-splitting reaction, while using the visible-energy photons available in the solar spectrum. Establishing direct electrical contact between absorbers is advantageous for commercialization due to ease of implementation. Despite the promise of this type of tandem configuration, few functional direct-contact tandem PCs have been demonstrated and solar-to-hydrogen efficiencies remain low. Bismuth vanadate ($BiVO_4$) is a promising oxygen-evolving PC that has been demonstrated in direct-contact tandem configurations. GaP is a known hydrogen-evolving PC that offers improved optoelectronic properties over the metal oxides typically paired with $BiVO_4$, potentially offering an avenue to higher solar-to-hydrogen efficiencies. In the present study, $BiVO_4$ films were prepared on GaP by dropcasting, electrophoretic deposition (EPD), and electrodeposition (ED), and the interfacial charge transfer properties were examined using surface photovoltage spectroscopy (SPS). SPS is a highly surface-sensitive, non-destructive technique providing information about the magnitude and direction of charge separation and the position of energy states within a material. Large surface photovoltages of -1.7 V, -1.2 V, and -1.4 V are achieved in thin dropcast, EPD, and ED films, respectively, under vacuum. These data demonstrate a strong interaction between GaP and $BiVO_4$, resulting in a junction that separates electrons toward GaP and holes toward the $BiVO_4$ surface. SPS further observes sub-bandgap signals ca. 1.2 eV, revealing the presence of mid-gap states at the GaP-$BiVO_4$ interface. These mid-gap states under illumination <1.9 eV consistently generate more than half of the surface photovoltage that is observed in samples under super-bandgap illumination. This demonstrates a prominent role of the sub-bandgap states in the charge separation mechanism. To learn more about this junction under operating conditions, SPS was performed on samples in contact with liquid water. These measurements show an equalizing effect on the surface photovoltages, suggesting that the GaP/water interface takes over the charge separation mechanism. The interaction between interface states and water will also be discussed. This investigation reveals the challenges in directing charge transfer in systems that incorporate multiple electronically active interfaces.

3:45 PM EN07.11.10

Structural Phase Transition from the Stannite to the Wurtz-Stannite Structure Investigated by Neutron Powder Diffraction—The $Cu_2Mn(Ge_xSn_{1-x})S_4$ Solid Solution David C. Matzdorff[1,2], Maxim Avdeev[3,4], Galina Gurieva[1] and Susan Schorr[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany; [3]Australia's Nuclear Science and Technology Organisation, Australia; [4]School of Chemistry, Australia

The research of quaternary Cu-based chalcogenide semiconductors has caught a large interest for photovoltaic applications, as these materials consist of non-toxic and earth abundant elements. While being environmentally friendly and low cost, materials like Cu_2MnGeS_4 or Cu_2MnSnS_4 are very promising candidates for use in tandem solar cells, because they can cover a wide bandgap range of 1.52-1.72 eV [1, 2]. This study presents new insight into the crystal structure of the solid solution $Cu_2Mn(Ge_xSn_{1-x})S_4$ via neutron powder diffraction.
Since Cu^+ and Ge^{4+} are isoelectronic cations and Mn^{2+} is electronic similar to Cu^+ and Ge^{4+}, they cannot be differentiated in a structural analysis based on X-ray powder diffraction data alone. However, their neutron scattering lengths are considerably different, that is why we apply neutron diffraction to analyze the crystal structure of $Cu_2Mn(Ge_xSn_{1-x})S_4$ mixed crystals. Moreover, the basis of our investigations is a careful determination of the chemical composition of the mixed crystals by WDX spectroscopy. This is important, because it was shown for other quaternary chalcogenides (e.g., Cu_2ZnSnS_4 and $Cu_2ZnSnSe_4$) that even small deviations in composition (off-stoichiometry) can have a critical influence on the band gap energy of the material [3].
The endmembers of the $Cu_2Mn(Ge_xSn_{1-x})S_4$ solid solution crystallize in different structure types: Cu_2MnSnS_4 crystallizes in the tetragonal stannite-type structure (space group *I-42m*), whereas Cu_2MnGeS_4 adopts the orthorhombic wurtz-stannite structure (space group $Pmn2_1$). Thus, within the solid solution a structural transition from the tetragonal to the orthorhombic crystal structure can be expected.
In the presented study $Cu_2Mn(Ge_xSn_{1-x})S_4$ mixed crystals were synthesized by solid state reaction of pure elements in evacuated silica tubes at temperatures of 800°C. The chemical composition and homogeneity of the synthesized polycrystalline powder materials were investigated by WDX spectroscopy using an electron microprobe system. LeBail refinement of the powder X-ray diffraction data was used to determine the lattice parameters of the mixed crystals. The final cation distribution in the unit cell was defined by applying the average neutron scattering length analysis method [4], which forms the basis to conclude on the crystal structure and structural disorder and elucidate the mechanism of structural phase transition.
The results of the chemical composition study in combination with structural characterization and optical bandgap evaluation from diffuse reflectance of $Cu_2Mn(Ge_xSn_{1-x})S_4$ mixed crystals will be presented. These investigations enabled us not only to determine the type and concentration of intrinsic point defects, but also to deduce the complex cation re-distribution process within the crystal structure which transfers the stannite- to the wurtz-stannite-type structure. It will be shown that Sn-rich mixed crystals ($0 \leq x \leq 0.29$) adopt the stannite type structure, whereas Ge-rich mixed crystals ($0.68 \leq x \leq 1$) of this series adopt the wurtz-stannite type structure. Within $0.29 > x > 0.68$ two chemically identical but structurally different quaternary phases coexist, adopting the tetragonal and the orthorhombic structure respectively.

Financial supports from HZB Graduate School MatSEC (Materials for Solar Energy Conversion). The authors gratefully acknowledge the Australia's Nuclear Science and Technology Organisation (ANSTO) for providing us beamtime (proposal number 13403) at the ECHIDNA end station.

A Metastable O6 Phase with Stable Cation and Anion Redox Reactions Yanfang Wang[1,2]; [1]University of Birmingham, China; [2]Southern University of Science and Technology, China

Lithium rich metal oxides (LRMOs) are promising candidates for cathode materials in next generation batteries because of their high capacities (>250 mAh/g) contributed by both cationic and anionic redox reactions (ARRs). Progressive energy (*i.e.* capacity and voltage) loss resulting from oxygen loss and transition metal (TM) migration in LRMOs is the major bottleneck to their development and commercialisation. Previous work to mitigate this has focused primarily on tailoring local cation ordering in O3 structures or using O2-type structures. Despite improvements to the voltage decay, longer-term (> 50 cycles) capacity retention remains relatively poor.

Here, we propose a new approach to obtain stable cationic and anionic redox activity using O6-type structures. Although O6 structures have been captured as intermediate phases formed during de-/lithiation or on thermal treatment of O2-type cathode materials, their metastability makes directly synthesizing O6 phases challenging. By combining ion-exchange with optimized moderate heat treatment, we detail the first report, to the best of our knowledge, of a phase-pure directly-synthesized cobalt-free O6-type material, $Li_{0.693}[Li_{0.153}Ni_{0.190}Mn_{0.657}]O_2$. It presents a reversible capacity of ~250 mAh/g within the potential window of 2.0-4.8 V vs Li/Li^+ at 10 mA/g. Upon long-term cycling in an all-fluorinated electrolyte, it delivers an initial capacity of 195 mAh/g at 100 mA/g, of which 96.0% is retained after 100 cycles with only slight voltage decay; this capacity retention is superior to current state-of-the-art cobalt-free O3- or O2-type cathode materials which utilise ARRs, marking a step-change in lithium-ion cathode chemistry.

The underlying mechanisms responsible for the material's superior performance have been proposed via detailed multimodal characterization, combining *ex situ*/ *in situ* XRD, *ex situ*/ *in situ* Raman, *ex situ* EPR, *ex situ* XANES, *ex situ* XPS, and electrochemical experiments. The O6 phase undergoes first-order phase transformations in both highly-delithiated states and highly-lithiated states, forming O2-phases via facile gliding of TMO_2 slabs. Despite multiple O6-to-O2 phase transformations, the face-sharing geometry of LiO_6 and TMO_6 octahedra is retained. This means that the irreversible TM migration, and thus voltage fade associated with formation of the spinel phase, is suppressed by the strong electrostatic repulsion between adjacent TM ions. The all-fluorinated electrolyte promotes the formation of a stable cathode-electrolyte interphase (CEI) which allows the high-voltage (> 4.5 V) nickel redox reactions and ARR to stabilize immediately after the first cycle; this, along with the ease and stability of the O6/O2 interconversions, is the origin of the excellent capacity retention.

We believe that this work is of sufficiently widespread appeal given (i) the significant advance in addressing the primary roadblock that poor cycle-stability places in the way of development and commercialization of high-capacity cathode materials utilizing ARRs; (ii) the new vein of research into O6-type structures and other metastable cathode structures that is likely to be initiated by this work and; (ii) the demonstration of a dual-pronged approach to achieve cycle stability: the judicious choice of local atomic structure paired with the stable CEIs afforded by advanced electrolyte compositions.

8:15 AM EN07.12.03
Investigation on Gd Doped BFO as a Stabilizer for Capacity Retention of CNT-Sulfur Composite Electrodes of Li-S Batteries Rajesh K. Katiyar, Claudia C. Zuluaga Gomez, Balram Tripathi, Gerardo Morell, Brad R. Weiner and Ram S. Katiyar; University of Puerto Rico-San Juan, United States

In this work, bismuth ferrite powder modified via Gadolinium (Gd) with spontaneous polarization is adopted to modify the carbon nanotube (CNT)-sulfur composite cathode owing to its special interaction with polysulfides. We synthesized these composite cathodes via ball milling of Sulfur and CNTs and Gd-doped BiFeO3 (BFO) was coated on a polypropylene separator. As a matter of fact, Gd-modified BFO in interaction with CNT-sulfur composite acts as a stabilizer to develop a stable cathode. However, carbon nanotubes have distinct qualities like high aspect ratios, increased surface area, and high surface-to-volume ratio. Our results show that Gd-modified BFO in interaction with CNT-sulfur composite cathode can effectively suppress the shuttling of polysulfides and then greatly improve the electrochemical properties of the lithium-sulfur battery in terms of cycle stability, rate performance, reaction kinetics, self-discharge behavior.

8:30 AM EN07.12.04
Abstract Presented (ON-DEMAND ONLY) Aqueous Zn-based Energy Storage Devices Working Under Extreme Conditions Zhixiao Xu and Xiaolei Wang; University of Alberta, Canada

Aqueous zinc-based energy storage devices hold great promise for grid-level energy storage yet are challenged by dendritic growth and low Coulombic efficiency under both normal and extreme conditions. In the past years, we have developed Zn batteries and capacitors working under extreme conditions through engineering electrode, electrolyte, and binder. The first project is the making of ultrafast, stable, high-loading and wide-temperature zinc ion supercapacitors through the incorporation of activated carbon (AC), aqueous binder, and concentrated electrolyte. AC exhibits large surface area, hierarchical porous structures, and abundant heteroatom dopants, aqueous binder enhances electrode-electrolyte wettability enabling high-mass-loading electrode, and concentrated electrolyte gives high Zn stripping/plating efficiency, high ionic conductivity as well as suppressed hydrogen bonding interaction in water realizing ultralow frozen temperature. Three keys combined unlock unprecedented ZICs with a large capacitance of 436 F g −1 (capacity: 200 mAh g −1), ultrahigh rate up to 200 Ag −1 , ultralong cycles (0.3 million), ultrahigh loadings (10 mg cm −2) under lean electrolyte (8.8 µL mg −1), and wide-temperature operation (-60~60 °C), leading to a maximal energy density of 134.8 Wh kg −1 and power density of 118.4 kW kg −1 . A proton/Zn 2+ ion co-interaction mechanism was revealed in the AC electrode. With low cost and extreme functionalities, this work opens an avenue towards practical supercapacitors beyond normal conditions. The second project is the development of Zn-free polymer anode that enables ultrafast rates (100 A g -1), ultralong life (1 million cycles), and ultrahigh-loadings (50 mg cm -2) through DFT calculation, polymer preparation, and electrolyte optimization. The optimal polymer possesses suitable electronic structure and a large π-conjugated structure and its storage mechanism involves reversible Zn 2+ /proton co-storage at the carbonyl site. The polymer-based full cells demonstrate ultrahigh power densities and ultralong lifespans, far surpassing those of corresponding Zn-metal-based devices.

8:45 AM EN07.12.05
Passivation of NCA Cathodes Enables NCA/PEO-LiTFSI/LTO Lithium-Ion Batteries Joseph Sullivan[1], Finn Frankenberg[2] and Arijit Bose[1]; [1]The University of Rhode Island, United States; [2]Technische Universität Braunschweig, Germany

Poly(ethylene oxide) (PEO) with bis(trifluoromethane) sulfonimide (LiTFSI) lithium salt is a well-studied electrolyte system for safer lithium-ion batteries. The PEO-LiTFSI electrolyte does not passivate the aluminum within the cathode, leading to corrosion and severe capacity crash when used with high voltage cathode materials. This study describes a single step method to protect a 4V-class cathode from aluminum degradation and failure. An interfacial investigation of the lithium nickel cobalt aluminum oxide (NCA) cathode material with a PEO-LiTFSI electrolyte follows. We show that a one charge-discharge pre-cycle with liquid electrolyte containing $LIPF_6$ prevents the capacity crash observed without passivation and enables the use of NCA as a cathode with PEO-LiTFSI.

9:00 AM EN07.06.14
Ni-Co-Based Bimetal Organic Framework as Superior Electrode Material for Hydrogen Evolution Reaction and Supercapacitors Shiva Bhardwaj[1,2], Rishabh Srivastava[1,2], Teddy Mageto[1,2] and Ram Gupta[1,2]; [1]Pittsburg State University, United States; [2]National Institute for Material Advancement, United States

Metal-organic framework (MOF) has a uniform crystal structure with adjustable porosity, a large surface area, and a good adsorption affinity. These properties made MOFs suitable materials for energy storage applications. As the requirement for rapid energy increases continuously, it results in the development of supercapacitors (SCs) and electrocatalysts. SC possesses high power density and high charge storage capacity, whereas electrocatalysts can modify the reaction rate for hydrogen production during the water-splitting reaction. This work introduces the highly efficient electrode materials derived from nickel (Ni) and cobalt (Co) compounds and their combination for application in SCs and electrocatalytic activity. The samples were synthesized using the hydrothermal method at 160 degree celsius, where glutaric acid was used as an organic ligand. The Ni-MOF showed the highest specific capacitance (C_{sp}) of 706 F/g at 1 A/g, whereas bi-metallic NiCo-MOF showed a C_{sp} of 978 F/g at 1 A/g. Furthermore, the catalytic activity has been deployed for FC application using hydrogen evolution reaction (HER). The Ni and Co-MOF both show 208 mV overpotential at 10 mA/cm^2, whereas the NiCo-MOF required 182 mV to reach 10 mA/cm^2 with a Tafel slope of 89 mV /dec. These results demonstrate a new method for developing highly efficient electrodes for SCs and electrocatalysts.

9:05 AM EN07.08.03

Techno-Environmental Modelling of Energy Storage Systems for a Remote Telescope Isabelle Viole, Guillermo A. Valenzuela Venegas, Marianne Zeyringer and Sabrina Sartori; UiO, Norway

A new radio telescope in the Atacama desert, Chile, is currently under design and envisaged to be powered by an islanded energy system of photovoltaic arrays during the day-time and a hybrid energy storage system for non-sunny hours. Similar isolated solar energy systems employ Lithium-ion or Lead-acid batteries as storage, which either increase the pressure on critical materials like lithium and cobalt or contain lead which mining brings a set of harmful environmental impacts. Hydrides based on intermetallic compounds are emerging as a viable solution for energy storage in stationary applications and are particularly appealing due to their abundance and non-toxicity. Here, by developing a multi-objective techno-environmental optimization, we size a power system that can fuel the telescope's demand economically while also maintaining a low life cycle carbon footprint. The optimization includes life cycle inventory data of potential components next to costs, including mono- and bifacial monocrystalline photovoltaic arrays, lead-acid and lithium-ion batteries, hydrogen storage in metal hydrides and as compressed gas, alkaline and PEM electrolyzers as well as PEM fuel cells.
Pure techno-economical optimization without life-cycle inventory optimizes towards power systems with up to 32% of curtailed photovoltaic power. Levelized costs of electricity resulted in $100.1/MWh with storage systems using Li-ion batteries and $171.5/MWh for systems relying on hydrogen produced on-site. With our optimization, we propose a system resulting in a low life cycle carbon footprint and acceptable electricity prices, analyzing indirect carbon emissions of the stationary system as well as costs.
The life-cycle carbon footprint optimization performed allows both the remote telescope in question and other off-grid energy systems to make informed decisions on sustainable solutions to fuel their power needs.
The authors acknowledge funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 951815 (AtLAST - Towards an Atacama Large Aperture Submillimeter Telescope).

High-Performance Solid-State Electrolytes by Ultra-fast High Temperature Sintering (UHS) Liangbing Hu and Qi Dong; University of Maryland, United States

We recently reported an ultrafast high temperature sintering (UHS) for solid state electrolytes (Science, 2020, May Cover). The long sintering time of conventional syntheses can lead to Li loss in garnet SSEs caused by the evaporation of Li and the formation of secondary phases that lead to lower ionic conductivity. In contrast, the UHS technique enables us to tune the sintering time in units of seconds, which provides excellent control in terms of the Li content and grain growth. I will discuss our progress on applying UHS method to sintering various solid-state electrolyte, from compositions to microstructures. By programming the temperature and time (T-t), we can establish process diagrams to sinter porous vs. dense structures. The rapid sintering also allows us to sintering multilayer solid-state electrolytes with significantly reduced interlayer diffusion.

11:00 AM EN08.01.02
Effects of Aluminum Concentration on the Structure and Electrochemical Properties of $Li_7La_3Zr_2O_{12}$ Alexandra C. Moy[1], Alicia Manjon Sanz[2] and Jeff Sakamoto[1]; [1]University of Michigan, United States; [2]Oak Ridge National Laboratory, United States

The need for improved battery performance and safety has created the impetus to replace carbon-based anodes used in state-of-the-art batteries with lithium metal. However, it is generally known that lithium metal anodes cannot cycle with state-of-the-art liquid electrolytes due to dendrite formation. Owing to its stability and stiffness, the solid-state electrolyte lithium lanthanum zirconium oxide (LLZO) is known to physically stabilize lithium during cycling. In order to induce high conductivity, LLZO is commonly doped with aluminum. However, it is not known what other structural and electrochemical effects variable aluminum doping may produce. Additionally, the effect of structure and defects on the conductivity is not yet fully understood in LLZO. Thus, there is a need to better understand the effect of aluminum concentration in LLZO to determine how it may or may not affect its other properties.

LLZO with variable levels of aluminum was fabricated using rapid induction hot pressing. Phase purity, lattice site occupancy, and structural information were determined via neutron powder diffraction as a function of temperature. Electrochemical impedance spectroscopy was used to determine activation energy of bulk lithium-ion conductivity. This work presents a correlation between the structural and electrochemical properties of LLZO as a function of aluminum concentration and temperature, increasing the understanding of the effects of aluminum doping on LLZO and the intrinsic understanding of the relationship between conductivity and structure. With this understanding, optimal design and fabrication of solid-state electrolytes can be determined to allow for the implementation of lithium metal anodes into advanced battery technology.

11:15 AM EN08.01.03
On High-Temperature Thermal Cleaning of LLZO Solid-State Electrolytes Kostiantyn Kravchyk[1,2], Huanyu Zhang[2] and Maksym V. Kovalenko[2]; [1]Empa – Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zurich, Switzerland

The deployment of $Li_7La_3Zr_2O_{12}$ (LLZO) garnets as Li-ion solid-state electrolytes in Li-metal solid-state batteries is partially hindered by their chemical reaction with water and carbon dioxide, leading to the formation of a Li_2CO_3/LiOH contamination layer on the LLZO surface.[1, 2] The latter causes high Li/LLZO interfacial resistance, voltage polarization at the Li anode, and induces the formation of Li dendrites.[3] To address this issue, in this work, we investigate the applicability of high temperature annealing (600 – 900 °C) as a method for thermal cleaning of LLZO. Through an in-depth analysis of the LLZO surface using X-ray photoelectron spectroscopy, hard X-ray photoelectron spectroscopy, *in-situ* grazing incidence synchrotron X-ray diffraction and Raman spectroscopy, we have found that high-temperature thermal cleaning has an inherent issue. On the one hand, heat-treatment allows a significant reduction in Li_2CO_3/LiOH contamination. On the other hand, the use of high temperatures of 600 − 900 °C leads to the formation of the $La_2Zr_2O_7$ phase on the LLZO surface as a result of Li losses. The effect of both factors on the Li/LLZO interfacial resistance, voltage polarization and critical current density of Li/LLZO/Li symmetrical cells have been thoroughly investigated by electrochemical impedance spectroscopy and galvanostatic cycling measurements.

Electrochemical Effects of Proton Exchange and Contamination Formation on LLZO Solid Electrolytes Sunny Wang, Edward Barks, Celeste Melamed, Xin Xu and William C. Chueh; Stanford University, United States

Cubic Lithium Lanthanum Zirconium Oxide (LLZO) and its aliovalently doped counterparts are amongst the most promising solid electrolyte candidates due to their high bulk ionic conductivity and stability with Lithium metal. However, its performance as a solid electrolyte is significantly hindered by detrimental side reactions. LLZO readily undergoes Li+/H+ exchange in the presence of protic solvents such as water. In air, the exchanged Li+ can subsequently undergo surface reactions that result in the formation of lithophobic contaminants such as Lithium carbonate. These surface reactions detrimentally affect the electrochemical performance of LLZO by removing Li+ from the bulk electrolyte and exasperating current constriction phenomena at the Lithium metal interface.

In this work the surface chemistry of LLZO under different treatment conditions is systematically examined and correlated to the interfacial electrochemistry. The impact of surface contaminants and proton exchange on Lithium plating dynamics, bulk ionic conductivity, constriction impedance and charge transfer are discussed.

SESSION EN08.02: Solid-State Batteries Devices and Solid Electrolytes II

Sulfide-Based Hybrid Solid Electrolytes for All-Solid-State Lithium-Ion Batteries Young-Jun Lee, Seung-Bo Hong, Han-Jo Lee, Hui-Tae Sim and Dong-Won Kim; Hanyang University, Korea (the Republic of)

All-solid-state lithium batteries (ASSLBs) with sulfide electrolytes have attracted considerable attention owing to their enhanced safety and high energy density. The successful development of ASSLBs relies on resolving the many issues related to solid electrolytes. The brittleness of solid electrolyte pellets prepared by pressing sulfide powder makes it difficult to prepare a thin sheet. Therefore, typical sulfide-based solid electrolytes used in ASSLBs have a thickness of more than 500 μm to prevent mechanical breakage of the pellet, which leads to a decrease in the ionic conductance and energy density of the ASSLB. Moreover, making an electrolyte pellet by cold pressing results in formation of numerous voids in the solid electrolyte, which blocks ion transfer in the electrolyte. In addition, the high interfacial resistance between the solid electrolyte and composite electrodes caused by poor solid-solid interfacial contacts deteriorates the cycling performance of ASSLB. To date, rubber-based polymer binders have been commonly used to prepare sheet-type thin electrolyte sheet. However, rubber-based binders significantly reduce the ionic conductivity. Herein, we prepared thin and robust sheet-type electrolytes using an ion-conducting cross-linking agent. The cross-linking reaction allowed the three-dimensional network structure of sulfide electrolyte, resulting in enhancement of mechanical strength of the electrolyte. In addition, a cross-linked sheet exhibited high flexibility that enables roll-to-roll processing. The sheet-type cross-linked solid electrolyte was applied to all-solid-state lithium-ion cell (graphite/$LiNi_xCo_yMn_{1-x-y}O_2$), and its electrochemical performance was evaluated and compared with that of a cell employing a sheet-type solid electrolyte treated with rubber-based binders.

1:45 PM EN08.02.03
Preparation of Thin Halide Electrolyte by Tape Casting and Li Metal/Halide Interlayer Exploration Fengyu Shen[1], Michael McGahan[2], John D.

Pietras[2], Marca M. Doeff[1], Vincent S. Battaglia[1] and Michael Tucker[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Saint-Gobain, United States

Halide solid-state electrolytes attract significant attention due to their high room-temperature ionic conductivity (>10^{-3} S/cm), low processing temperature, and good compatibility toward oxide cathode materials. Similar to sulfide electrolytes, the halide electrolytes can be densified through pressing, which can lower the cost of electrolyte manufacture. The scale-up of halide electrolytes by tape casting is challenging as halide materials are reactive with most of the traditional solvents in the battery industry. Moreover, halide materials are incompatible with Li metal, and interfacial layers (ILs) between Li metal and halide electrolytes are needed if Li metal is used as an anode. Our study shows non-polar solvents, such as toluene, are compatible with the Li_3YBr_6 halide material. An electrolyte with thickness <50 µm is prepared by tape casting, with a small amount of binder. It's room temperature ionic conductivity is higher than 10^{-4} S/cm. We also explore various ILs, such as Li_3N, for mitigating the reaction between Li metal and halide electrolyte. Li/IL/halide/IL/Li symmetric cells show good stability even at current density of 0.5 mA/cm^2. The performance of the interlayer is also evaluated in full cells with a high voltage cathode.

2:00 PM EN08.02.04

Lithium Thioborate Solid-State Electrolytes for Practical, High-Energy All-Solid-State Lithium Metal Batteries Sarah Holmes; Stanford University, United States

Solid-state batteries (SSBs) using a lithium metal anode have the potential to transform the energy density and safety of rechargeable batteries for EVs, consumer electronics, and the grid. There is a strong need to improve the chemical/electrochemical stability, ionic conductivity, and fundamental understanding of new materials for the solid-state electrolyte (SSE) before commercialization. Lithium thioborates (LBS) are a new class of SSEs with ionic conductivity predicted to be up to 80 mS cm^{-1}, making them exciting SSE candidates with unexplored potential. Our work focuses on developing and studying LBS compounds for application in all-solid-state batteries.

Through careful optimization, we have developed a multigram-scale, solvent-free synthesis for high-purity LBS compounds. We have synthesized and fully characterized pure-phase LBS materials $Li_2B_2S_5$, Li_3BS_3, and $Li_{10}B_{10}S_{20}$ using X-ray diffraction, FTIR, and electrochemical analysis. Of all LBS stoichiometries, $Li_{10}B_{10}S_{20}$ is the most promising candidate for SSBs, with experimental Li^+ conductivity of 0.34 mS cm^{-1} and negligible electronic conductivity. $Li_{10}B_{10}S_{20}$ demonstrates an exceptional voltage window of 1.3-3.0 V vs. Li/Li$^+$, wider than most sulfur-based SSEs. At room temperature, in Li-LBS-Li symmetric cells, $Li_{10}B_{10}S_{20}$ has shown high critical current density of 1.0 mA cm^{-2} and stable cycling for hundreds of hours at reasonable current densities as high as 0.3 mA cm^{-2}. In NMC-LBS-Li full cells using a solid composite cathode, we have demonstrated cycling at C/10 rates with minimal capacity degradation at room temperature and reasonable pressure. These initial results using $Li_{10}B_{10}S_{20}$ are highly encouraging for future studies on this exciting new class of electrolytes.

2:15 PM EN08.02.05

Succinonitrile-Lithium Salt Composite as a Solid Catholyte for LLZO-Based All-Solid-State Batteries Wooseok Go, Michael Tucker and Marca M. Doeff; Lawrence Berkeley National Laboratory, United States

All-solid-state batteries (ASSB) have come into the spotlight as next-generation batteries because of their potential high energy density and low flammability. LLZO ($Li_7La_3Zr_2O_{12}$) is a prominent solid electrolyte material for ASSBs due to its high ionic conductivity (>1 x 10^{-4} S/cm at room temperature) and compatibility with Li metal. However, for its use in ASSBs, there are challenges including forming intimate contact with the active electrode material. Because both LLZO and the cathode active material are rigid, employing a soft solid catholyte between them can be a solution to ensure intimate contact. The solid catholyte must be ionically conductive, and stable for oxidation (> 4.5 V vs. Li/Li$^+$).

Organic Ionic Plastic Crystals (OIPC) are a class of materials that are soft and waxy at room temperature. When the OIPC is mixed with Li salts, the mixture has high ionic conductivity and a wide electrochemical window. Succinonitrile (SN) is an OIPC material, and SN with Li salts is reported to have high ionic conductivity (> 1x10^{-4} S/cm) and good oxidation stability (>5 V vs. Li/Li$^+$) [1]. Despite the favorable properties of the SN-Li salt composite as a solid catholyte, studies for their use with LLZO are still limited. For example, the investigation of compatibility with LLZO, and contact formation between the composite and LLZO has rarely been reported.

In this talk, Succinonitrile-Lithium salt composites are investigated for their use as a solid catholyte in LLZO-based ASSBs. The properties of composite with different Li salt concentrations, their compatibility with LLZO, and their contact formation with LLZO will be shown. The performance of all-solid-state cells with the mixtures will also be demonstrated at room temperature. It is hoped that this work can motivate efforts toward forming intimate contact between the LLZO and cathode using OIPC materials.

3:00 PM EN08.02.06

Investigation of the Stability of the Poly(ethylene oxide)|$LiNi_{1-x-y}Co_xMn_yO_2$ Interface in Solid-State Batteries Yuriy Yusim[1], Dirk Hunstock[1], Raffael Ruess[1], Alexander Mayer[2], Dominic Bresser[2], Stefano Passerini[2], Jürgen Janek[1] and Anja Henss[1]; [1]Justus Liebig University Giessen, Germany; [2]Karlsruhe Institute of Technology, Germany

Solid-state lithium batteries (SSLBs) are known to provide superior safety and increased energy density compared to conventional lithium metal batteries (LIBs) with liquid electrolytes. However, for commercial applications SSBs based on poly(ethylene oxide) (PEO) have only been combined with $LiFePO_4$ (LFP), a low-voltage active cathode material (CAM).[1] Using high voltage CAM such as $LiNi_{1-x-y}Co_xMn_yO_2$ (NCM), cells experience fast capacity fading, the cause of which is not fully understood.[2] According to electrochemical impedance measurements in a three-electrode setup, we show that the NCM/PEO interface is still the Achilles' heel in PEO-based SSBs at high voltages. We demonstrate that the electrochemical cycle stability depends on the cut-off potential and the molecular weight of PEO. This is supported by impedance measurements. In addition, using X-ray photoelectron spectroscopy (XPS), we confirm the formation of C=O bonds due to the oxidative degradation of the solid polymer electrolyte (SPE) at high potentials, which is consistent with previous reports.[3] Considering the structure of PEO, the formation of C=O in the main chain indicates chain breakage, in turn resulting in a decrease in viscosity. Using PEO with high molecular weight (8 Mil g mol^{-1}), secondary electron microscopy (SEM) shows that after cycling to 4.3 V vs. Li$^+$/Li the pores of the composite cathode are filled by PEO. This indicates that the mechanical properties deteriorate due to the oxidative degradation of the SPE at the cathode side.

Hydrophobic Polymer Coatings for Enhanced Air Stability of Inorganic Solid Electrolytes for All-Solid-State Batteries Kyu Tae Kim, Jehoon Woo, Hiram Kwak and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

Achieving improved safety in energy storage devices has been intensively pursued as the demand for electrification increases. All-solid-state Li batteries (ASLBs) employing inorganic solid electrolytes (SEs) are considered the Holy Grail because of the possibility to achieve not only enhanced safety but high energy/power density. Sulfide and halide-based SEs are considered promising because of their superionic conductivity and deformability. However, they suffer from poor air stability, which hinders the commercialization of ASLBs. Sulfide-based SEs react with humid air and release H_2S gas with rapid structural degradation. Halide-based SEs also suffer from irreversible degradation to form MCl_3-H_2O and LiCl-H_2O. The poor chemical stability of these inorganic SEs causes not only the degradation of the electrochemical performance of ASLBs but drastically increased processing costs because the strict exclusion of moisture is required. Thus far, several strategies to enhance air stability of inorganic SEs have been proposed: i.e., elemental substitution, functional additives, and surface treatment. However, those strategies have limitations, such as limited applicability, severe decrease in ionic conductivity, and insufficient air stability.
In this study, we report on our universal hydrophobic polymer coating strategies for enhanced air stability of inorganic SEs. The hydrophobic coating layer impedes the diffusion of moisture into the SEs and enhance the air stability. Furthermore, the structural degradation mechanism in humid air is discussed. Finally, to investigate practical application, dry room compatibility of the protected SEs will be presented.

3:30 PM EN08.02.08
Development of a New Generation High-Energy Lithium Metal Polymer Battery Jean-Christophe Daigle, Ki Seok Koh, Annie-Pier Larouche, Frédéric Roussel, Francis Barray, Zhang Xuewei and Kim Chisu; Hydro-Québec, Canada

In the race for the electrification of transportation, many companies are competing to develop more efficient solid-state batteries for commercial applications. Since the landmark discovery of using polyethylene oxide (PEO) as a lithium-ion carrier for lithium metal batteries by Armand in 1978, solid-state batteries based on polymer electrolytes have been deeply scrutinized;[1] Viable commercial applications have been provided by Blue Solutions since 2011.[2] Despite their many advantages, such as the ability to use lithium metal as a negative electrode as well as reduced cell weight and enhanced overall safety, the use of polymer electrolytes remains limited. Additionally, the low overall ionic conductivity and transport number (t+), poor high-voltage stability, and elevated operating temperature remain obstacles for their wide implementation in electric vehicles (EVs).

In this presentation, we outline our efforts to develop a high-energy and long-life cycle NMC – Polymer Electrolyte - Li metal pouch cell. Major challenges are addressed in this pursuit, including stability of polymers with NMC, stable interface between all components, preventing dendrite growth, and developing a scalable process.

Using a star-shaped polymer as electrolyte, we developed a specific formulation to accommodate high C-rate cycling. This polymer is easily scalable for the industrialisation and requires only a negligible amount of solvent to be processable. Considering the need to minimise the process cost and diminish the ecological footprint, this feature provides meaningful advantages for the commercialisation.[3-4]

Another major achievement was the development of new Organic Ionic Plastic Crystal (OIPC), which was implemented as catholyte in the electrode formulation. Our new formulation allows the continuous production of cathode electrode using conventional coating machines used in Li-ion battery industry. Based on the unique properties of the new OIPC family, we achieved high C-rate with a good capacity retention more than 500 cycles at C/6 – 1 C.[5]

This technology was successfully scaled up at the format of 1 Ah pouch cell, and will be further scaled up to large format cells > 20Ah using our in-house pilot line in 2023.

Investigation of Exothermic Reaction Pathways in Solid-State Batteries: Implications for Safety Megan Diaz, Alex Bates, Yuliya Preger, Loraine Torres-Castro and Randy Shurtz; Sandia National Laboratories, United States

It has been assumed that replacing the liquid electrolyte (LE) in a Li-ion battery (LIB) with a nonflammable solid electrolyte (SE) provides inherent safety. However, results from prior thermodynamic modeling[1] show that batteries containing a SE still have the potential to reach high temperatures during certain failure scenarios. Even if these temperatures do not lead to ignition of the battery contents, they could ignite surrounding flammable packaging material. The reaction pathways leading to thermal runaway are not well understood.

This work investigates those pathways for battery materials undergoing external heating and compares the results with thermodynamic modeling. The following battery configurations were explored: all solid-state batteries (ASSBs), solid-state batteries (SSBs) containing some amount of LE, and LIBs. A Ta-doped LLZO SE was used in the ASSB and SSB configurations. Differential scanning calorimetry (DSC) was used for thermal characterization of individual and combinations of battery components as well as complete microcells to differentiate between contributing factors in heat release scenarios. Calorimetry was halted and materials characterization completed at each distinct exotherm to isolate specific reaction pathways. Microstructure changes were characterized in a scanning electron microscope (SEM) and crystal structure transitions and chemical compositions were obtained through x-ray diffraction (XRD). Avoidance or mitigation of critical component-level interactions leading to thermal runaway will help pave the way towards improving SSE battery safety.

Combining 3D Printing and Field Assisted Sintering to Process Garnet-based Solid-state Electrolyte and Composite Cathode Bor-Rong Chen[1], Asa Monson[1], Arin S. Preston[1], Spencer Doran[1,2], Jorgen F. Rufner[1], Donna P. Guillen[1] and Eric J. Dufek[1]; [1]Idaho National Laboratory, United States; [2]Oregon State University, United States

Garnet-based lithium-ion conductors have been investigated as a promising solid electrolyte material exhibiting superior conductivity and stability compared to sulfur- and polymer-based ones. However, the fabrication of garnet-based solid-state batteries is challenging due to the high temperature (1000-1250 °C) and long duration (~12 hr) necessary for densification as well as the brittle nature of ceramics when processing thin layers below millimeters. To achieve thin and dense garnet layers using an energy efficient approach, we combine two advanced manufacturing technologies, digital light processing (DLP) and field assisted sintering (FAS), to produce $Li_7La_3Zr_2O_{12}$ (LLZO) electrolyte layer and $LiCoO_2$ (LCO)–LLZO composite cathode.

DLP is a unique 3D printing technology capable of layer-by-layer printing of multiple components in a single print [1]. In this work, we demonstrate that LLZO layer and LLZO/LCO composite cathode stacks printed with controllable solid mass loading, dimension, and composition. The ceramic prints are subsequently densified using FAS, during which an electric field is applied to the sample to create local Joule heating that aids densification to near theoretical density [2]. Using FAS, LLZO can be densified with a significantly shorter dwell time (<10 min) and lower temperature (900-1100 °C) compared to conventional routes. DLP-printed workpieces with controlled mass and homogeneous distribution of ceramic particles also enable FAS to produce objects thinner than its traditional limit at a millimeter-scale. By establishing the DLP-FAS process flow, we produce free-standing, sub-millimeter-thick LLZO layers. The thickness is further reduced when co-sintered with LLZO-LCO composite cathode serving as a support layer. The LLZO/cathode stack is then coupled with Li metal anode and full battery performance is evaluated.

This DLP-FAS workflow not only saves the energy and time during sintering, but also introduces several other advantages in solid-state battery processing, including reduced number of processing steps, preservation of grain and interface structures, and minimizing interdiffusion during co-sintering of LLZO and cathode material. Using DLP, fine adjustments of layer thickness and compositions, such as multi-layer structures or graded mixtures, are also achievable. In the future, this DLP-FAS process flow will provide more opportunities to fabricate various designs and chemistries of solid-state batteries.

Assessing Mesoscopic Chemo-mechanical Coupling Effects on Effective Transport Properties of Solid Electrolytes based on a Fourier Spectral Method Bo Wang, Kwangnam Kim, Liwen Wan, Marissa Wood, Tae Wook Heo and Brandon Wood; Lawrence Livermore National Laboratory, United States

The geometrically complex microstructures of solid electrolytes have profound impacts on the macroscopic behavior and performance of all-solid-state Li-ion batteries. To understand such processes, it is critical to accurately evaluate the effective ionic transport properties across a highly inhomogeneous microstructure with known materials properties of individual homogeneous domains, a process also known as the homogenization. For liquid electrolytes in porous electrodes, the most common approaches include simple analytical methods such as the Bruggeman model that correlates microstructural factors (*e.g.*, tortuosity, porosity) and transport properties; and numerical methods for directly solving the transport equations over a digital representation of the complex porous microstructures. However, solid electrolytes exhibit distinct microstructural features, which are significantly different from the porous electrode counterparts. In addition, conductive Li ions transport through the host solid electrolytes often give rise to highly heterogeneous and anisotropic strain/stress fields via the chemo-mechanical couplings, which bring challenges to accurately evaluating the effective transport properties using the existing methods. Here, we present a thermodynamically consistent mesoscopic model for quantifying the chemo-mechanical coupling effect on the transport properties of arbitrary inhomogeneous microstructures. We also discuss its numerical implementation to efficiently solve the coupled steady-state transport and mechanical equilibrium equations incorporating fully anisotropic local materials properties. Specifically, the chemo-mechanical effects enter the coupled equations by a stress-gradient-driven drift term in the transport equation and a chemical expansion term in the mechanical equilibrium equation. To achieve numerical efficiency for the strongly inhomogeneous materials properties, we combine the Fourier spectral-based superposition method and the iterative perturbation method. As a representative example, we will show how we apply our model to computing the effective ionic diffusivity of polycrystalline $La_3Li_7Zr_2O_{12}$ (LLZO) solid electrolytes and porous LLZO-$LiCoO_2$ composites with local materials parameters derived from atomistic simulations. We will also discuss the impact of the chemo-mechanical coupling on the effective properties systematically and quantitatively using our established modeling framework.
This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

PEO/LLZTO Composite Electrolytes for Li-S Batteries Ai-Yin Wang, Chun Han Kuo and Han-Yi Chen; National Tsing Hua University, Taiwan

Lithium-sulfur batteries (LSBs) have the advantages of high specific capacity and high energy density, which attracted attention in the past decade.

However, poor safety and polysulfide shuttle phenomenon are the two most criticized reasons for liquid LSBs. Using solid-state electrolytes can overcome those problems, but compared with liquid electrolytes, solid electrolytes have lower ionic conductivity and poorer electrode/electrolyte interface contact in all-solid-state LSBs. Herein, we combined polymer polyethylene oxides (PEO), Li-ion conducting ceramic powder, $Li_{6.4}La_3Zr_{1.4}Ta_{0.6}O_{12}$ (LLZTO), dispersant, and plasticizer to form PEO/LLZTO composite electrolyte. The ionic conductivity of PEO/LLZTO composite electrolyte is approximately 10^{-4} S cm^{-1} at room temperature. Furthermore, the capacity of the all-solid-state LSB assembled with the sulfur cathode, Li metal anode, and PEO/LLZTO composite electrolyte can reach up to >1000 mAh g^{-1}. After 100 cycles at a current density of 0.2C at room temperature, the S//PEO/LLZTO//Li batteries still exhibited high capacity retention of up to 70%, showing high potential for all-solid-state LSB applications.

5:00 PM EN08.03.03
Development of Operando X-Ray Diffraction-Raman Dual System for a Solid Battery Hyuksang Kwon and Yong-Il Kim; KRISS, Korea (the Republic of)

Li-ion batteries (LIBs), becoming one of the daily necessities in human lives, have been widely used primarily for the achievement of carbon neutrality, toward which the replacement of fossil-fuel-based vehicles with eco-friendly electric vehicles are progressing rapidly. In addition, if the urban air mobility market opens within the next 10 years, the environmental safety and stability of these batteries will become key issues. Currently, there is significant enthusiasm for research on solid batteries using solid electrolytes owing to the safety issues of batteries using liquid electrolytes. Thus, the research and development of advanced batteries utilizing the chemical and electrical stability of solid batteries, high-voltage anode materials, and lithium anode materials have been an extensive. For the measurement technology, challenges arise on spatial tracking of non-uniform electrochemical and interfacial chemical reactions in a cell, and understanding the cause of such reactions for the pursuance of safe battery design. The non-uniform lithiation/delithiation upon battery material location also requires the development of advanced measurement systems that incorporate two or more specialized techniques.
In situ/operando Raman spectroscopy is a technique that characterizes dynamic battery materials. Moreover, X-ray diffraction (XRD) is an essential technique for conducting secondary battery research to understand a crystal structure and perform multiphase quantitative analysis. Both techniques are a part of the state-of-the-art technologies that aim for a highly realistic environmental system with the most confidential measurements toward the characterization and development of next-generation materials. We have developed the XRD-Raman dual system, which is advantageous in assessing the non-uniform electrochemical reaction of the active material. Home-made fiber-type Raman system was unified with the conventional XRD system. The excitation laser can be irradiated to the sample in variable angles. The Raman signal, scattered from that, was collected into an off-axis parabolic mirror, which directs it to the spectrometer and detector. In addition, we developed a special coin cell to observe the dynamic behavior of the battery material in the assembled device. First, we chose transparent materials and attached them to the holed coin cell lid, so that the X-ray and visible light source can simultaneously transmit and reflect. Second, we fabricated the coin cell with a gap between the chosen transparent film and cathode materials to reduce the unwanted background. This coin cell enabled for XRD-Raman measurements to be performed during the battery operation under the same environmental conditions. The XRD-Raman dual operando measurement technology for material diagnosis in real systems will be of great help in improving the performance of secondary batteries.

Comparison of Different Cathode-Solid Electrolyte Interface Solutiuons for High-Voltage All-Solid-State Sodium Batteries Xiaochen Yang[1,2], Yu Chen[1,2], Yingzhi Sun[1,2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Lab, United States

The use of inorganic solid-state electrolytes in composite cathodes is challenging due to their rigid nature and poor interfacial contact with the active electrode material. Various cathode-solid electrolyte modifications have been proposed to minimize the interfacial resistance, but they vary in their high-voltage stability. We will present results on Na-solid-state batteries using a sodium super ionic conductor (NASICON)-type solid-state electrolyte and the high-voltage $Na_3(VOPO_4)_2F$ cathode charged up to 4.3V. The high-voltage stability of three different interfacial engineering concepts is compared: 1) liquid electrolyte addition; 2) a cathode composite with solid-state polymer electrolyte; 3) or a layer of plastic-crystal electrolyte. We find that the addition of both liquid electrolyte and polymer electrolyte leads to a rapid capacity loss within 10 cycles due to their oxidation at high voltage. In contrast, the plastic-crystal interface exhibits a vastly improved electrochemical performance with more than 90% capacity retention after 200 cycles. In addition, the plastic-crystal interface maintains similarly good high-voltage cycling stability at both room temperature and elevated temperate (50°C), which demonstrates its compatibility for operating at high-voltage.

Ionic Transport Across Disordered Interfaces with Atomic-Scale Simulations Oskar K. Garcia[1,2], Kwangnam Kim[2], Liwen Wan[2] and Nicole Adelstein[1,2]; [1]San Francisco State University, United States; [2]Lawrence Livermore National Laboratory, United States

The solid state battery material Li7La3Zr2O12 (LLZO) is one of the most promising solid
electrolytes. If improvements can be made to this material and its interfaces with the cathode, it may be possible to replace current liquid electrolyte batteries with this safer, more energy dense alternative. To better understand LLZO at the interface with the common cathode material LiCoO2, we calculate the elastic and electronic properties of Co-doped LLZO.

5:00 PM EN08.03.08
An Advanced Impedance Analysis for Interfacial Reaction of Sulfide-Based Solid-State Batteries in Rapid Cycling Sung Soo Shin[1,2] and Hyoungchul Kim[2]; [1]Kumoh National Institute of Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Interfacial features are primary factors of the overall electrochemical performance in solid-state electrochemical devices. They mainly influence ionic resistance as well as electronic conduction depending on their shape and distribution. So far, researches have been focused on strengthening the interfacial structure by various architecturing methods (e.g., multiscale structuring, core-shell coating, micropatterning) to enhance the mechanical stability and increase energy density. Furthermore, analytical approaches to demonstrate this enhancement in interfacial structure are also gaining interest. Electrochemical impedance spectroscopy (EIS) with the conventional fitting approach for Nyquist plot has mostly been utilized for quantitative investigation of each electrochemical response in electrodes and electrolytes without damaging cells. However, as the complexity of the cell's electrochemical reaction rises, so does the degree of freedom in circuit layout, which limits the precision of the measurement of individual resistance components.
In this study, we suggest an advanced analysis tool based on the distribution of relaxation times (DRT) method to accurately determine the electrochemical components of the complicated solid-state interfacial properties in sulfide-based solid-state batteries. Based on the advanced approach, we constructed precise equivalent circuit for the composite cathode of solid-state batteries. It also confirmed that the conventional fitting approach overestimated one of the electrode resistance by 40%, and identified the new resistance component from the lithium depletion layer. Finally, we validated that our results are in good agreement with the computational methods, and we established that this method is appropriate for quantitatively analyzing complicated interfacial

reactions in solid-state batteries.

Improving Lithium Metal Deposition in Solid Polymer Electrolyte Batteries with Thin Alloying Anodes Michael J. Counihan, Pallab Barai, Anil Mane, Jeffrey W. Elam, Venkat Srinivasan and Sanja Tepavcevic; Argonne National Laboratory, United States

Solid-state lithium metal batteries (SSLMBs) are the key to high energy density storage for electric vehicle applications. Solid polymer electrolytes (SPEs) used in SSLMBs offer the advantage of low manufacturing cost and provide soft interfaces for battery electrodes to keep contact without high pressures required for other solid electrolytes. However, lithium metal anodes in conjunction with SPEs have numerous chemical and mechanical challenges that limit the cycle-to-cycle efficiency and lifetime of the battery. Most notable is dendrite formation, which leads to cell shorting and dead lithium and can be caused by uneven plating on the anode surface, whether it be lithium metal or another current collector like copper in anode-free cell designs. Here, we investigate how adding a thin layer (<100 nm) of a metal or metal oxide can improve the performance characteristics of lithium metal batteries based on poly(ethylene oxide) (PEO)-based SPEs. If the metal is capable of alloying with lithium, the thin layer converts to a lithiophilic Li_xM alloy that provides a better surface for more uniform lithium metal deposition and limits dendrite formation compared to the non-alloying copper anode. We systematically detail the alloy phases, overpotentials, and reversibility of numerous alloying metals like Al, Zn, and Au and show that Coulombic efficiencies over 95% with no external pressure are possible. This thin film alloy design maintains the high energy density of lithium metal and could also be used with other solid-state and liquid electrolytes to help remedy dendrite formation and lithium metal loss.

5:00 PM EN08.03.12
Hierarchical Interface Modeling of All-Solid-State Lithium Metal Battery Based on Energy Band Theory Heebae Kim[1], Jinil Cho[1], Seonmi Pyo[1], Heejun Yun[1] and Youn Sang Kim[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Advanced Institute of Convergence Technology, Korea (the Republic of)

Development of practical all-solid-state Li-metal batteries (ASSLB) is essential for a breakthrough in battery technology. Compared to conventional lithium-ion batteries using liquid electrolyte, ASSLBs have higher energy density, superior safety, and wider operating temperature range. However, fabrication of all-solid-state battery with Li-metal anode (LMA) and inorganic solid-state electrolyte (SSE) is a far challenge. Two critical issues are hindering the development of ASSLBs as following: large impedance of non-conformal electrode-electrolyte contact and electrochemical instability at the interface. Solid materials, being composed into all-solid-state battery, possess their own distinctive electrochemical and physical properties. When these materials in the forms of electrode or electrolyte are assembled into an electrochemical cell configuration, solid–solid interfaces are subsequently built inside the energy storage system. For realization of practical ASSLBs, interfacial stability at the LMA–SSE contact must be assured because the direct contact causes interfacial reactions leading to battery failure. Therefore, intrinsic instability of inorganic SSE against LMA is required to be prevented. Preceding researches have focused on developing the interface modification methods to enhance ASSLB's long-term cycling stability. But it is confined to a phenomenological solution if modification strategy is established without in-depth understanding of the interface. Also, the fact that rechargeable batteries are operated by behavior of charges inside electric field is often overlooked. The LMA-SSE interface of ASSLB is under in situ electric field during charging process, and the SSE possesses semiconducting properties unlike liquid electrolytes. Consequently, governing mechanism of interface stabilization cannot be identified by using only the conventional electrochemical techniques or by considering solely the material science perspective. For these reasons, solid-state physics concepts of electrical contacts and conduction are necessary to be discussed in ASSLB research.

This study demonstrates the significance of interface stabilization strategy via energy band alignment. The intrinsically unstable LMA–SSE interface is effectively improved by nanoscale titanium deposition on the electrolyte’s surface. And the pure transition metal nanolayer is transformed into an ion-conducting crystal structure through electrochemical interactions with Li-metal. The Li symmetric cell with titanium compound self-induced interlayer (TSI) has successfully maintained its constant overpotential over 1000 cycles and the significantly reduced impedance, whereas the cell having no interface modification exhibits erratic voltage profiles and is easily failed by repetitive charge–discharge process. Subsequently, the cell components can preserve their functions during the repetitive charge–discharge process. Such improvements are achieved by the formation of TSI functioning as stable Li-ion conductor and electron buffer at the anode-electrolyte interface, which is demonstrated by in-depth electrochemical analyses and is fully supported by widely accepted energy band theory. XRD analysis has confirmed the formation of self-induced interlayer, EDS analysis has shown its structural robustness and uniform elemental distribution, and depth-profiling XPS measurement has confirmed the effect of electron blocking phenomenon across the interface. The revealing results provide not only comprehensive understanding of the interfacial phenomena, but also fundamental interface modification method applicable to various types of all-solid-state battery. Furthermore, rigorous stability requirements of automotive applications are expected to be satisfied by the innovative interface modeling.

5:00 PM EN08.03.13
Structural Changes in the Silver-Carbon Composite Anode Interlayer in Solid-State Batteries Varnika Agarwal, Dominic S. Jolly and Peter Bruce; University of Oxford, United Kingdom

Solid-state batteries, in which a lithium foil anode is used in conjunction with a ceramic solid electrolyte, promise to improve the energy density and safety of cells. However, charging solid-state batteries at practical rates on the order of 1-10 mA cm^{-2} can lead to cell failure. Solid-state batteries fail at high rates of charge because, as Li metal is plated to the anode, dendrites (filaments of Li metal) penetrate through the ceramic electrolyte, short-circuiting the cell. One approach to mitigate this problem has been to introduce an interlayer between the ceramic electrolyte and the lithium anode to facilitate homogeneous Li deposition and protect against dendrite penetration; with inorganic, metal, and carbon-based interlayers having been shown in the literature to increase charging critical currents.
In this work, we study the structural changes of interlayers in cells pairing a lithium metal anode and a Li_6PS_5Cl solid electrolyte by a combination of techniques including electrochemistry and *operando* powder X-ray diffraction. In addition, the relationship between the rate of charge, the Li-ion diffusivity of the interlayer, and the effectiveness of the interlayer in protecting against dendrite growth are discussed.

5:00 PM EN08.03.14
Prelithiated Ga_2O_3/C Nanocomposites as Self-Healing Host Materials for Stable Lithium Metal Anodes in Solid-State Batteries Sungwoo Park, Kyubin Shim, Hyun Woo Kim and Hae Jin Kim; Korea Basic Science Institute, Korea (the Republic of)

To achieve safe and high energy density rechargeable batteries, it is essential to adopt lithium metal anodes (LMAs) in solid-state batteries (SSBs). Because, lithium metal has excellent electrochemical properties including both high theoretical capacity (3860 mAh/g) and exceptionally negative potential (-3.04 V vs. NHE), which provides for increasing energy density by reducing total space and/or weight of SSBs. However, Li dendrites or filaments growth caused by unstable interfacial reactions and contact between Li metal and solid electrolytes during electrochemical cycling are obstacles hindering solid-state Li-metal batteries.
In the aspect of anodes engineering, rational design of 3D host materials decorated with lithiophilic sites is one of reasonable approach to suppress the

growth of Li dendrites or filaments by effectively regulating Li deposition. Among the various lithiophilic materials, gallium (Ga) has been considered as a self-healing anode material due to its low melting point (29.8 °C). This unique property can facilitate form a conformal electrode-electrolyte interface in SSBs. However, its fluidic feature at close to room temperature, makes it difficult to realize nanostructured design.

In this study, Ga_2O_3/C nanocomposites were simply synthesized via microwave-induced hydrothermal reaction for 20 min and subsequent carbonization. The nanocomposites exhibited that Ga_2O_3 nanodots with diameter of ~ 10 nm are densely embedded in thin carbon matrix. To evaluate stable Li plating ability of Ga_2O_3/C nanocomposites, coulombic efficiency (CE) was obtained in liquid electrolytes after specific prelithiation process. The composite electrodes presented low initial Li nucleation overpotential of 20.0 mV, and initial high CE was stably maintained over 200 cycles under the conditions of 1.0 mAh/cm^2 at 1.0 mA/cm^2. It could be confirmed by in-situ XRD analysis that the excellent performances of Ga_2O_3/C electrodes are attributed to prelithiation process resulting in lithiophilic Ga phase in electrodes. The effects of Ga phase on stable interface contact between electrode-solid electrolyte during electrochemical cycling were evaluated by controlling cell measurement temperature (above and below Ga melting point) at solid-state half-cell assembled by using PEO-based solid electrolytes. Furthermore, cell performances of carbon matrix without Ga_2O_3 were also compared at same temperature to identify the effects of cell operating temperature on PEO-based solid electrolytes in LMAs.

5:00 PM EN08.03.15

Revealing the Roles of Interface Design for Ga-Doped Garnet/Polymer Composite Electrolyte of Solid-State Lithium Batteries Purna C. Rath[1], Wei-Lun Hsu[2], Tai-Chou Lee[2] and Jeng-Kuei Chang[1,2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]National Central University, Taiwan

$Li_7La_3Zr_2O_{12}$ (LLZO)-based composite solid electrolyte (CSE) are considered to be the most promising electrolytes in solid-state lithium metal batteries (SSLMBs) due to the advantages of high safety and potentially high energy density. However, unsatisfactory interfacial connections of LLZO at both cathode and anode solid junctions are the key bottlenecks. To reduce the internal resistance of SSLMBs, three strategies have been employed in this work. First, Ga concentration in $Li_{7-3x}La_3Ga_xZr_2O_{12}$ (LGLZO) was optimized. The significant impacts of the Ga stoichiometry on the battery performance are investigated. Second, an LGLZO CSE layer is fabricated directly on top of a $LiFePO_4$ (LFP) cathode using a spin-coating technique. The CSE slurry infiltrates the cathode layer, forming a Li^+ conduction network and ensuring intimate contact between the CSE and the cathode. The advantages of a spin-coated CSE over a conventional freestanding CSE in terms of the charge transfer resistance and the battery charge-discharge properties are disclosed. Third, an ionic liquid (IL) connectivity layer is added at the Li/CSE interface to improve wettability. The IL interlayer homogenizes Li^+ flux throughout the interface and prevents hot spots for Li dendrite formation, thus suppressing interface-side reactions. The optimal ionic conductivity of the CSE is ~1 × 10^{-3} S cm^{-1} at 60 °C. With such an ingenious arrangement, a satisfactory LFP capacity of 141 mAh g^{-1} at 1 C and a great cyclability of 96% capacity retention after 300 cycles are achieved. We believe that the proposed dual interface design is simple and affordable and is an efficient strategy to significantly improve practical SSLMB performance.

SESSION EN08.04: Cathode Design and Materials for Solid-State Batteries

8:00 AM *EN08.04.01

Designing Cathode Materials and Composite Electrolytes for Li-ion Batteries and Beyond Lianzhou Wang; University of Queensland, Australia

Li-rich layered oxides (LRLOs) are ones of the most promising cathode materials for next generation high-energy-density lithium-ion batteries (LIBs) because of their extraordinary specific capacity over 250 mA h/g. Such high capacity originates from the “activation” of Li from transition metal layer in the Li_2MnO_3 phase. However, the activation process is kinetically slow, and the relevant phase transformation as well as the electrode /electrolyte side reactions at high voltage region cause serious capacity and voltage decay. In this talk, we present our recent studies on the electrochemical activation mechanism and capacity/voltage decay challenges. A series of *ex-situ* and *in-situ* characterisations reveal the structural evolution mechanism of the cathode materials, and the optimised materials deliver a high capacity of ~270 mA h/g and with good capacity retention of >98% over 300 cycles. We will also discuss our recent works on the atomic layer protection of a new high-voltage cathode material with excellent cycling stability of over 1000 cycles, the design of integrated printable solid-state battery systems for flexible electronics, and the development of new gradient composite electrolytes for solid-state sodium ion batteries.

8:30 AM EN08.04.02

Designing Zero-Strain Li-Ion Cathodes Xinye Zhao, Yaosen Tian, Zhengyan Lun, Zijian Cai, Tina Chen, Bin Ouyang and Gerbrand Ceder; University of California, Berkeley, United States

Cathode materials for Li-ion batteries (LIBs) commonly suffer from chemo-mechanical structural degradation during cycling. The repeated (de-)lithiation processes induce severe volume change and deteriorate the structural integrity of cathode particles, cathode coatings, and the cathode/electrolyte interface [1]. Especially for all-solid-state batteries, solid electrolytes lack the mechanical compliance to tolerate the structural change of the cathode particles. The local expansion and contraction of the cathode particles push the solid electrolyte away, resulting in increased cell impedance and capacity loss [2-4]. Therefore, to improve the capacity retainability and cycle life of all-solid-state Li-ion batteries, it is crucial to develop cathodes that exhibit low volume strain to minimize the structural degradation during cycling. We have used well-calibrated computational techniques to systematically investigate the roles that redox chemistry, structure, disorder, inactive elements, and metal coordination play in determining the volume change of cathode upon delithiation, leading to the exciting conclusion that zero strain compounds are possible. Based on our design rules, we have experimentally synthesized $Li_{1.3}V_{0.4}Nb_{0.3}O_2$ and $Li_{1.25}V_{0.55}Nb_{0.2}O_{1.9}F_{0.1}$ with low volume change upon cycling [5]. In this presentation, we will present our established guidelines in detail and discuss the significance of zero-strain for advancing all-solid-state batteries.

Surface Coating by Mechanofusion Modulates Bulk Charging Pathways and Battery Performance of Ni-rich Layered Cathodes Dong Hou and Feng Lin; Virginia Tech, United States

Alkali metal-based batteries (e.g., lithium batteries) are considered the most effective energy storage candidate for portable electronics, power grids, and electric vehicles due to their considerable energy density, power density, cycle life, safety, and competitive prices. The Ni-rich Co-less ternary $LiNi_xMn_yCo_{1-x-y}O_2$ (NMC) (Ni>80%) is considered one of the most promising cathode materials due to its high discharge capacity (>200 mAh g^{-1}) and high energy density (>750 Wh kg^{-1}). Common issues in these Ni-rich NMCs are poor cycling performance and undesired degradation at high voltages. Surface coating is considered an effective way to mitigate performance degradation for polycrystalline cathodes in batteries. However, the synergic effect between surface modification, bulk charge distribution, and particle microstructural evolution has not been systematically studied. Moreover, many coating methods are practically expensive, require intermediate processing steps, and have high standards for precursors, etc.

We utilize a dry surface modification method, mechanofusion, to achieve enhanced battery stability. The simplicity, high yield, and flexibility make it cost-effective and highly attractive for processing at an industrial scale. The underlying mechanisms responsible for performance improvement are unveiled by a systematic study combining multiple probes, e.g., 3D nano-tomography, spectroscopic imaging, in situ synchrotron diffraction, and finite element analysis. Mechanofusion affects bulk crystallography by introducing partially disordered structure, microstrain, and local lattice variation. Furthermore, the crack initiation and propagation pattern during delithiation are regulated and the overall mechanical fracture is reduced after such surface coating. We validate that mechanofusion can alter the bulk charging pathways. Such a synergic effect between surface modification and bulk charge distribution is fundamentally important for designing next-generation battery cathode materials.

9:00 AM EN08.04.04
Improved Electrochemical Performance of Co-free Li-rich Layered Oxides Caused by Temperature-driven Chemical Segregation Dries De Sloovere[1,2], Kunkanadu Rajappa Prakasha[3], Jekabs Grins[4], Aleksander Jaworski[4], Thomas Thersleff[4], Gunnar Svensson[4], leif Olav Jøsang[5], Anne Dalager Dyrli[5], Andreas Paulus[1,2], Jan D'Haen[1], Hemesh Avireddy[3], Joan Ramon Morante[3], Marlies K. Van Bael[1,2], An Hardy[1,2] and Jordi Jacas Biendicho[3]; [1]UHasselt and Imec, Belgium; [2]EnergyVille, Belgium; [3]Catalonia Institute for Energy Research, Spain; [4]Stockholm University, Sweden; [5]Ceramic Powder Technology AS, Norway

While solid-state lithium batteries are regarded as a promising technology because of their potential safety and electrochemical stability, the gravimetric energy density of the positive electrode material remains a limiting factor for the cell energy density.[1] The current lithium-ion battery technology is dominated by the use of layered, cobalt-containing oxides with general stoichiometry $LiNi_xMn_yCo_zO_2$ (NMC, with x + y + z =1) as positive electrode material.[2] The large-scale production of these materials therefore relies heavily on cobalt, which raises concerns because of the latter's high cost, scarcity, and vulnerable global supply chain. Recent research efforts therefore focus on the elimination of cobalt from the active positive electrode material, while simultaneously increasing its energy density.

More specifically, extensive efforts are placed on the development of lithium-rich layered oxides, as they can combine a high specific capacity with a high operating potential and lower cost. Generally, these materials can be represented by the formula $[xLiMO_2{*}(1 - x)Li_2MnO_3$ (M = Mn, Co, Ni, etc.)], where the monoclinic (*C*2/*m*) Li_2MnO_3 structure closely resembles the rhombohedral (*R*-3*m*) $LiMO_2$ structure, but with a different cation ordering. Their high energy density results from the combination of traditional cationic redox processes with anionic redox processes of the oxygen sublattice. Further, the high manganese content of these materials implies that they are relatively cost-effective.

This presentation will focus on the synthesis and electrochemical performance of $Li_{1.1}Ni_{0.35}Mn_{0.55}O_2$ as a cobalt-free, lithium-rich layered oxide for (solid-state) lithium-ion batteries. The oxides were synthesized by spray pyrolysis of an aqueous precursor followed by calcination. Performing the latter at 900 °C caused an increase in particle size. Furthermore, powder neutron diffraction, and HAADF-STEM combined with EDX and EELS showed that calcination at this temperature led to a pronounced structural segregation between the aforementioned rhombohedral and monoclinic phases, where the former corresponded to nickel-rich facets, and the latter corresponded to manganese-rich regions. In half cells, this material delivered a discharge capacity of 160 mAh g^{-1} at C/3, with a capacity retention of 80% after 150 cycles. This contrasts with the material calcined at 700 °C, which showed no appreciable capacity retention in the same conditions. At 1 C, the former material had a discharge capacity of 100 mAh g^{-1}. Furthermore, it showed a slower voltage decay than is observed for the oxides calcined at lower temperatures.

The formation of larger, structurally segregated particles was shown to mitigate degradation reactions within the cathode, thereby improving its electrochemical performance in various aspects. This work therefore provides a simple but effective strategy to improve the performance of cobalt-free, lithium-rich layered oxides which can be used in solid-state lithium-ion batteries.

This work was supported by Horizon 2020 LCBAT-5 COBRA project 875568.

Novel Polymer Binder with Superior Performance in the Composite Cathode for Sulfide All-Solid-State Lithium Batteries Seung-Bo Hong, Yoo-Rim Jang, Young-Jun Lee and Dong-Won Kim; Hanyang University, Korea (the Republic of)

The safety concern of commercialized lithium-ion batteries (LIBs) is a critical problem to be solved. Accordingly, all-solid-state lithium batteries (ASSLBs) with non-flammable solid electrolytes have been considered promising alternatives. Among various types of solid electrolytes, the sulfide electrolytes with high ion conductivity are received a lot of attention. However, the realization of sulfide-based ASSLBs is still challenging due to the difficulty of producing composite cathodes with high active mass loading. To avoid the delamination of cathode components and mitigate mechanical stress generated during cycling, a small amount of polymer binder should be incorporated into the composite cathode. Acrylonitrile-butadiene rubber (NBR) is the most common binder used in preparing composite cathode. In our study, we investigated a new polymer binder that can improve the cycling performance of ASSLBs. The composite cathode prepared with new binder enables the realization of an ASSLB with better cycle life than the case of an ASSLB employing a composite cathode with NBR.

9:30 AM EN08.04.06
Micro-Architected Lithium Cobalt Oxide Electrodes toward 3D Solid-State Batteries Yuchun Sun and Julia R. Greer; California Institute of Technology, United States

Lithium-ion batteries (LIBs) are the primary candidates for advancing energy storage needs, but current LIBs suffer from energy-storage and power limitations of their slurry electrodes, as well as the safety concern from liquid electrolytes. Thickness of commercial slurry electrodes is highly limited by Li ion transport. This constraint on electrode thickness limits the mass ratio between active materials and current collectors, and thus the energy and power density of LIBs. One approach to overcome this limitation is to fabricate 3D architected electrodes using additive manufacturing techniques. In this work, lithium cobalt oxide (LCO) is fabricated into 3D micro-architected structure through a novel hydrogel infusion process. In this process, a blank 3D architected organogel is printed through vat photopolymerization and soaked in water to form a blank hydrogel, where lithium and cobalt ions in an aqueous solution are then swelled into the 3D hydrogel structure. After calcination, LCO micro-lattice with 50 μm beam diameter is obtained, giving a crucial lithium-ion diffusion length of 25 μm. This approach enables LCO cathode to be flexibly architected into 3D geometries, for example the interdigitated plate configuration, toward the realization of 3D Li-ion batteries with high energy and power density. A carbon anode of the same 3D architecture can be fabricated and combined with the LCO cathode, followed by conformal coating and in-situ polymerization of a photo-polymerizable oligo(ethylene glycol)-based gel polymer electrolyte resin on 3D electrodes, giving a 3D solid-state lithium-ion battery.

9:45 AM EN08.04.07
New Hybrid Nano-Architecture of Sulfur Electrode for Lithium-Sulfur Batteries. Mariam Ezzedine, Fatme Jardali, Ileana Florea and Costel-sorin Cojocaru; Ecole Polytechnique, France

Lithium-Sulfur batteries have the potential to provide a much greater energy storage capacity than current Lithium-ion batteries. However, Lithium-Sulfur batteries are hampered by challenges arising from the cell level, such as poor conductivity of sulfur, its volume expansion, and the lithium polysulfides shuttle effect. The technology developed in our lab overcomes these fundamental challenges by implementing an innovative electrode architecture that exploits the properties of vertically aligned carbon nanotubes (VACNTs). The hierarchical-assembled-nanostructured battery positive electrode is based on carbon nanotube carpets grafted by 100% sulfur nanomaterial. Coupling it with metallic lithium as negative electrode results in high energy and power, and long-life Lithium-Sulfur battery (Figure 1). The positive electrode topology enables to store more electrical charge more rapidly than any other commercial electrode, positively impacting the power and energy storage capacity of the battery. The Lithium-Sulfur batteries exclude inactive components (such as binders/additives essential for traditional Lithium-ion batteries), thus eliminating the “dead weight” found in the today’s batteries.
Electrochemical performance tests have shown that the Lithium-Sulfur batteries developed in our work have substantially improved capacity performance, stability and cycle life compared to conventional Lithium-Sulfur batteries. At a discharging rate of 2C (i.e., 30 minutes), the cells have shown a stable specific capacity of 400 mAh g^{-1} over 1000 cycles.

The Electrostatic and Elastic Conditions for Quasi-static Dendrite Propagation in Solid-State Electrolytes Cole D. Fincher[1,2], Yet-Ming Chiang[1,2], Brian Sheldon[3] and Craig Carter[1,2]; [1]MIT, United States; [2]Massachusetts Institute of Technology, United States; [3]Brown University, United States

We have demonstrated that dendrite propagation possesses a marked dependence upon the mechanical state of the electrolyte and upon the applied overpotential [1]. The conditions for the arrest or propagation depend on a trade-off between energy released during infinitesimal growth against the infinitesimal increase due to surface energy. The released energy has at least two sources: elastic relaxation and the change in the electrostatic field due to the growth of a conducting dendrite. The implications of these results for electrolyte design are illustrated with general stability diagrams. Extension to dendrites propagating with finite velocities will be discussed.

Pitfalls of Critical Current Density Tests to Investigate Alkali Metal Electrodes Till Fuchs, Felix Richter and Jürgen Janek; Justus-Liebig-University Giessen, Germany

Using lithium metal as anode material promises a drastic increase in energy and power density in solid-state batteries. However, morphological challenges such as local contact loss of the metal electrode or dendrite growth occur during cell cycling,(1) limit the applicable current density. Designing reliable and reasonable testing protocols is of utmost importance to ensure an error-free analysis of the Li|Solid Electrolyte(SE) interface.

Testing the so-called “critical current density” (CCD) via a stepwise increase in applied current density in an alternating direction is often applied. These CCD tests should determine the maximum current density a cell can withstand before undergoing critical failure, which suggests that the CCD is a material property of the SE itself. However, our analysis shows that the CCD is neither an inherent cell nor an SE property. It highly depends on several external factors, such as the used current profile, exact interface conditions, applied pressure and temperature and even the cell geometry and size. This is evident from the spread of CCD values over orders of magnitude obtained on very similar materials in different studies.(2)

Therefore, to interpret the results obtained by CCD tests, it is necessary to know the microscopic mechanism that causes cell failure. This could be a direct failure of the SE, e.g. by cracking and dendrite formation, or it could also be a pore formation that precedes the growth of dendrites and acts as a precursor for short-circuiting by focusing the current at remaining contact spots. As all these effects overlap and gradually worsen and influence each other during a CCD test, data interpretation is quite challenging. We therefore suggest a differentiation between the different failure mechanisms by carefully tailoring the test protocol to induce the desired case, being either a direct short-circuiting or a short-circuiting as a result of pore formation.

For example, we suggest using an intermediate pressure and a waiting time between the current steps of a test to close potentially forming pores when investigating the SE. If instead the SE is a constant during the experiment and the interface conditions are changed, e.g. by interlayers or surface treatments, we suggest the omission of stack pressure and instead concentrate on longer current steps to not miss voiding at the interface. Generally, we hope our guidelines on how to investigate the Li|SE interface will help to streamline the efforts made by the community and ensure a better comparability between the results of different groups.

Elucidating Interfacial Stability of the Electrolyte/Cathode Interfaces in Solid-state Batteries Yi-Tzu Wu, Jing-Sen Yang and Ping-Chun Tsai; National Taiwan University of Science and Technology, Taiwan

Emerging solid-state electrolytes (SSEs) with superior ionic conductivity have been developed for all-solid-state batteries (ASSBs). However, most SSEs experience noticeable interfacial incompatibility with most conventional cathodes, so ASSBs are subject to significant cycling degradation. Through experimental characterization techniques, it is hard to clarify the main interfacial degradation factors, identify the decomposition products, and allow an atomic scale visualization of interfacial reactions. In this study, *ab-initio* calculations are used to determine phase, chemical and electrochemical stability of various prominent SSEs and cathodes as a function of the state-of-charge (SoC). Specifically, SSE/cathode interfaces of superior oxide-, sulfide-, and halide-based SSEs and conventional layered-, spinel-, and olivine-structure cathodes are investigated. Factors controlling interfacial stability are revealed and stable SSE/cathode interfaces are identified. The *ab-initio* understanding of the SSE/cathode interfacial stability allows the development and design of a variety of stable solid-to-solid interfaces.

Theoretical Understanding of the Deposition and Growth of Lithium in a Solid State Lithium-ion Conducting Electrolyte Xiao-Dong Zhou, Yudong Wang and Anil Virkar; University of Louisiana at Lafayette, United States

All-solid-state lithium batteries have been extensively pursued for next-generation energy storage, in which the state-state electrolyte (SSE) is a key component. The deposition of metallic lithium inside an SSE has been observed and is a concerning issue for development of the forefront all-solid-state lithium batteries. Unlike lithium dendrites that form and grow from the surface of Li-metal anode, metallic lithium can nucleate and propagate directly inside the bulk SSE, which can cause an instant failure of SSE.

In this work, we first present a theoretical model that is built based on non-equilibrium thermodynamic theory while taking consideration of the electronic conduction in an SSE. The electronic conductivity is a key variable to determine the chemical potential of lithium. The distribution of chemical potential of lithium is then calculated based on transport properties of an SSE. When the lithium chemical potential is higher than the sum of the elastic energy and surface energy, the change of Gibbs free energy for lithium formation is less than zero, which is the thermodynamic criterion for the deposition of lithium in an SSE. We will present our ongoing experimental research, as well as the electrochemical and materials characterization, to elucidate the approaches to control the deposition of lithium in an all-solid-state battery.

Nanoscale Imaging of Li-ions Through Ion Mass Spectroscopy Marina S. Leite; University of California, Davis, United States

Determining where Li ions preferentially accumulates during charging/decharging is critical for understanding and controlling undesired chemical reactions that ultimately lead all-solid-state batteries to fade. Here, we implement time-of-flight secondary ion mass spectroscopy (ToF-SIMS) in oxygen free and controlled environment to image the distribution of Li-ions in all-solid-state batteries formed by Si/LiPON/$LiCoO_2$, with nanoscale spatial resolution. Specifically, we resolve Li ions distribution within all active layers of the batteries upon cycling, and identify the formation of a solid-electrolyte interphase (SEI) at the LiPON-$LiCoO_2$ interface after the first charging. Our method is extended to energy-storage devices with $Li_xV_2O_5$ anode and V_2O_5 cathode, as will be discussed.

Real-Time Solid Interface Observation Using Synchrotron X-Ray Computed Tomography for All-Solid-State Battery Seongjun Kim[1], Michael Wang[2], Cole D. Fincher[2], Yet-Ming Chiang[2], Tim Fister[1], Alan Kastengren[1] and Paul Fenter[1]; [1]Argonne National Laboratory, United States; [2]Massachusetts Institute of Technology, United States

For a few decades, the lithium-ion batteries (LIB) have changed the numerous aspects of modern industry. Particularly, the vehicle industry is the one of the most affected areas as rising of the LIB. Despite the rapid expansion of the market, the state-of-art LIBs are still not getting full trust from the public because of anxiety about safety, cost, and environmental issues. All-solid-state batteries (ASSB) are a novel battery system that can change the paradigm of the battery ecosystem in the future. This solid-state system is making people look forward to them because they can overcome the problems of conventional LIBs. However, it has still many steps to achieve the commercial ASSBs as always. Therefore, possessing deep scientific and engineering knowledge on the new system is essential.

Exploration for searching solid electrolyte has been found various types of electrolytes including argyrodites, garnets, and LISICON/NASICON-type structure. Among them, some doped garnet-type solid electrolyte (i.e., $Li_7La_3Zr_2O_{12}$ or LLZO) have high ionic conductivity (~ 1 mS cm^{-1} at 298 K) and high shear modulus (60 GPa) along with high stability against Li metal and air atmosphere. However, existing suggested ASSB model have been limited by the contact of the solid interfaces. The rigidity of solid state along with volume changes of the electrodes lead a degradation of interface contact from void evolution and dendrite formation. The degradation eventually increases the interfacial resistance resulting in cell failure. Therefore, observation of dynamics on the solid interfaces and electrolyte becomes necessary procedure to achieve the high performance ASSBs.

Synchrotron X-ray computed tomography (XCT) is a non-destructive method that can characterize the solid-solid interfaces with varying scales, ranging from sub-micron to centimeters. The three-dimensional (3D) morphological variation can be detected by the XCT technique, which is helpful to identify the transformation on the electrolyte interface. Despite the great advantages, the high Z-element (i.e., La, Ta, and Zr) of the garnet-type electrolyte absorbs a large amount of x-ray, as a result, the tomography images with clear phase contrast is difficult. Contrary, the contrast sensitivity of low Z-element like Li can be decreased at high-energy x-rays for high Z-elements. Taking into account the x-ray attenuation of the atomic weight materials, the proper cell design and measurement strategy are critical for the interface characterization.

Several strategies and cell construction for tracking the morphological transformation of high Z materials will be discussed. With calculation on the tolerable x-ray beam pathway that can travel through the solid electrolyte, the multiple mechanical factors such as dimension and morphology of the cell is modified for high quality x-ray tomography imaging. Additionally, the void or defect appearance and crack evolution by different current densities in Li|LLZO|Li symmetric cell are investigated along with the discussion the interfacial behavior on the solid interface.

This presentation provides much information to build a measuring technique for solid state interface of ASSB and insights on the phenomenon of cell failure from interface deterioration.

Recent Advances in *Operando* X-Ray Photoemission/Absorption Spectroscopy to Probe the Electrified Electrolyte/Electrode Interfaces in All-Solid-State Batteries Mario El Kazzi; Paul scherrer Institute (PSI), Switzerland

All-solid-state batteries (ASSBs) are a rising alternative for boosting the volumetric energy density and promising a superior safety. However, Li-ion transport across the solid electrolyte (SE)/active materials (AMs) interfaces is limited by poor mechanical contact and parasitic (electro-)chemical side reactions. The fundamental understanding of such interface has not been fully achieved yet mainly due to the limitations in current surface-sensitive analytical techniques, especially in *operando* mode.

In this contribution, we will review the recent developments in *operando* X-ray photoemission (XPS) and absorption (XAS) spectroscopy, to monitor in real-time the interface evolution of operational ASSB working electrodes (WE). *Operando* measurements are made possible thanks to the unique and versatile electrochemical custom-made cell designed to operate in ultra-high vacuum, providing reliable electrochemistry.[1] We will highlight how the combination of in-house *operando* XPS and synchrotron-based *operando* XAS using soft and hard X-rays can provide a reliable platform to investigate (i) the (electro-)chemical evolution of the SE/AMs interfaces, (ii) the surface modifications of the AMs and (iii) the electronic properties across electrified solid-solid interfaces. Different examples will be presented describing in a novel way the interface degradation mechanism observed in real time upon cycling.

Specifically, we show results from *operando* XPS performed on $LiCoO_2$ (LCO) and $(Li_2S)_3$-P_2S_5 (LPS) WE, where we identified LPS oxidation byproducts and its onset oxidation at 2.3 V vs. InLix followed by Co-ions diffusion into the LPS forming CoS_x species at 2.9 V. Consequently, negative localized charges have been detected embedded into the LPS at the interface with LCO. Furthermore, we demonstrated the presence of a sharp potential drop, confirming previous theoretical predictions of a narrow space layer charge at the interfaces between WE and SE in ASSB.[2,3]

In *operando* XAS performed at the Mn, Ni and Co L-edges, as well as at the S and P K-edges of the $LiNi_xCo_yMn_zO_2$ (NCM) and LPS WE, we evidenced a surface chemical reaction when LPS comes in contact with NCM, leading to the formation of sulfates and reduced Co and Ni. These chemical and electrochemical interface reactions are further enhanced upon the first charge, while after several cycles the interface reaches a self-passivation regime where the degradation reactions are highly attenuated resulting in relatively stable cycling performance.

A Study of the Li-LLZO Interface via Plasma Focused Ion Beam Marco Siniscalchi and Chris Grovenor; University of Oxford, United Kingdom

Despite the considerable interest that lithium garnet ceramic solid electrolytes have attracted, their application in solid-state batteries is still limited by the penetration of lithium filaments through the electrolyte resulting in short circuits at small critical current densities. It is still not fully understood how these lithium filaments nucleate and propagate through the solid electrolyte. In this study, we show that during cycling lithium metal can deposit in the sub-surface porosity of the solid electrolyte. We demonstrate that this sub-surface lithium is present in occluded pores and has no apparent electrical connection path to the plated lithium electrode. As a consequence, large pressures develop within the solid electrolyte and lead to internal cracks, along which more lithium can plate and eventually short-circuit the cell. Such degradation mechanism was visualized at the interface between a lithium electrode and LLZO solid electrolyte via focused ion beam (FIB) milling and scanning electron microscopy. In addition, we obtained detailed three-dimensional reconstruction of interface features such as spallation cracks, which are possible sites for the nucleation of lithium filaments. These results elucidate the formation mechanism of lithium filaments and suggest effective surface engineering strategies for their prevention.

In-situ 4D-STEM Biasing of Model Lithium-Sulfur Batteries Hadas Sternlicht[1], Benjamin Savitzky[1], Alpesh K. Shukla[2], Colin Ophus[1] and Andrew M. Minor[1,3]; [1]National Center for Electron Microscopy, Molecular Foundry, Lawrence Berkeley National Laboratory, United States; [2]ZoNexus, LLC, United States; [3]University of California, Berkeley, United States

While Sulfur has been reported as a promising cathode material given its high capacity and energy density, practical use of Lithium-Sulfur batteries is impeded by challenges such as the low electric conductivity of Sulfur. This work aims to determine the structure-chemistry relationship in Lithium-Sulfur batteries upon biasing, which is crucial for identifying the mechanisms that alter Lithium-ion transport and affect battery performance. To do so, Lithium-Sulfur micrometer length-scale solid state batteries are fabricated, biased and studied entirely *in-situ* using 4D-STEM. This approach allows focus on a single controllable interface. A full air-free setup was developed and is being used to transfer samples to and from the glove box during sample preparation and characterization. Carbon is introduced to and coated on the Sulfur cathode, in order to exploit the improved properties associated with the

Sulfur(Carbon) cathode compared to Sulfur. These include improved conductivity, and prevention of Sulfur loss via vapor pressure. Variations in the microstructure are studied by tracking the reaction products, Li_2S and other Li_xS compounds.

Modeling of the Potential Distribution and the Electrical Double Layer in Solid-State Batteries Yue Qi; Brown University, United States

The electrical double layer (EDL) is a key feature of all electrochemical interfaces, controlling the kinetics and thermodynamics of both electron transfer and ion transfer reactions, and therefore the performance of all solid-state batteries (ASSB). Unlike in a liquid electrolyte with an EDL made of solvated ions, the EDL in a solid electrolyte is made up of charged point defects. Thus, the well-known Poisson-Boltzmann equation at electrode/liquid-electrolyte interfaces no longer holds in SSBs. This problem is even more challenging, as ion insertion and/or reaction with the electrode alters the material and thus band alignments at the electrode/solid-electrolyte interfaces.

In this talk, a density functional theory (DFT)-informed theoretical framework was established to predict the interface potential profiles. We first assumed the electrochemical potential for Li^+ ions reached a constant at the open circuit equilibrium condition, then derived the relationship among the electrostatic potential, the lithium chemical potential, Fermi level, ionization potential, and the work function. This relationship yielded quantitative profiles of the electrostatic potential and electronic energy level alignments across the entire solid-state batteries.

The electrostatic potential jump at the electrode/electrolyte interface creates intrinsic barriers for Li^+ transport across the interface. The predicted potential jump was directly compared to the Kelvin probe force microscopy (KPFM) measurements and correlated with the interfacial impedance. The interfacial potential jump was then predicted for 48 ASSBs made of different electrolyte and electrode materials. A number of cathode/electrolyte pairs with low "intrinsic" potential barriers were identified, suggesting these promising interfaces will most benefit from engineering efforts to reduce "extrinsic" interfacial impedance, such as increasing the interface contact area.

To obtain the electrostatic potential variation as a function of the distance to the interface, a more general model for the EDL at a solid-state electrochemical interface based on the Poisson-Fermi-Dirac equation was developed. The EDL structure is presented in various materials that are thermodynamically stable in contact with a lithium metal anode. The model further allows designing the optimum interlayer thicknesses to stabilize the interface without introducing additional electrostatic barriers for lithium ion transport at relevant solid-state battery interfaces.

Multiscale Modeling of Ion Transport Phenomena at Interfaces in All Solid-State Batteries Liwen Wan, Kwangnam Kim, Aniruddha M. Dive, Bo Wang, Tae Wook Heo and Brandon Wood; Lawrence Livermore National Laboratory, United States

Ion transport at interfaces dictates the performance of all solid-state batteries. For example, it has been routinely observed that in many superionic oxide conductors, lithium-ion transport kinetics are orders of magnitude slower at the interfaces, such as grain boundaries or interfaces with common electrode materials, compared to the bulk phases. The ability to understand, predict and precisely control ion transport kinetics at these interfaces are therefore critical and would have a transformative impact on the development of solid-state battery technologies for practical applications. Here, I will address the need for a multiscale and multiphysics modeling framework to unravel the mechanisms of ion transport at complex interfaces and predict the kinetics of ion transport in solid-electrolyte/cathode composite architectures that are relevant for all solid-state lithium batteries. I will use the garnet-type solid-electrotype and lithium cobalt oxide cathode as an example to demonstrate the predictive power of such a multiscale, multiphysics modeling framework towards establishing the correlations between ion transport and local atomic structure, chemical environment, and mesoscopic microstructure features in the cathode/electrolyte composites.

10:45 AM EN08.08.03
Small Correlation Between P-S Building Block and Ionic Conductivity in Amorphous Li–P–S Super-Ionic Conductors Byungju Lee[1], KyuJung Jun[2] and Gerbrand Ceder[2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]University of California, Berkeley, United States

Amorphous Li-P-S materials have been widely used as solid-state electrolytes for all-solid-state batteries because of their high ionic conductivity (10^{-4}–10^{-3} S cm^{-1}) as well as good synthetic accessibility and processability. Despite the potential of these materials, their amorphous structures have made it challenging to quantify the relation between structure and conductivity. In this paper, we use *ab initio* molecular dynamics simulations to investigate the role of the local structure and density in determining the conductivity of amorphous Li–P–S structures with different polyanion units. We observe similar rates for Li-ion hopping regardless of the local P–S polyanion environment in these amorphous materials, indicating that the path connectivity at a larger length scale may be controlling the overall Li conductivity. This finding will serve as an important guideline in the continued development of amorphous solid electrolytes for advanced all-solid-state batteries.

Phase-field Simulations of Failure in LLZO: How Flaw Size and Distribution Affect Electrochemical Tolerance Scott Q. Monismith[1], Remi Dingreville[2] and Jianmin Qu[3,1]; [1]Tufts University, United States; [2]Sandia National Laboratories, United States; [3]Stevens Institute of Technology, United States

The solid electrolyte, $Li_7La_3Zr_2O_{12}$ (LLZO), is a promising next-generation candidate material for lithium metal batteries. However, LLZO-based cells exhibit crack growth and subsequent Li metal plating, leading to short circuit and failure. In our work, we develop a coupled electrostatics-mechanics phase-field model which characterizes the growth of cracks; this model comprises deterministic and stochastic frameworks to describe the failure of LLZO with a single crack and multiple randomly distributed cracks respectively. Our single-crack model demonstrates that crack propagation under applied electrostatic loads follows an inverse-square law of failure, analogous to classical fracture mechanics. Multiple-crack simulations show that the Weibull model applies to both constant voltage and constant current conditions. Furthermore, an interfacial region of flawless crystal leads to substantial increases in both critical overpotential and critical current. The totality of these results provide some guidance for the rational operation of LLZO-based cells in an industry setting as well as some possible routes for improvement of the material's microstructure for long-term operability.

11:15 AM EN08.08.05
Probing Interfacial Degradation at $Li_7La_3Zr_2O_{12}$|$LiCoO_2$ Interfaces in All Solid-state Batteries Using Machine Learning Interatomic Potential
Kwangnam Kim[1], Aniruddha M. Dive[1], ShinYoung Kang[1], Nicole Adelstein[2], Brandon Wood[1] and Liwen Wan[1]; [1]Lawrence Livermore National Laboratory, United States; [2]San Francisco State University, United States

All solid-state batteries (ASSBs) are emerging next-generation energy storage technologies that promise improved safety with potentially higher energy density compared to conventional Li-ion batteries. However, the interfacial instability between the solid electrolyte (SE) and electrodes hinders their practical applications. For example, cation interdiffusion across the interface can alter the composition and atomic structure of the interface as well as the bulk phases that affect Li-ion transport. Severe interfacial degradation may also occur that lead to the formation of undesired secondary phases that can block Li diffusion. To mitigate this issue, fundamental understanding of the intrinsic physico-chemical properties of the SE/electrode interfaces is required, which necessitates advanced computational methods that can accurately predict the chemical processes that govern the early-stage of interfacial degradation and the reaction products as well as dynamic properties at the interfaces.

In this talk, we will present the direct probing of structural and chemical evolution at the $Li_7La_3Zr_2O_{12}$SE/$LiCoO_2$ cathode interfaces by a machine learning (ML) interatomic potential. The ML potential was developed based on artificial neural network trained by the energies and atomic forces of structure data sampled from ab-initio molecular dynamics (AIMD), which was proved to reproduce the structural and dynamic properties of the interfaces and bulk phases similar to AIMD. Using this ML potential, we performed large-scale MD simulations on a series of interface models varied by initial compositions and atomic arrangements. We will discuss interfacial disordering propensities with different interfacial chemistry as well as observations of cation interdiffusion and its implication towards Li-ion diffusion. We emphasize the critical need of accurate large-scale atomistic simulations, which can be enabled by ML potential, to resolve the atomic details of the interface and unravel the structure-property relationship at the interface that governs Li-ion transport and dictates the performance of ASSBs.

11:30 AM EN08.08.06
Understanding the Physical and Mechanical Properties of Solid Electrolyte and Protective Layer on the Inhibition of Li Dendrite Growth by Phase-Field Method Yao Ren[1], Bharat Pant[1], Yue Zhou[2] and Ye Cao[1]; [1]The University of Texas at Arlington, United States; [2]The University of Texas at Dallas, United States

Lithium (Li) dendrite growth in Li batteries is a long-standing problem, which causes critical safety concerns and severely limits the advancement of rechargeable Li batteries. Replacing a conventional liquid electrolyte with a solid electrolyte of high mechanical strength and rigidity, or introducing a protective layer at the electrode-electrolyte interface (EEI) have become potentially approaches to mitigate the Li dendrite growth. However, there still lacks an accurate understanding of the roles of the physical and mechanical properties of the metal electrode, the EEI, and the electrolyte in the Li dendrite growth. Recently, phase-field model which uses a field variable to capture the evolutions of complicated microstructures in materials, has been successfully employed to investigate the Li dendrite growth in Li metal batteries. However, most models do not fully consider the effects of the elastic and plastic properties of the electrode and electrolyte, the complicated microstructure of the solid composite electrolyte, or the existence of a physical protective layer at the EEI on the Li dendrite growth. In this talk, I will discuss our recent works on the development of a phase-field model coupled with multi-physics behaviors to understand the mechanism of Li dendrite growth. It is revealed that Li dendrite can also be effectively inhibited by solid electrolytes of high elastic modulus and initial yield strength. Meanwhile, the role of the yield strength of the Li metal is also critical when the yield strength of the electrolyte becomes low. It is also discovered that the introduction of the nanofibers to form nanochannel arrays in polymer composite electrolyte confines the Li-ion transport along uniaxial direction, reduces the Li-ion concentration gradient across the electrode/electrolyte interface, and inhibits the Li dendrite growth. Finally, introducing a protective layer of lower Li ion diffusion barrier than the electrolyte results in a much smoother electrode/electrolyte interface during the electrodeposition. The simulation results are compared with experimental results from our collaborators to validate the model. Our work thus provides a deeper understanding of the mechanism of Li dendrite growth and its suppression, as well as a design strategy for solid electrolyte and protective layer for improved Li anode stability. Our model can potentially be extended to other electrode-electrolyte interfacial problems in energy storage materials beyond Li metal batteries.

Dedicated Forcefields for Efficient Simulation of Electrode:Electrolyte Interfaces in Solid State Batteries Stefan N. Adams; National University of Singapore, Singapore

A transition to ceramic all-solid-state batteries is widely expected to achieve safer energy storage systems with higher energy density. To overcome hurdles slowing down the development of such energy storage systems, it is necessary to understand more in detail the key processes at their buried interfaces. This should allow for a more rational design and tailored evolution of the interfaces, which largely govern the device performance and cycle life. In order to gain such a deeper understanding we need both experimental operando probing and advanced simulation approaches, but both remain so far challenging. High

fidelity ab initio calculation methods offer high accuracy and transferability, but their computational cost severely limits the size and complexity of models that can be analysed as well as the periods over which processes can be monitored by ab initio molecular dynamics simulations. Classical molecular dynamics (MD) simulation methods using empirical “reactive” forcefields reduce the computational cost for a comparable system size or simulation period by many orders of magnitude and have a more favourable scaling behaviour, so that more complex structure models can be handled. Here “reactive” refers to forcefields that are able to describe ion transport and chemical reactions, where atoms change their bonding partners over the runtime of the simulation.
A crucial matter of concern especially for screening applications is the transferability of such empirical forcefield. We demonstrated how our bond-valence based transferable softBV forcefield successfully enables the design of new solid electrolytes or insertion-type electrode materials and the analysis of ion transport processes therein [1,2].
As a two-body forcefield, it enables fast simulations for complex structures over long periods, but inevitably shares the tendency of two-body forcefields to maximize coordination numbers if free volume facilitates a reorganization of the atoms. This vulnerability of two-body forcefields is overcome in a computationally efficient way by introducing an embedded-atom-method(EAM)-inspired bond valence sum(BVS)-based new class of transferable forcefields with machine-learning optimised parameters [3]. With the help of several application examples it will be discussed how the high computational efficiency (due to a linear scaling of the computational effort with system size) as well as the availability of parameters for most inorganic compounds renders our softBV-EAM forcefield suitable for simulating electrode:electrolyte interfaces, entire electrochemical cells, or neuromorphic devices. Thereby the approach enables a systematic high throughput screening in the search for high compatibility electrode:electrolyte materials combinations or in the rational interface engineering by suitable coatings. The next step will be to enable also the description of redox reactions and systems with alkali metal electrodes.

Quantitative Phase Field Modeling of Dendrite Growth of Lithium Metal Anode Jin Zhang, Alexander F. Chadwick and Peter W. Voorhees; Northwestern University, United States

Dendrite growth is one of the main challenges to the success of using lithium metal anodes in solid-state batteries. The ability to simulate detailed dendrite growth in 3D under experimental conditions will benefit the community by providing a fundamental understanding of the growth mechanism and interfacial stability. This opens new possibilities to explore and design application-dependent battery materials and structures to suppress dendrite growth. Here, we developed a quantitative phase field model based on nonequilibrium thermodynamics in a fully variational and thermodynamically consistent way. The proposed model reproduces the Nernst equation, captures reaction kinetics like Butler-Volmer and Marcus-Hush, and can also include elastic stress. We verify our model against analytical solutions from sharp interface models with simple geometries to demonstrate that our model can give quantitative predictions. The proposed model enables the simulation of systems of experimental size with realistic materials parameters in three dimensions. We show simulations of dendrite growth as a function of applied voltage/current, demonstrating the effects of nucleation density and the mossy-to-dendritic lithium transition. The model can be easily extended to model other alkali metal anodes.

Reaction and Ionic Migration at the Electrode-electrolyte Interface in Solid State Batteries from Machine Learning Molecular Dynamics Jingxuan Ding and Boris Kozinsky; Harvard University, United States

Understanding the interfacial reactions between the Li-metal anode and solid-state electrolyte (SSE) and the Li ion diffusion mechanism are keys for developing stable and efficient solid-state batteries. Yet, theoretic studies are hindered by the high computational costs of ab initio molecular dynamics in both spatial and temporal dimensions. We combine on-the-fly active learning based on Gaussian Process regression (FLARE) with local equivariant neural network interatomic potentials (Allegro) to construct a symmetric battery of Li-metal anode and SSE and perform machine-learned molecular dynamics (MLMD) of tens of thousands of atoms over several nanoseconds with ab initio accuracy. Prominent reactions are observed at the interface with product phases forming a transition layer spanning a few tens of angstroms. Li ions near the interface are observed to migrate from the anode into the electrolyte and eventually diffuse within the SSE. Finally, we examine how off-stoichiometry affects the reaction rate of the interface and enhances Li ion diffusion.

Computational Insights into Interfacial Effects on Li-Ion Diffusivity in $Li_7La_3Zr_2O_{12}$ and $LiCoO_2$ Nicole Adelstein[1], Oskar K. Garcia[1], Kwangnam Kim[2], Brandon Wood[2] and Liwen Wan[2]; [1]San Francisco State University, United States; [2]Lawrence Livermore National Laboratory, United States

The garnet $Li_7La_3Zr_2O_{12}$ (LLZO) is one of the most promising solid electrolyte candidates due to its large electrochemical stability window against a lithium anode, reasonable ionic conductivity, from 10^{-4} to 10^{-3} S/cm, and mechanical strength. However, the effect of its interface with the cathode requires investigation. We picked the common cathode $LiCoO_2$ (LCO) and simulated the effect of interdiffusion of Co into LLZO. Co-doping in LLZO and Co-vacancies in LCO will affect the electronic, elastic, and diffusion properties of the materials. Nudged elastic band calculations were used to calculate the change in the activation energy barrier for Li-diffusion due to a Co-vacancy in LCO and a Co-dopant in LLZO. While these defects show Li-ion diffusivity, our results show that diffusion is still possible through these non-stoichiometric compositions that we expect to find at the interface of LLZO and LCO.

Current Collectorless Transparent Thin Film Lithium Ion Batteries Ji-Won Choi[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic

of); [2]KIST-School of the Korea University of Science and Technology (UST), Korea (the Republic of)

The next-generation transparent energy sources are required with the acceleration of development of smart lenses, glasses, smart windows, transparent displays and the body sensors. A battery with fully transparent materials has not yet been reported since conventional battery components, except from the electrolyte, are opaque. All of the transparent battery research reported so far has a structure using active materials with a fine line width, and this method is a battery made to appear opaque but transparent by creating a micro-pattern below the human eye resolution. This approach includes drawbacks like such a complex process, low energy density, and a packaging system that takes up a lot of space. Therefore, by stacking transparent battery materials, we have created a battery whose materials are all transparent.
In previous research, we have developed transparent cathode, $LiFeMPO_4$. Its wide bandgap of 3.7 eV, high transparency over 70% makes it promising candidate for cathode of transparent battery. However, a full-cell has never been fabricated due to the absence of a transparent anode. Therefore, we developed a transparent anode that does not require an anode current collector for full cell production.
In this study, we developed an Zn doped SnO_2(ZTO)/$AgTi_xCr_y$ (ATC)/Zn doped SnO_2 (ZTO) multilayer anode that exhibits high transmittance (90%), low sheet resistivity (8.8 Ω/sq), and high discharge capacity (1036.9μAh/cm^{2}μm). Due to the high electrical conductivity of the anode itself, anode current collector is not required, therefore the fabrication process can be simplified.
All-solid-state full cell was fabricated with $LiFeMPO_4$ cathode and ZTO/ATC/ZTO anode, LiPON with radio frequency (RF) sputter. Using glass substrate with ITO deposited as a cathode current collector, we created a cell with a total thickness of 1.5 µm excluding substrate. Electrochemical analysis is done in the glove box, checking charge/discharge profiles with 100 cycles. The transparency of full cell was verified by UV Spectroscopy in 550 nm.

4:00 PM EN08.09.07
SiN_x Anode for Transparent Thin Film Battery by CCS Sputtering Yaelim Hwang[1,2], Ho Won Jang[2] and Ji-Won Choi[1,3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]KIST-School of the Korea University of Science and Technology (UST), Korea (the Republic of)

In recent years, as the development of smart paper, smart windows, medical diagnostic smart lenses, and transparent displays is accelerated, the development of next-generation energy sources with flexibility or transparency is required. The only transparent component used in lithium-ion battery construction is the electrolyte, making it challenging to manufacture transparent batteries. The transparent anode of all-solid-state batteries has not been studied. We have created the transparent cathode $LiFePO_4$ in previous study. It is a promising candidate for the cathode of a transparent battery due to its wide bandgap of 3.7 eV and great transparency (76.3%). However, since a transparent anode is not present, a full-cell transparent battery has never been created.
In this study, we report the optimized composition of Ag-doped SiN_x to improve the electrical conductivity of SiN_x. The effect of Ag doping on electrical conductivity and electrochemical characteristics in transparent SiN_x anode is investigated using the continuous composition spread (CCS) method. By utilizing two 90° off-axis RF sputtering guns facing each other, the CCS approach allows for the simultaneous study of a large number of compositions. Here, we investigate the optimal transparent SiN_x-Ag anode composition in terms of their optical absorption spectra, electrical performance and lithium storage capacities. The results come out very clear that doping Ag into SiNx can improve not only the electrical conductivity, but also the performance of the electrochemical system. Ag doped SiN_x transparent anode is successfully approached to thin film battery and we have optimized SiN_x-Ag content with high electrochemical properties balanced with the transmittance.

SESSION EN08.10: Anode Design and Anode-Free in Solid-State Batteries

Stable Li Plating in "Li^0-free" Solid-state Batteries Enabled by Seeded Li Nucleation Catherine Haslam and Jeff Sakamoto; University of Michigan, United States

Solid-state batteries utilizing Li metal anodes have the potential to offer increased safety and higher energy density compared to state-of-the-art Li-ion batteries. To achieve this increase in energy density, the Li metal anode must be thin (<25 µm). Manufacturing of thin Li metal anodes is complicated by the reactivity of Li metal, which forms a thin passivation layer even in controlled environments. The "Li^0-free" cell manufacturing approach provides an alternative to these challenges. "Li^0-free" cells are manufactured with a bare anode current collector (CC) and the Li metal anode is plated in-situ at the CC/solid-state electrolyte (SSE) interface during the first charging step using the Li stored in the cathode active material.
Thus far, all demonstrated "Li^0-free" cells rely on high pressure or temperature formation steps to achieve intimate contact at the CC/SSE interface. Sulfide SSE "Li^0-free" cells utilize high-pressure pre-forming steps (490 MPa) and/or high-pressure cycling (15 MPa) to maintain CC/SSE contact, while oxide SSE "Li^0-free" cells require high-temperature (900 °C) bonding of the CC to the SSE surface. Previous studies of oxide SSE "Li^0-free" cells have suggested that the uniformity of the Li plating can be improved by decreasing the CC/SSE adhesion strength. This encourages debonding between the CC and SSE as opposed to fracture of the CC during Li plating. However, when the CC is placed on an oxide SSE instead of bonded at high temperatures, Li penetration of the SSE causes short-circuiting. Enabling stable Li metal plating in cells with no CC/SSE bonding would both simplify the manufacturing of "Li^0-free" cells by eliminating high-pressure or high-temperature pre-forming steps, and possibly improve the uniformity of the plated Li. This study evaluates the feasibility of in-situ Li anode plating in "Li^0-free" cells with no CC/SSE adhesion utilizing the oxide SSE $Li_7La_3Zr_2O_{12}$ (LLZO). It is shown that stable Li metal plating can be achieved with no CC/SSE adhesion strength by seeded nucleation of Li metal on the SSE surface. The in-situ formed Li anode morphology is characterized during both plating and stripping using cross-sectional scanning electron microscopy and electrochemical impedance spectroscopy. These results illustrate the importance of controlled Li nucleation during in-situ Li plating, as well as demonstrate the feasibility of stable Li metal plating in "Li^0-free" cells without the requirement of CC/SSE bonding.

Understanding Alloy Interlayer Evolution in Anode-Free Solid-State Batteries Stephanie E. Sandoval, Douglas L. Nelson, John Lewis and Matthew T. McDowell; Georgia Institute of Technology, United States

To achieve high energy density and high specific energy in solid state batteries, "anode-free" battery configurations have garnered a great deal of interest. With no active material at the anode current collector, anode-free systems substantially increase volumetric energy density compared to standard Li-ion batteries and lithium metal batteries with excess lithium. The anode-free configuration additionally simplifies manufacturing by removing the need to process lithium metal. To advance this technology, however, it is critical to understand Li growth and stripping on current collectors while also investigating methods to spatially control these processes. Previous work which probed the effects of alloy interlayers in liquid electrolyte systems using *operando* optical microscopy has found that silver thin films enable higher CE than bare current collectors and cause different deposition and stripping dynamics[1]. Silver layers have also shown beneficial effects in enabling long-term cycling of solid-state batteries (SSBs)[2], but there is a lack of knowledge regarding the mechanisms by which they improve performance. Here, we investigate the structural and morphological evolution of alloy interlayers in SSBs using cryogenic and plasma focused ion beam (cryo-FIB, PFIB) methods correlated with electrochemical measurements. Improved Coulombic efficiency and cycling stability are observed when using silver and gold interlayers compared to bare copper. The origin of these performance improvements are investigated using cryo-FIB and PFIB to uncover morphology evolution at the solid-state interface. We observe non-uniform lithium growth on bare copper throughout cycling, while uniform lithium growth is observed in silver- and gold- modified interfaces. Interestingly, the silver and gold interlayers undergo different morphological evolution, which affects cycling behavior. Electrochemical impedance spectroscopy (EIS) is used to understand and investigate the influence of the alloy interlayers on interfacial impedance during cycling, which is correlated to morphology evolution. Over the first five cycles, bare copper electrodes exhibit a relatively large increase in impedance while the alloy-modified interfaces exhibit only minor increases in impedance throughout cycling. Furthermore, *operando* EIS measurements show distinct signatures due to contact loss for the bare copper. This work provides new understanding of the mechanisms governing the behavior of alloy interlayers in anode-free SSBs, which is important for engineering high-performance and high-energy devices.

9:00 AM EN08.10.04
Lithiated ZnO Nanorods into Li Anode for All-Solid-State Batteries with High Rate Capability by Enhancing Li Replenishing Rate Joonhyeok Park, Jaeik Kim, Jiwoon Kim, Seungwoo Lee, Ungyu Paik and Taeseup Song; Hanyang University, Korea (the Republic of)

Recent advances in all-solid-state batteries (ASSBs) based on sulfide-based electrolytes raise hope for the practical use of the Li anode as it is likely to suppress dendritic growth. However, their practical use has been limited by a poor rate capability caused by the Li dendrite growth. And the Li migration rate at the interface between the anode and solid electrolyte (SE) is faster than the Li replenishing rate by atom diffusion inside of Li bulk, resulting in void formation at the interface between the anode and SE under the operation with high current density. These voids increase the localized current density, leading to the Li dendrite growth. Here, we demonstrate an ASSB system with high rate capability by employing lithiated ZnO nanorods into Li anode. Lithiated ZnO nanorods, capable of Li-ion conduction, provide the passage for Li transportation from the Li bulk to the interface between the Li and SE, improving the replenishing rate. The lithiated ZnO nanorods in Li enable interfacial integrity by suppressing the void formation at the Li/SE interface even under the high current density. ASSBs employing Li anode with lithiated ZnO nanorods exhibit stable cyclability without short circuit at 0.3 C during 300 cycles and a superior rate capability.

9:15 AM EN08.10.05
Rational Design of Si-based Anode Material for High Performance All-Solid-State Batteries Jaeik Kim, Jiwoon Kim, Minsung Kim, Joonhyeok Park, Ungyu Paik and Taeseup Song; Hanyang University, Korea (the Republic of)

Silicon is a promising anode material for all-solid-state batteries due to its high theoretical capacity and low working potential. However, the poor cycle stability caused by electrical and ionic contact loss resulting from the significant volume change of the Si associated with Li should be addressed. Here, we report Si nanoparticles embedded in carbon nanofiber (CNF) coated with solid electrolyte (LPSCl) (Si/CNF@LPSCl) as anode material to achieve high energy density and cycle stability for all-solid-state batteries. By embedding Si in the CNF, more favorable strain release and robust electronic pathways are available. The uniform coating of LPSCl on the surface of Si/CNF composite enhances the interfacial stability between the active material and the solid electrolyte, which improves electrochemical properties by maintaining the contacts. The Si/CNF@LPSCl composite electrode shows a reversible capacity of 1172 mAh g−1 at 0.1C and a stable cyclability of 84.3% at 0.5C after 50 cycles. Especially, the concentration of active material (Si/CNF@LPSCl) in the electrode could be increased without apparent performance degradation due to the improved interfacial stability, which enables a reduction of the fabrication cost and the increase of the energy density.

Nanomaterials for Lithium-Sulfur Battery Applications Jackie Y. Ying, Ayman A. AbdelHamid and Jian L. Cheong; Institute of Materials Research and Engineering, Singapore

We have synthesized high surface area nanomaterials of transition metal nitride, carbonitride and carbide nanoparticles that are highly dispersed on 3D carbonaceous structure. Taking advantage of their high electronic conductivity and surface properties, we have developed the nitrides and carbides as polysulfide (PS) regulators to tackle problems in lithium-sulfur (Li-S) batteries (e.g. shuttle phenomena, insulating sulfur). In particular, V_2CN/C nanocomposite has shown a greater redox activity than TiN/C and NbC/C. It has also demonstrated a superior performance with an initial specific capacity of 1055 mAh g^{-1} at 0.2 C and sulfur loading of 4.5 mg cm^{-2}, and a practical areal capacity and capacity retention of ~ 4.2 mAh cm^2 and 89%, respectively, after 300 cycles.

We have also designed a hybrid quasi-solid electrolyte (HQSE) comprised of $Li_7La_3Zr_2O_{12}$ (LLZO) sheet-based solid framework imbibed with liquid electrolyte. The LLZO HQSE has good contact with electrodes, high mechanical stability and Li-ion conductivity, excellent compatibility with Li metal anode, and impressive thermal stability. It results in a high-performance Li-S hybrid quasi-solid system with a very good safety profile. A remarkable rate capability (~515 and ~340 mAh g^{-1} at 1 and 2C, respectively) has been achieved at a loading density of 1.5 mg cm^{-2}.

11:00 AM EN08.11.02
Mechanisms Understanding and Kinetic Enhancements of All-Solid-State Li Sulfur Batteries Hongli Zhu; Northeastern University, United States

All solid-state lithium-sulfur batteries (ASSLSBs) are believed to deliver high energy density and remarkable safety than conventional Lithium-Sulfur batteries using liquid electrolytes. However, the low utilization of active material (sulfur) caused by sluggish reaction kinetics greatly hindered the development of ASSLSBs. It is significant to fabricate an advanced electrode where sulfur has efficient electron/ion accessibility.
Porous carbon host, which has been widely used in liquid cells, is proposed to address the challenges. However, the conventional porous carbon host used in liquid cells can not be directly used in ASSLSBs, because the nonmobile solid electrolytes can not reach the sulfur confined in the pores buried deeply inside the carbon. An ideal porous carbon host should own a large specific surface area to provide sufficient sites for sulfur, but it is critical that the pores should only locate at the out surface of the carbon. Till now, though many works reported the application of porous carbon in ASSLSBs, but none of them discussed the structure requirement of porous carbon. Here, for the first time, we discussed the ideal structure of the porous carbon and developed a polyacrylonitrile-derived porous carbon fibers (named PPCF) with a unique core-shell structure where a layer of micropores cover on dense core contributing to a high specific surface area. As a result, the ASSLSBs employing this PPCF showed an outstanding electrochemical performance.
Furthermore, we grew MoS2 nanosheets and applied it in ASSLSBs. The chemical and electrochemical compatibility among MoS2, sulfur, and sulfide SSE can greatly improve the stability of the cathode and therefore maintain pristine interfaces between the different compositions for stable ion and electron transport. The presence of electrical-conductive metallic 1T MoS2 and its uniform distribution on carbon fiber without aggregation benefit the electron transfer between carbon and sulfur. Meanwhile, the unique layered structure of MoS2 can be intercalated by a large amount of Li atoms and therefore facilitate both ionic and electronic conductivity. In consequence, the charge transfer and reaction kinetics were greatly enhanced, and the decomposition of SSEs was successfully relieved. As a result, our ASSLSB delivered an ultrahigh initial discharge capacity of 1456 mAh g-1 with ultrahigh initial coulombic efficiency and maintained high-capacity retention of 78 % at 0.1 C after 220 cycles. The batteries also obtained remarkable rate performance of 1069 mAh g-1 at 1 C. This study pioneered new idea that fabricating the high performance ASSLSBs through developing surface functionalized and stabilized conductive carbon additives with metal sulfides.
Last, we revealed that the Li-S redox reaction in ASLSBs undergoes a two-step transformation. First, the active material S8 converts into a short-chain polysulfide intermediate Li2S2 and further reacts into the final product Li2S during discharging process. During the charging process, Li2S converts back to Li2S2 first and then to S8, resulting in a reversible reaction. The sluggish reaction kinetic in the ASSLSBs will cause incomplete reaction and generation of Li2S2.

11:15 AM EN08.11.03
Characterization of the Deposition Behaviour of Sodium at the Copper | Solid Electrolyte Phase Boundary for Reservoir-Free Solid-State Sodium Batteries Till Ortmann[1], Till Fuchs[1], Ziming Ding[2,3], Qianli Ma[4], Frank Tietz[4], Christian Kübel[2,3,3], Marcus Rohnke[1] and Jürgen Janek[1]; [1]Justus Liebig University Giessen, Germany; [2]Technische Universität Darmstadt, Germany; [3]Karlsruhe Institute of Technology (KIT), Germany; [4]Forschungszentrum Jülich GmbH, Germany

Reservoir-free battery concepts have gained attention in literature due to simpler cell manufacturing, lower material and energy consumption, lower cost, and higher energy density. Instead of using a sodium metal foil as anode, a metal anode is formed in situ by plating sodium on a current collector (CC) by extraction of Na^+ from a fully sodiated cathode active material during first charging of the cell. Beside the columbic efficiency, one of the major challenges for reservoir-free sodium batteries is the homogeneous cathodic deposition of sodium metal on a CC.[1] The cathodic deposition of sodium on CC in contact with liquid electrolyte has been analyzed in several studies while for solid electrolyte no study exists.
For the first time, we analyzed the cathodic deposition of sodium on copper CC in contact with $Na_{3.4}Zr_2Si_{2.4}P_{0.6}O_{12}$ solid electrolyte. Using a combined approach of galvanostatic electrochemical impedance spectroscopy (GEIS) and cryogenic electron microscopy, we analyzed the evolution of the deposition behavior at different current densities and external temperatures. For vapor deposited copper films, inhomogeneous plating with partial delamination at the $Cu|Na_{3.4}Zr_2Si_{2.4}P_{0.6}O_{12}$ is observed. Additionally, a penetration of sodium whiskers through the CC is likely for thin copper films (~ 200 nm), while this can be prohibited by using thicker films (~5 μm).
Inhomogeneous deposition was confirmed by in situ SEM experiments revealing a preferential growth at surface flaws and defects. In a first step, the thin film CC is penetrated by a large whisker which grows continuously. After a certain time, small nucleation spots underneath the CC can be observed. The shape of the penetrated whiskers shows a pronounced dependency on the applied external current and temperature. At low current densities, facet structures are observed while increasing the current density led to a random shape of the whisker. The presented results highlight the importance of external conditions on the deposition behavior of sodium which are essential for reservoir-free solid-state sodium batteries.

11:30 AM EN08.11.04
Molten Sodium Penetration Through Solid-State NaSICON Electrolytes Under High Current Ryan C. Hill[1], Amanda Peretti[2], Adam M. Maraschky[2], Leo J. Small[2], Erik D. Spoerke[2] and Yang-Tse Cheng[1]; [1]University of Kentucky, United States; [2]Sandia National Laboratories, United States

High conductivity solid electrolytes, such as NaSICON, are poised to play an increasingly important role in safe, reliable battery-based energy storage, enabling a new class of sodium-based batteries. Coupled demands of high current densities (≥0.1 A cm^{-2}) and low temperature (<200 °C) operation, combined with increased discharge times for long duration storage (>12 h), challenge the limitations of solid electrolytes. Here, we explore the penetration of sodium into NaSICON at 0.1 A cm^{-2} in a symmetric molten sodium cell. Previous studies of β''-alumina proposed that Poiseuille pressure-driven cracking (Mode I) and recombination of ions and electrons within the solid electrolyte (Mode II) can cause metal accumulation within solid electrolytes, but a comprehensive study at high current density is necessary. To understand and differentiate these modes in NaSICON, this work employs unidirectional galvanostatic testing of Na|NaSICON|Na symmetric cells at 0.1 A cm^{-2} over 23 hours at 110 °C. While galvanostatic testing shows a relatively constant, yet increasingly noisy voltage profile, electrochemical impedance spectroscopy (EIS) reveals a significant decrease in cell impedance which can be correlated with significant sodium penetration, as observed in scanning electron microscopy (SEM). Metal accumulation from the stripping-side electrode suggests that Mode II failure may be far more prevalent than previously considered. Further, these findings suggest that total charge transported per unit area (mAh cm^{-2}), as opposed to current density (mA cm^{-2}), may be a more critical parameter when examining solid electrolyte failure. Together, these results provide a better understanding of the limitations of NaSICON solid electrolytes under high current density and can guide the design of coatings to improve electrode-electrolyte interfaces.

This work was done in collaboration with Sandia National Laboratories and was supported through the Energy Storage Program, managed by Dr. Imre Gyuk, within the U.S. Department of Energy's Office of Electricity. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

11:45 AM EN08.11.05
Scalable Manufacturing of Selenide Solid-state Electrolytes for Sodium-ion Batteries Saeed Ahmadi Vaselabadi[1], Katie J. Palmer[2], William Smith[1] and Colin A. Wolden[1]; [1]Colorado School of Mines, United States; [2]Rose-Hulman Institute of Technology, United States

Sodium-ion batteries are garnering enormous attention for large-scale energy storage applications due to their low cost, enhanced sustainability, and decent performance. Moreover, their energy density and innate safety could be further improved by substitution of solid-state superionic conductors for conventional liquid electrolytes. Among the various classes of electrolytes, inorganic Na-based solid-state electrolytes, and specifically ternary chalcogenides and their derivatives are promising candidates that can achieve high ionic conductivity and low mechanical stiffness. Replacement of sulfide with selenide anion can provide larger channel size for ionic transport and lower binding energy between the anionic lattice framework and Na ions, leading to higher ionic conductivity. Conventional synthesis routes of selenides include mechanochemistry and high-temperature solid-state reactions which are energy-intensive and not amenable to scale-up. Herein, we employed solution chemistry through precursor and solvent engineering to design a scalable and cost-efficient solution route for the production of air-stable Na_3SbSe_4. Specifically, we showed a simple pseudo metathesis route toward the production of binary Sb_2Se_3 as a precursor that could further be extended to the formation of ternary Na_3SbSe_4 in two different synthetic routes: alcohol-mediated redox and alkahest amine-thiol approaches.
For Sb_2Se_3 preparation, elemental Se was reduced using $NaBH_4$, a common reducing agent, and further reacted with $SbCl_3$ via metathesis reaction to form Sb_2Se_3 and NaCl as a byproduct in an aqueous solution. Recovered amorphous Sb_2Se_3 was crystalized through mild heat treatment and used as is with no apparent impurities in the electrolyte reactions. In the alcohol-mediated route, the electrolyte was successfully synthesized in ethanol using a similar redox solution coupled with Sb_2Se_3 and NaOH as a basic agent. In the other approach, an amine-thiol solvent mixture is utilized as an alkahest system for the dissolution of elemental Se and Na and further reaction with the binary precursor to obtain Na_3SbSe_4. The electrolyte recovered from the alcohol solution without any post-reaction treatment has remarkable ionic conductivity (0.19 mS cm^{-1}) and low electronic conductivity ($1.6*10^{-6}$ mS cm^{-1}) at room temperature on par with reported performance from other conventional routes. Electrolytes obtained from the amine-thiol route produced a similar performance ($\sigma_{Na+} = 0.26$ mS cm^{-1}) via heat -treatment at 300 °C. These novel solution-phase approaches showcase the diversity and application of wet chemistry in producing selenide-based electrolytes for all-solid-state sodium batteries.

SESSION EN08.12: Solid-State Batteries with Li/Na Metal II

Friday Afternoon, April 14, 2023
Moscone West, Level 2, Room 2008

1:30 PM EN08.12.01
Visualization Li Through Neutron Images in Sulfide-Based All-Solid-State Batteries Hongli Zhu; Northeastern University, United States

Lithium-metal (Li0) anode is considered the holy grail for all-solid-state lithium batteries (ASLMBs) owing to its exceedingly high energy density; in practice, most reported ASLMBs deliver unsatisfactory stability, mainly stemming from the incompatibility between the solid-state electrolyte (SE) and Li0 anode. To stabilize the interface, one strategy is introducing an interlayer between SE and Li0. Ideally, this interlayer should meet high ion conduction and electron insulation to avoid the direct deposition of Li0 at the SE|interlayer interface. Yet, there have been reported the use of mixed ionic-electronic conductors (MIEC), like the silver-carbon composite and graphite, can suppress the dendrite issue successfully. It seems the electron insulation is optional. A deep understanding of MIEC is critical for interlayer design and stable cycling life. Therefore, in our work, we investigated the mechanochemistry and mechano-electrochemistry behavior of a graphite interlayer, a typical MIEC, in the ASLMB by using operando neutron imaging and operando Raman spectroscopy. This work aims to provide insight into the design of the interlayer for the development of high-performance all-solid-state lithium metal batteries.
We believe that the following four highlights of this work will make it attractive to the broad readership of MRS:
1) For the first time, operando neutron imaging and Raman spectroscopy were coupled to investigate the mechanochemical and mechano-electrochemical reaction mechanisms of the interlayer in ASLMBs. Operando neutron imaging was used to effectively visualize the evolution of Li (either Li0 or Li+) during the battery test, and operando Raman spectroscopy was supplementarily used to distinguish the Li behaviors between intercalation and plating, at the MIEC interlayer.
2) The mechanochemistry and mechano- electrochemistry is studied individually step by step to well understand the Li evolution before and after charging, which is critical because the composition in MIEC after the mechanochemical reaction determine the Li evolution pathway in the following mechano-electrochemical reactions.
The MIEC interlayer was first proved with a complex composition but not the pristine pure material after the mechanochemical reaction. Under a high stacking pressure, the graphite interlayer did not remain pure graphite but transformed into a complex Li-graphite interlayer composed of Li0, diluted graphite intercalation compounds, and SE. The subsequent battery performance was highly determined by the chemistry of this Li-graphite interlayer.
3) We proved the lowest overpotential at the Li0 side is the most critical condition for the interlayer. We fundamentally investigated the mechano-electrochemical behavior at the MIEC interlayer. During the battery charging, the Li+ behavior at the interlayer was the result of three competing mechanisms: transport, intercalation, and deposition. Our results indicate the preferential deposition of Li0 is the Li-graphite|SE interface first and then plate at the Li-graphite interlayer, with no intercalation occurring. The lowest nucleation energy at the interface and the preexisting Li-metal filament trigger the Li-plating behavior.
4) We discussed the working mechanism of the interlayer in ASLMBs and proposed a new criterion for the required characters for the interlayer: a lower nucleation overpotential at the Li meal and MIEC interface. The conventional view that the interlayer should be electron insulation is not comprehensive, limiting many alternative materials owning electronic conductivity, i.e. MIEC, to be used as the interlayer.
5) Continuum modeling was conducted to explain the Li behavior in the graphite. The Li extrusion-intercalation under high pressure leads to the formation of the unique Li-graphite interlayer during the mechanochemical step. The MIEC dominates the Li transport during the electrochemical step, which leads to Li plating instead of Li intercalation.

1:45 PM EN08.12.02
Revealing the Hidden Dopant Effect on the Driving Force of Li Conduction and Dendrite Formation Mechanism in Cubic LLZO Solid Electrolytes Feye-Feng Lu and Hong-Kang Tian; National Cheng Kung University, Taiwan

Garnet-type oxide cubic LLZO (c-LLZO) with doping of super-valent cations is a promising solid electrolyte because of the enhanced ionic conductivity of around 10^{-3} S/cm. Different dopants have been proposed, such as Al, Ga, and Ce. However, the ionic conductivity is still limited and is not simply determined by the charge of dopants or the Li vacancy concentrations. The interaction between the Li and dopants and the complicated local environment due to various configurations of Li is still unclear. To comprehensively reveal the dopant effect in c-LLZO, we have investigated the c-LLZO bulk and surfaces with different dopants (Al, Ga, and Ce) via First-principle-based Density Function Theory (DFT) calculations. For screening out the energetic-favorable atomic structures, we have excluded the electrostatically-unfavorable Li configurations. It is found that the dopant atom tends to occupy the empty 24d sites (*tetrahedral*) in c-LLZO and results in three Li vacancies at the nearby 96h sites (*octahedral*) after doping. To further understand the dopant effect on the driving force of Li conduction, we calculated the vacancy formation energy of all the Li atoms as an indication of the Li chemical potential. The Li chemical potential increases and decreases by around 0.05 eV after doping with Ga and Al, respectively. It indicates that the Li atoms are thermodynamically more "mobile" when Ga is introduced, which agrees well with experimental results. Moreover, by calculating the Density of States (DOS) and Bader charge, it appears that Ga attracts more electrons than Al, resulting in a "more positive" environment for Li atoms that enhance Li conduction. Besides, the effect of different dopants on the surface electronic properties has been investigated, and the "trapping electron" tendency is evaluated to connect to the Li dendrite formation. We have also proposed a possible dopants/replacement that may be able to enhance the Li conduction and surpass the Li dendrite formation altogether.

The Impact of Li Surface Heterogeneity and Morphology on Performance in Solid-State Batteries Andrew S. Westover[1], Ritu Sahore[1], Erik Herbert[1,2], Sergiy Kalnaus[1], Robert Sacci[1] and Wan-Yu Tsai[1]; [1]Oak Ridge National Laboratory, United States; [2]Michigan Technological University, United States

Solid-state Li metal batteries have the potential to enable both fast charging and more than a 30% increase in energy density. Two of the most pervasive and limiting challenges in these materials are the interface between the Li metal and the solid electrolyte and the formation of Li filaments that penetrate the solid electrolyte leading to cell shorting. Currently, most efforts to solve these problems are focused on solid electrolytes. Here we present our work investigating the Li side of the equation. This work compares four thin Li sources (<40 µm), three rolled Li from commercial suppliers, and a fourth prepared in-house using thermal evaporation. Using X-ray photoelectron spectroscopy (XPS) and attenuated total internal reflection infrared spectroscopy (ATIR), we determined that the surface layers on these different Li films varied significantly in composition and thickness. Subsequent electrochemical testing of these films in liquid, polymer, and ceramic solid electrolytes, showed that variation in the surface thickness and chemistry significantly impacted the interfacial resistance. Furthermore, an analysis of cell failure due to shorting led to the clear conclusion that in addition to the surface contamination, the Li microstructure also had a significant impact in determining when failure will occur.**Acknowledgments:** Simon Thompson and the DOE EERE Vehicle Technology office Battery Material Research Program for funding supporting this work.

2:45 PM EN08.12.05
Organic-Additive-Derived Cathode Electrolyte Interphase Layer Mitigating Intertwined Chemical and Mechanical Degradation for Sulfide-Based Solid-State Batteries Chanhyun Park[1], Juho Lee[1,2], Sangpyo Lee[1], Yu Jin Han[2], Jinsoo Kim[2] and Sung-Kyun Jung[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Energy Research, Korea (the Republic of)

Keeping both the chemical and physical state of the electrode–electrolyte interface intact is one of the greatest challenges in achieving solid-state batteries (SSBs) with longer cycle life. Herein, we demonstrate the use of organic electrolyte additives in the cathode electrolyte interphase (CEI) layer to mitigate the intertwined chemical and mechanical degradation in sulfide-based SSBs. Lithium difluorobis(oxalato)phosphate (LiDFBOP) and argyrodite (Li_6PS_5Cl) is used as a model system, with the LiDFBOP-derived CEI layer induced by irreversible oxidation above 4.12 V (*vs.* Li^+/Li) during the formation cycle exhibiting dual functions. This CEI layer retards the rate of chemical degradation between the cathode active particles and solid electrolyte at high charging potential and helps maintain intimate physical contact even at a low stack pressure of 0.75 MPa. The improved physical contact enables delivery of a high initial capacity, while chemical stability suppressing the sulfite or sulfate formation has a more dominant effect on the long-term cycle stability. This study presents a new perspective and strategies for designing cathode coating materials for sulfide-based SSBs beyond the typically used inorganic oxide materials.

3:00 PM EN08.12.06
Chemical Vapor Treatment on High Nickel Cathode Towards Improved Battery Performance Rajesh Pathak, Anil Mane and Jeffrey W. Elam; Argonne National Laboratory, United States

One of the recent strategies to improve battery performance is to remove the residual lithium compounds (RLCs) from the cathode surface. Ni-rich cathode materials easily absorb moisture and CO_2 that forms RLCs such as LiOH and Li_2CO_3. Such RLC deteriorates the active material's integrity and reduces the Li-ion diffusion coefficient which leads to poor battery cycling performance. Development of Li_3PO_4 as a robust cathode electrolyte interphase (CEI) is another strategy that can provide a physical barrier between the cathode and liquid electrolyte to prevent a solid-liquid interfacial reaction, prevent intergranular cracking and phase transformation, and enable fast lithium-ion transport and high Young's modulus. We reported chemical vapor treatment on NMC811. The surface impurities such as lithium carbonate (Li_2CO_3) and lithium hydroxide get removed after the reaction with an atomic layer depostion-precursor forming Li_3PO_4, releasing CO_2, CH_4, and O_2. In addition, the strong covalent bonding of the PO^{4-} group contributes to high thermal stability, low charge transfer resistance, and high voltage performance. As a result, CVT on NMC811 showed improved electrochemical performance and better rate capability compared to bare NMC811.
Keywords: chemical vapor treatment, high nickel cathode, cathode electrolyte interphase, longer, and high-rate capability

3:15 PM EN08.12.07
Pair Distribution Function Analysis of Local Motion in Double Paddlewheel $Na_2NH_2BD_4$ Megan Murphy[1], Bernadette Cladek[2], Matthew G. Tucker[2] and Jordi Cabana[1]; [1]University of Illinois at Chicago, United States; [2]Oak Ridge National Laboratory, United States

Global concerns over the need for clean sources of renewable energy have motivated research into next generation battery science. Solid-state batteries can be employed in place of traditional, liquid electrolyte batteries, to increase energy density and safety. Recently, $Na_2NH_2BH_4$ (NNB) has been identified to have an ideal structure, and vacancies needed to be employed as a solid electrolyte in Na-ion batteries. NNB is a defect antiperovskite with double paddlewheel anions, that demonstrates high ionic conductivity following a complex, Na-disordered transitional phase change. Currently, there is poor understanding of the pathways Na moves through, within the structure, that cause the intrinsic, high conductivity seen with NNB.
This study uses in-situ neutron PDF measurements of NNB to elucidate local disorder of the polyanions that promote Na migration due to their free rotation. In depth determination of translational, rotational, and bond disorder within both the polyanions and the local structure is performed. Large-box modeling of the data using reverse Monte Carlo profiling is also used to study this double paddlewheel effect and view snapshots of Na ion pathways within the structure. Through this work, insights into local ion disorder within the solid electrolyte lattice are illuminated and will play a key role in furthering solid-state battery technology.

Development of High-Capacity Anodes Toward Practical All-Solid-State Batteries Employing Sulfide Solid Electrolytes Yoon Seok Jung; Yonsei University, Korea (the Republic of)

Solidification of electrolytes with inorganic superionic conductors is considered to significantly improve the safety of lithium-ion batteries. Moreover, inorganic solid electrolytes (SEs) have the potential of stabilizing high-capacity electrode materials. Currently, Li metal and Si anodes are considered promising to achieve the high energy of all-solid-state batteries. Although it has been revealed that most SEs also suffer from side reactions (reduction) in contact with Li metal anodes, various interfacial engineering has proved to be effective in improving the performance. Specifically, it was shown that an introduction of Ag-C interlayer in Li-free all-solid-state cells enabled reversible cycling of in situ formed Li metal anodes. However, the use of nanoparticles of Ag may act as a hurdle for the practical application. Besides, high-capacity Si anodes have also been investigated for all-solid-state batteries. The SE-free Si anodes demonstrated drastic outperformance over the conventional Si anodes including SEs. This result was indebted to the absence of parasitic side reactions caused by SEs in the anodes. However, the electrochemical performance was obtained under unrealistically high operating pressures.
In this presentation, we report on our recent results of the strategies to develop high-capacity anodes of Si and Li metal for all-solid-state batteries. Specifically, it will be discussed how interlayer engineering for Si anodes enables stable operation at mild operational pressures, which is critical for practical all-solid-state batteries.

11:00 AM *EN08.13.02
Moisture Stability of Sulfide Solid-State Electrolytes Yubin Zhang[1], Fang Hao[1] and Thomas A. Yersak[2]; [1]Optimal Inc., United States; [2]General Motors Global R&D, United States

In this presentation we will detail a comprehensive study on the moisture stability of sulfide solid-state electrolytes in dry room environments. Although sulfide SSEs have many favorable attributes, this class of materials suffers from poor stability with water. Sulfide SSEs react with water to form gaseous H_2S and a variety of solid byproducts like Li_3PO_4 and LiOH, which go on to increase the interfacial impedance of solid-state batteries. Lab-scale research typically utilizes gloveboxes with < 1 ppm water, however, the large-scale manufacturing of Li-ion batteries occurs in -40 °C dewpoint dry rooms with around 126 ppm water. Consequently, the moisture stability of sulfide SSEs must be addressed if the manufacture of solid-state batteries based on sulfide SSEs is to be scaled up. Here, we are the first to characterize the moisture stability of sulfide SSEs according to both H_2S and the degradation of ionic conductivity at different moisture setpoints ranging from -76 °C to -40 °C dewpoint. A variety of different SSE compositions are studied; namely, $(Li_2S)_{75}(P_2S_5)_{25}$, $(Li_2S)_{70}(P_2S_5)_{30}$, $(Li_2O)_7(Li_2S)_{68}(P_2S_5)_{25}$, $(Li_2O)_7(Li_2S)_{63}(P_2S_5)_{30}$, and $(Li_2S)_{75}(P_2S_5)_{25}$ + 20 mol% LiI. We find that moisture stability improves with 75 mol% Li_2S modifier content and the introduction of a Li_2O co-modifier. After a 30 minute exposure in a -40 °C dewpoint dry room environment we found that $(Li_2S)_{75}(P_2S_5)_{25}$ + 20 mol% LiI powder generated 0.1 cc/g H_2S and its ionic conductivity decreased by over 50%. However, when SSE powder was exposed as a slurry in a dodecane carrier the same SSE composition generated 0 cc/g H_2S and its ionic conductivity only dropped by 14%. Our results show that sulfide SSEs have acceptable moisture stability when appropriately processed in a dry room environment.

11:30 AM *EN08.13.03
Li Metal Anodes for All Solid State Batteries—The Role of Unrecoverable Voids Kelsey B. Hatzell; Princeton University, United States

Alkali metal anodes (e.g.; Li) are energy dense alternatives for conventional anode materials (e.g. Graphite). However, Li metal undergoes significant volume change during electrochemical cycling which can lead to catastrophic cell failure due to irreversible dendrite formation and/or delamination. Recently, there have been numerous reports which demonstrate large degrees of voiding at high stripping rates and capacities which can drive discontinuities at the lithium metal-solid electrolyte interface. Therefore, a major challenge is finding operating conditions to suppress void formation during dynamic operation. There has been a lot of work focusing on how stack pressure can be used to recover interfacial properties upon cycling but contradictory reports demonstrate varying degrees of success. In this work, we studied the creep-induced interfacial aspects of Lithium metal and garnet LLZO solid electrolytes that impact the high-capacity stripping/plating (5 mAh/cm^2) of Li. Due to its intrinsic chemical stability against Li metal, LLZO is an excellent model system to evaluate the chemomechanics of Li metal. Via combining imaging, electrochemistry, and advanced pressure monitoring tools we can start to discuss how voids form and potential pathways for mitigation.

12:00 PM EN08.13.04
Enhanced Ionic Conductivity of Protonated Antiperovskite via Tuning on Paddlewheel Effect Chaohong Guan, Yu Yang, Ouyang Runxin, Huirong Jing, Jieqiong Yang and Hong Zhu; Shanghai Jiaotong University, China

The thermodynamically more stable lithium halide hydroxide, Li2OHCl, is experimentally easier to synthesize than Li3OCl. However, the protonated antiperovskite has the low ionic conductivity at room temperature due to the limited reorientation of OH anions. Here, density functional theory calculations were performed to determine the stability, elastic properties and Li diffusions of brominated Li2OHCl (Li2(OH)0.9Br0.1Cl and Li2OHCl0.9Br0.1). The Br substitution weakens the local bonding interactions and promotes the reorientation of OH anions, then increasing the ionic conductivities. Based on this, the reorientation of OH anions is further accelerated by substituting Cl by BH4 anions, and this novel protonated antiperovskite, Li2OHBH4, exhibits the high ionic conductivity of 2.8 mS/cm at room temperature. Our work highlights combining multi-factors, the overall soft lattice and the soft rotation mode of anion groups correlated to Li migrations, can effectively optimize the Li ionic conductivity, which might be a universal descriptor to further screen or design other classes of solid state electrolytes.

12:15 PM EN08.13.05
Heavily Se-Doping Influence on the Structure and Properties of Na_3SbS_4 Selim Halacoglu, Xiaolin Guo, Varun Shreyas, Yang Li, Badri Narayanan and Hui Wang; University of Louisville, United States

Solid-state sodium metal batteries using sulfide-based solid electrolytes (SEs) have attracted considerable attention in terms of their high theoretical specific capacity, safety, and abounding resources. Sodium chalcogenide ionic conductors are great candidates as solid electrolytes in solid-state sodium batteries. Their high ionic conductivity of 10^{-4}~10^{-2} S cm^{-2} at room temperature, and their attractive chemical stability in the air give them great advantages. However, the synthesis method of chalcogenide solid electrolytes is required to be simple, efficient, and with a scalable approach. In this presentation, we will introduce a solvent-free and low-temperature synthesis method for heavily Se-doped Na_3SbS_4 chalcogenides with compositional control and doping contents. Se-doping in Na_3SbS_4 results in a substantial change of Sb-S bonding in Raman spectra, and enhanced ionic conductivity at room temperature. Furthermore, the electrochemical stability of heavily Se-doped Na_3SbS_4 is also demonstrated in solid-state Na||FeS_2 battery within the voltage window of 1.0-2.7 V. This technique is promoting the practical applications of chalcogenide SEs in solid-state batteries.

Understanding Molecular Design for a Stable Lithium Metal Electrolyte Interface Zhenan Bao; Stanford University, United States

Lithium (Li)-metal batteries are attractive due to their high energy density. However, the drastic reactivity of Li metal limits its battery performance due to the formation of a naturally heterogeneous solid-electrolyte interphase (SEI) on the surface. In this talk, I will discuss understanding of molecular design concepts for electrolyte solvents and artificial SEIs to enable stable cycling of Li metal batteries.

11:00 AM *EN09.01.02
Ionic Peltier Effects and Thermal Conductivities of Battery Electrolytes: Studying Factors Controlling Heat and Ion Transport Zhe Cheng, Arghya Patra, Patrick Kwon, Jarom Sederholm, Beniamin Zahiri, David Cahill and Paul V. Braun; University of Illinois at Urbana Champaign, United States

Quantitative measurements of the thermal conductivity and ionic Peltier effect of common organic battery electrolytes can provide new insights into ion solvation and the barriers encountered by ions moving through battery electrolytes as well as how the flow of heat is controlled by the composition of battery electrolytes. Measurement of ionic Peltier effects required developing an ultrasensitive temperature difference metrology approach which we show has with a temperature difference resolution up to ±4 μK. This approach enables the probing of mK-level temperature responses of ionic Peltier effect, even in the presence of parasitic Joule heating using symmetric coin cell with Li metal or $Li_{0.75}CoO_2$ electrodes. We observed large ionic Peltier coefficients (up to 408 mV) in liquid electrolytes which are only weakly dependent on temperature but strongly dependent on ion concentration and electrolyte chemistry. The large ionic Peltier coefficient is related to the enthalpy barrier for ion hopping, providing insights to the mechanism of ion transport. While ions carry some heat, the majority of heat carried by a battery electrolyte is carried by phonons, and how this varies with battery electrolyte composition can be provided via measurements of thermal conductivity performed in conjunction with electrochemical and Peltier effect studies.

11:30 AM *EN09.01.03
Design Wide-Temperature and Fast Charging Battery Electrolyte Zheng Chen; University of California, San Diego, United States

Improving the wide temperature operation of rechargeable batteries is vital to the operation of electronics in extreme environments, where systems capable of higher energy, high-rate discharge and long cycling are in short supply. In this talk, we will show electrolyte designs to achieve high-energy density and stable cycling performance in wide temperature range. We will first demonstrate the holistic design of dual-ion batteries, which circumvent the sluggish ion desolvation process found in typical lithium-ion batteries during discharge. These batteries are enabled by a novel ester electrolyte, which simultaneously provided high electrochemical stability and ionic conductivity at low temperature. The dual-ion cells, when compared to industry-type graphite || $LiCoO_2$

full-cells demonstrated an 11 times increased capacity retention at -60 °C for a 10 C discharge rate, indicative of the superior kinetics of the “dual-ion” storage mechanism. More importantly, the fundamental understanding developed for dual-ion cells was then extended to search for other high-capacity, high-rate electrodes, which leads to further improved energy density and stability for both high and extremely low temperatures, demonstrated by rechargeable Li metal batteries using both high-Ni oxide and sulfur cathodes.

SESSION EN09.02: Electrolytes and Interphases II

1:30 PM *EN09.02.01
Synergistic Impact of (Multi)-Functional Electrolyte Components on Interfacial Chemistry and Phenomena in Lithium-Based Batteries Isidora Cekic-Laskovic; Forschungszentrum Juelich, Germany

Although considered as the systems of choice for many portable, mobile and stationary applications, existing battery technologies still face diverse challenges limited by the fundamental behavior of the active and inactive materials used. More precisely, electrolyte and its *ad hoc* interfacial chemistry are often identified as the main limiting and critical factors. Being the component bridging while interacting with all other active and inactive battery parts, electrolyte plays a key role in terms of design and control of the redox processes as well as regarding material interactions, performance, long-term stability, cost and safety of a battery. Due to the complexity of interactions taking place, the advancement of existing and development of novel electrolyte formulations is non-trivial and often leads to situations where specific targeted properties can only be improved at the expense of other relevant ones. For liquid electrolytes, a special focus is set on implementation of innovative, commercially available as well as newly synthesized ultrapure electrolyte components in optimum amount, particularly (multi)- functional additives/co-solvents/salt additives as effective approach towards desired advancements of electrolyte formulations. Although different classes of molecules have found their application in advancing the electrolyte performance, many questions regarding their role and effectiveness still remain unanswered. Comprehensive characterization by means of selected complementary electrochemical, analytical and structural methods enables establishment of structure-property-performance relationships that provide understanding and elucidation of main operation and failure mechanisms taking place comprising electrolyte│electrode interfaces and interphases.
This talk is an invitation to a journey through the design, development and extensive study highlighting synergy between targeted (multi)-functional electrolyte components advancing resulting formulations and lithium-based battery chemistries for targeted application(s).

2:00 PM EN09.02.02
Understanding Organic Components of Solid Electrolyte Interphase on the Lithium Metal Anode Jeffrey Lopez; Northwestern University, United States

Lithium ion batteries have become the dominant form of energy storage used in consumer electronics and, recently, electric vehicles. However, high costs have prevented widespread deployment of lithium ion batteries for applications other than portable electronics, and the safety issues associated with liquid organic electrolytes remain to be addressed. In order to enable the greater utilization of electric vehicles, allow for grid scale energy storage, and meet the demands of new electronic applications, new materials for high energy density batteries must be developed. High capacity electrode materials like lithium metal have the potential to facilitate these technologies, but lithium metal electrodes are presently limited by significant side reactions, poor quality deposition, and the potential to form hazardous dendrites. Therefore, it is important to develop a clear understanding of the surface reactivity and growth behavior of the lithium metal at the interface with the electrolyte in order to enable stable long-term cycling.

The products that form as a result of electrolyte decomposition reactions at the electrode interface are known to be extremely important in determining the final cell performance, yet characterizing the organic components of the solid electrolyte interphase (SEI) proves to be challenging with typical techniques. ATR-FTIR is a powerful method for characterizing organic species, but typical materials such as Ge, Si, and ZnSe react with lithium metal during deposition. In this talk, the development of a diamond based in situ ATR-FTIR cell will be discussed and its application to the characterization of organosulfur and fluorinated electrolytes will be discussed. Furthermore, SEI formation with respect to electrochemical potential and time will be described. With this understanding we provide new insights into the formation and chemical nature of SEI components that promote stable cycling of lithium metal electrodes.

2:15 PM EN09.02.03
High Entropy Electrolytes for High-rate Cycling Lithium Metal Batteries Sang Cheol Kim and Yi Cui; Stanford University, United States

Following the demonstration of the Li || TiS_2 battery chemistry in the 1970’s, the Li metal battery has been sought-after for its high energy density, but the reactivity of metallic Li has diverted research efforts to lithium-ion battery chemistries. Recently, the lithium metal battery has been reinvigorated as a viable battery chemistry with the aid of host electrodes, artificial interphases, solid electrolytes, and particularly liquid electrolyte engineering. Through molecular design and the use of highly fluorinated co-solvents, weakly solvating electrolytes with anion-rich Li^+ solvation structures have achieved superior interfacial stability and cycle life. However, despite their high stability, these weakly solvating electrolytes form ion clusters and possess compromised ionic conductivity, implying a trade-off in tuning solvation strength. While many of these strategies have relied on tuning the enthalpic interactions between Li^+ and its surrounding species, entropy as a design knob has largely gone unnoticed for liquid electrolytes. As one of the two descriptors for solvation thermodynamics, which dictates solvation structures and bulk electrolyte properties, entropy can be expected to be an important design parameter.
In this work, we introduce the concept of high entropy electrolytes (HEEs) that achieve improved ionic conductivity while maintaining excellent electrochemical stability. We carefully design experiments to minimize differences in solvation enthalpy by selecting structurally similar solvents, but increase entropy by deploying a large number of solvents. We find that increasing the molecular diversity and concomitantly the mixing entropy of weakly solvating electrolytes can reduce ion clustering while retaining anion-rich solvation structure, which we confirmed through synchrotron-based X-ray scattering and molecular dynamics simulations. Less clustered high entropy electrolyte with higher Li^+ diffusivity exhibit a 2-fold increase in ionic conductivity, enabling stable cycling at high current densities up to 2C (6.2 mA cm^{-2}) in anode-free NMC-Cu pouch cells. We substantiate the generality of the concept by verifying performance improvement in three disparate electrolyte systems. This work highlights a large unexplored design space of HEEs that can improve electrolyte properties for practical lithium metal batteries.

2:30 PM EN09.02.04

Interphase Design by Localized Super-Concentrated Electrolyte for High-Voltage and High-Power Lithium Metal Batteries Youngmin Ko[1], Michael A. Baird[2] and Brett A. Helms[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Batteries used in electric aircraft must deliver high-power on take-off and landing, providing in stride the ability to recharge at high voltage to make full use of the cathode capacity. Impedance rise associated with electrode–electrolyte interphases remains problematic with conventional electrolytes, resulting in unacceptable power fade. This is exacerbated when recharging cells at high voltage, which is where interphase generation remains poorly controlled. To address these issues, electrolyte design for high-voltage and high-power batteries should emphasize control over the interphase growth contributing to the impedance rise during charge. To this end, we will describe our recent efforts to alter the activity of various electrolyte components at electrode–electrolyte interfaces, granting access to exquisite control over interphase chemistry. Key to our success is the exploitation of ion clustering in locally super-concentrated electrolytes (LSCEs), which produces aggregates with intrinsically different reactivity than solvated species and from which new interphasial chemistries may be produced in-situ. We find in top-performing compositions that interphase stability is most affected by the activity of ethereal solvents in the formulations, particularly at high voltage, and that it is possible to design additives that suppress solvent activity even up to 4.5 V vs. Li/Li$^+$. Li/NMC811 cells cycled with de-novo designed LSCEs maintain 70% of their initial discharge capacity after 1000 cycles with 4 C discharge rate at charge cut-off voltage of 4.35 V, outperforming most reported electrolytes for Li metal batteries. Furthermore, by taking an informatics approach to interphase characterization, we reveal fundamental patterns of reactivity that inform future selection criteria for advanced battery electrolytes.

2:45 PM DISCUSSION TIME

3:00 PM BREAK

3:30 PM EN09.02.07
Self-assembled Protective Layer by Symmetric Ionic Liquid for Long-cycling Lithium-Metal Batteries Jinha Jang[1], Jae-Sun Shin[1], Sunghyun Ko[1], Hyunchang Park[1], Woo-Jin Song[2], Chan Beum Park[1] and Jiheong Kang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Chungnam National University, Korea (the Democratic People's Republic of)

A lithium (Li) metal is expected to be an ideal anode material for energy-dense storage devices due to its intrinsic high capacities (3,860 mAh g^{-1}). However, its practical implementation was hindered by a dendritic Li deposition, which exacerbates the cycling efficiency of Li-metal batteries. Herein, we present a novel ionic liquid (IL) electrolyte additive modified by symmetric alkyl chains to control the Li deposition. This symmetric design generated a self-assembled lithiophobic shielding layer on Li protuberances, leading to the smooth deposition of Li. In addition, our symmetric ILs stabilized electrode interphase with higher inorganic components by anchoring counter anions near the Li-metal electrode. As a result, our symmetric IL enabled reliable cycling of Li-$LiNi_{0.6}Co_{0.2}Mn_{0.2}O_2$ cell (three times excessed Li) with high Coulombic efficiency (~99.8%) over 250 cycles. In this presentation, I will discuss a new design protocol for IL-based electrolytes and provides a promising way to high efficiency, stable-cycling Li-metal batteries.

3:45 PM EN09.02.08
Polymerizable Zwitterionic Molecules and Their Synergism with Commercial Electrolyte Additives for Better Lithium-Ion Batteries Niguse A. Sahalie and Jonas Mindemark; Uppsala University, Sweden

Lithium-ion batteries (LiBs) have achieved great success in the electronics market and are now the industry standard for grid energy storage and the electrification of transportation. The practical achievable capacity of LiBs (for conventional electrodes like layered oxide cathodes and graphite anodes, among others) is rapidly approaching, and there is a strong market demand to develop new batteries with higher energy and power densities than those currently offered by commercially viable materials. To enable electric vehicles with an expanded range of operation, long battery lives, and quick "refueling," such next-generation LiBs must meet certain practical requirements. These include higher energy densities and fast charge-discharge rates, which hinge on new high-voltage, high-capacity, and high-power cathode materials and on stable electrolytes with higher ionic conductivities [1] [2].
In addition, current LiBs with layered oxide cathode material use expensive Cobalt which compromises the green profile and limits the cost reduction needed for their widespread uptake. In this regard, several cathode materials have been developed without cobalt. The LNMO ($LiNi_{0.5}Mn_{1.5}O_4$) cathode is one of the best candidates due to its high voltage and high-power capability features. However, most of the electrolytes undergo oxidative decomposition at such high voltages, preventing their real application. Assembling LNMO with high-capacity anode materials such as Silicon-graphite makes the matter worse, as such anode materials have their own serious issues that cause early cell failure. Different electrolyte formulations using different additives have been tested to mitigate such challenges on both the cathode and anode sides. However, problems with these electrolytes and additives arise from decreasing the conductivity of the electrolyte, the continuous formation of a resistive passivation layer, cost, safety, or sometimes even several of these happening to a single electrolyte.
Herein, in the BetterLiBs project, we have used thermally stable and polymerizable zwitterionic monomers (ZIMONS) blended with commercially available liquid electrolyte additives to improve the performance of high-voltage LiBs in full cell configurations. Zwitterionic monomers have equal numbers of positive and negatively charged functional groups, which can help to easily decouple the two charges of the electrolyte salt. As a result, the ionic conductivity of the electrolyte could be improved. The polymerizable features of ZIMONS are very important in forming a good passivation layer at the electrode/electrolyte interface, leading to stable cycling of the high-voltage cathode material. Therefore, the use of SEI-forming commercial additives together with ZIMONS could be an important approach for stable cycling of full cell LiBs.
The synthesis, screening, and optimization of more than a dozen ZIMONS for their electrochemical performance and their synergism with commercial additives are components of the BetterLiBs initiative. Performing cyclic voltammetry analysis in half cells, synthesized ZIMONS additives are already demonstrating a good stabilizing effect of LP57 electrolytes at both reduction and oxidation voltages. Cycling tests with different ZIMONS additives also show significant improvements in capacity and coulombic efficiency in the high-voltage LNMO configured with a silicon-graphite anode. This improvement in cycling stability is in good agreement with the decrease in cell resistance, which was studied by Intermittent Current Interruption (ICI) measurements. Other cell configurations with graphite anode materials are also being studied.

Non-Flammable Liquid Electrolytes for Lithium-Ion Batteries—Performance and Interfaces Florian Gebert; Uppsala University, Sweden

Battery safety, particularly regarding flammability, has come under increasing public and scientific scrutiny as lithium-ion batteries become ubiquitous in everyday life. Much effort is being put into formulating nonflammable electrolytes for lithium-ion batteries (LIBs), as electrolytes are usually the most flammable components of a typical battery cell. Due to the ongoing technical challenges surrounding solid electrolytes, non-flammable liquid electrolytes are an attractive medium-term solution. Two classes of compounds are generally used as nonflammable LIB solvents: fluorinated compounds and organophosphates. Fluorinated solvents generally have good electrochemical properties, but are expensive and come with well-known environmental and toxicity issues. On the other hand, phosphates are cheap, generally nontoxic and more environmentally benign, but currently unviable as they suffer from very poor electrochemical performance.

In this work, the advantages and disadvantages of these two types of non-flammable electrolyte classes are presented using representative compounds from each: difluoromethyl acetate, methyl 2,2,2-trifluoroethyl carbonate and triethyl phosphate. As a starting point, core performance measures such as cycling data, rate capability and cell resistance were collected. The compositions of the passivating films formed by these electrolytes on commercial LIB electrodes were characterized using electron microscopy and photoelectron spectroscopy, and their correlation with electrochemical properties are discussed. Issues specific to each class are explored in detail, such as fluorine dissociation and solvent-cointercalation.

Fast-Charging Limitations of Advanced Electrolytes for Lithium Metal Batteries Yuelang Chen; Stanford University, United States

Lithium metal batteries (LMBs) are being actively developed to meet the high-energy-density demand for electric vehicles (EVs). Fast charging is an important requirement for EV applications. While improving lithium metal Coulombic efficiency (CE) has been a focus for LMB electrolyte design, their performance under high current densities is less explored. Here, we evaluate the moderate-to-high-rate cycling stability of three recently developed advanced electrolytes, all of which are weakly solvating electrolytes with anion-derived solid electrolyte interfaces. All three electrolytes showed soft shorting behavior above various threshold current densities. Based on extensive characterizations, we propose a mechanism by which slow ion transport was the main factor that led to poor cycling stability due to concentration polarization, poor Li morphology, and closely packed residual solid electrolyte interphase (rSEI) structure. This work confirms the importance of fast ion transport for LMBs under moderate to fast charging conditions. Therefore, for electrolyte designs, improving CE must be accompanied by efficient ion transport in order to provide a viable solution to practical LMBs.

Designing Gel Polymer Electrolyte With Synergetic Properties For Rechargeable Magnesium Batteries Liping Wang[1], Zhenyou Li[1], Zhirong Zhao-Karger[1] and Maximilian Fichtner[1,2]; [1]Helmholtz institute Ulm, Germany; [2]KIT, Germany

The rapid market expansion for consumer electronics and electric vehicles urges the development of electrochemical energy storage devices with high energy density, low cost and high safety. In this regard, the development of multivalent-ion batteries is one feasible solution for such goals. Rechargeable magnesium batteries (RMBs) have emerged as attractive candidates among post-lithium batteries because of the particular features of metallic magnesium (Mg) as a metal anode. However, the realization of practical Mg batteries remains challenging and exploration of suitable electrolyte is imperatively necessary.
Recently developed non-corrosive magnesium tetrakis (hexafluoroisopropyloxy) borate $Mg[B(hfip)_4]_2$ (hfip = $OC(H)(CF_3)_2$) electrolyte exhibits outstanding electrochemical performance and good chemical compatibility in Mg-based systems.[1] The discharge/charge chemistry with this electrolyte has been demonstrated with the sulfur (S) cathode, which is considered as one of the most promising cathode materials, due to its high theoretical capacity (1675 mA h g^{-1}), low toxicity and high abundance. Nevertheless, Mg−S batteries with a liquid electrolyte are still facing critical issues correlated with the dissolution of the sulfur species during the discharging/charging process, so-called polysulfide shuttle effect, which leads to self-discharge and capacity fading.
The development of gel polymer electrolytes (GPEs) may provide a promising solution to alleviate the above issues. A GPE designed by trapping solvent molecules in a polymerized gel network may limit the dissolution and diffusion of soluble electrode materials. For Mg−S batteries, the utility of GPE could be an efficient approach to inhibit the diffusion of the polysulfide. Moreover, GPEs have some additional advantages, including improved safety (less internal short-circuit and less electrolyte leakage) and mechanical durability for electrochemical devices.
Herein, a novel magnesium tetrakis(hexafluoroisopropyloxy)borate ($Mg[B(hfip)_4]_2$)-based non-corrosive gel polymer electrolyte has been developed by an *in situ* polymerization method.[2] Polytetrahydrofuran (PTHF) is chosen as backbone to build the GPE, denoted as $Mg[B(hfip)_4]_2$-PTHF-GPE. This gel polymer electrolyte exhibits unprecedented properties in terms of high ionic conductivity (10^{-3} S cm^{-1}), reversible Mg plating/stripping capability (Coulombic efficiency ~99%, 1000 cycles) and low electrochemical overpotential. Moreover, the gel polymer electrolyte shows good compatibility with sulfur cathode. The stable open circuit potential of the Mg−S cells using $Mg[B(hfip)_4]_2$-PTHF-GPE demonstrates that the GPE can largely suppress the self-discharge of the cell. Furthermore, this GPE can be simply prepared from a liquid electrolyte and easily integrated into devices, which opens a new avenue for the development of magnesium batteries.

5:00 PM EN09.03.04
A New Class of Intermediate Temperature 1D Anionic Coordination Polymer Proton Electrolytes Albert Epshteyn[1], Brian L. Chaloux[1], Michelle D. Johannes[1], James Ridenour[2], Elias Pomeroy[2] and William Maza[1]; [1]U.S. Naval Research Laboratory, United States; [2]NRC Postdoctoral Associate, US Naval Research Laboratory, United States

Borosulfates and borophosphates are two examples of a recently-discovered new class of intermediate temperature (150 °C-400 °C) solid acid electrolytes that exhibit a 1D anionic coordination polymer structure. We have shown that the borosulfates exhibit extremely high proton conductivities under low humidity environments, while the borophosphates are much more thermally stable, but require significant humidity for proton conduction. We have made significant advances in developing and scaling-up solvothermal synthesis methodologies that can be varied to produce a different solid- state borosulfate and borophosphate structures (verified by SCXRD and PXRD) and exert significant crystallite size control. Examples will be presented of approaches for improving proton conductivities in these materials that include varying mixtures of cations, cation and carrier doping, as well as process optimizations to produce higher quality sintered monoliths.

Enhancing Anionic Exchange Membrane Robustness in Vanadium Redox Flow Systems via Multication Side Chain Addition Michael Lee, Sydney Stansberry, Bradley Swan and Chris J. Cornelius; Iowa State University, United States

A more robust energy storage system is needed to provide for increasing energy demands in the world. One highly robust and scalable technology is the vanadium redox flow battery (VRB). Limitations of the standard VRB cell membrane, Nafion, are many. Nafion is too expensive to scale up in numerous cell stacks. A highly acidic and oxidative environment has been shown to foul and degrade the polymer membrane. Also, a primary concern is the vanadium ion crossover through percolation channels which leads to self-discharge reducing the coulombic efficiency. Cheaper and more durable cell membranes have been investigated. Diels-Alder poly(phenylene) (DAPP) materials are very mechanically robust membranes that have the potential to be a cheaper alternative. DAPP with pendant methyl groups on the phenyl rings can be brominated and substituted with quaternary ammonium to create benzyltrimethylammonium groups (QDAPP). Specifically, these cationic groups have been shown to possess lower vanadium ion permeability than Nafion because of the electrostatic repulsion described by the Donna effect. However, higher water uptake at higher IEC values creates swelling and limits crossover prevention. Additionally, ex-situ degradation studies have shown that membranes are prone to oxidation earlier than Nafion. To combat oxidation of the membrane more sterically hindered polymers will be investigated in this work. By incorporating previously reported quaternary ammonium multication side chains with different alkyl spacer lengths it is thought that membrane durability of DAPP will be increased. Additionally, further improvement of the ion conductivity on the previously reported carbonate counter ion form is hoped to be gained with additional cationic groups. Planned studies for this project include cell diffusional studies to determine crossover, ex-situ degradation studies, in-plane and through-plane conductivity measurements, mechanical strength determination, toughness determination, and VRB performance factors such as coulombic and voltage efficiency as well as open current voltage decay and charge discharge behavior. Future studies involve blending QDAPP with varying degrees of IEC.

5:00 PM EN09.03.06
Synthesis and Organic Electrochemical Transistor Characteristics of IDT-based p-type Conjugated Polymers Sang Young Jeong[1], Jung Woo Moon[2], Soonyong Lee[1], Jeong Ho Cho[2] and Han Young Woo[1]; [1]Korea University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

Following the success of organic field effect transistors (OFET), organic electrochemical transistors (OECT), which also belong to a family of 3-terminal devices, was emerged with tremendous attention. Unlike OFET devices' area, the active layer of the electrochemical transistors is volumetric, rendering OECT devices with low operation voltage, high sensitivity and aqueous operability render it with potential as bioelectronics. Based on these contents, we have developed a new vertical OECTs (*v*-OECT) device architecture with polymer active layer vertically sandwiched in between drain and source electrode using two p-type donor-acceptor copolymers.
Two p-type polymers, namely PIDTPEG-BT and PIDTC16-BT was synthesized by applying IDT-BT backbone which had been succeeded in OFET and OPV application. Since the channel length of the vertical transistors is short in contrast to the lateral transistors, *v*-OECTs have the higher conductivity, due to the geometrical advantage of the *v*-OECTs, together with a higher degree of integration. By thermal annealing of active layer films, a different trend in transconductance was observed: increase in PIDTC16-BT and decrease in PIDTC16-BT, which is ascribed to the polymer orientation difference caused by thermal annealing evidenced by grazing-incidence wide-angle x-ray scattering (GIWAXS) measurements. These results provide guidance for further development of material design and device fabrication methods.

5:00 PM EN09.03.07
Cross-linking Chemistry on Solid-State Polymer Electrolytes in Lithium-ion battery Jia-Hua Chen[1], Wen-ya Lee[1], Ru-Jong Jeng[2] and Nae-Lih Wu[2]; [1]National Taipei University of Technology, Taiwan; [2]National Taiwan University, Taiwan

Solid polymer electrolytes, which improve the safety issues in commercial liquid electrolytes, are considered a promising solution for the next generation lithium-ion batteries. Even though sufficient ion conduction capability of solid-state electrolytes has been achieved to date, challenges for electrochemical stability and mechanical properties still remain. Controlling crosslinking chemistry is a promising way to achieve electrochemically stable electrolytes. In this work, we compare various crosslinking chemistry of thermally and photo-induced in-situ polymerization in Polyethylene glycol diacrylate(PEGDA)/butyl acrylate(BA)/succinonitrile(SN) electrolyte, including thiol-ene Michael addition and alkene–azide chemistry. Through comprehensive analysis and clarifying the effect of each crosslinking mechanism on the chemical structures of solid-state polymer electrolytes, we have found that appropriate polymerization is one of the key factors for stable battery performance. The work shows that the manipulation of crosslinking chemistry provides a efficient way to improve the electrochemical performance in lithium-ion batteries.

5:00 PM EN09.03.08
Strategic Usage of Redox Active Material and Sacrificial Zinc Electrode for Spontaneous Hydrogen Evolution Reaction Taeyup Jeong, Chandan C. Gudal, Byeongkyu Kim, Jae Wook Lee, Yong Seok Kim and Chan-Hwa Chung; Sungkyunkwan University, Korea (the Republic of)

Hydrogen is the cleanest and highly efficient source of energy than any of the fossil fuels. The carbon footprint left behind by the incineration of the fossil fuels are causing drastic changes in greenhouse gases which is leading unpredictable global warming and harsh climate changes endangering everyone and everything on the earth. Currently, the generation of hydrogen fuels at industrial level is by conversion of fossil fuel like natural gas, coal, and petroleum, which gives carbon footprint as by-product, here the generated hydrogen is referred as "grey hydrogen." When carbon cauterization process is used in the previous process, the hydrogen is referred as "blue hydrogen." Finally, there is "green hydrogen," which uses renewable energy to create hydrogen without emitting any greenhouse gases. Green hydrogen production does not produce greenhouse gases, which makes it advantageous as a clean energy source independent of the issue caused by global warming. However, the world's green hydrogen production is still significantly smaller than the general hydrogen production that emits greenhouse gases, so it is not attracting attention. Accordingly, research is being actively conducted to produce hydrogen by decomposing water through electrical energy using renewable energy power.
A general electrochemical water decomposition process is performed in a cell that separates both electrodes, anode, and a cathode, using a polymer electrolyte membrane, where oxygen evolution reaction (OER) and a hydrogen evolution reaction (HER) occur, respectively. At this time, a precious metal catalyst is used for an OER, which causes cost problems and has the disadvantage of a relatively slow reaction compared to HER.
In this study, to compensate these shortcomings, the redox reaction using redox active materials (RAM) were used instead of OER. These redox active materials can lower costs by utilizing different methods with metals, organic compounds, and polymers. They can also make up for issues with current oxygen generation process through reversible redox reactions. In addition, beyond compensation for the shortcomings, it was designed so that the HER could occur voluntarily through the low negative potential of the RAM. Since the standard reduction potential of the hydrogen production reaction in a general acid solution (pH 0) is 0 V (vs. SHE), the cell is driven using a cation exchange membrane (CEM) and a bipolar membrane (BPM) according to the pH condition of the redox active substance (RAM) used in the anode. The system can be driven by a spontaneous reaction if the standard reduction potential of the RAM utilized has a negative potential lower than the standard reduction potential of the hydrogen synthesis reaction. After the HER, the oxidation of the zinc sacrificial electrode has a standard reduction potential of -1.23 V (vs. SHE at pH 14) can voluntarily reduce RAM and generate power. As a result, it is possible to voluntarily produce power and green hydrogen by consuming only the Zn sacrificial electrode.
In this study, the spontaneous hydrogen production reaction process was studied using Zn and RAMs. Electricity is generated both during the reduction of the redox active material with Zn and during the reaction that produces hydrogen from the reduced redox active material. This is a benefit of eco-friendly

systems, green hydrogen production, and power generation, and it is implied that it is more energy-efficient than conventional electrochemical systems' hydrogen generation.

5:00 PM EN09.03.09

Phosphine Modulation for Enhanced CO_2 Capture: Quantum Mechanics Predictions of New Materials Charles B. Musgrave[1], Aleksandrs Prokofjevs[2] and Bill Goddard[1]; [1]California Institute of Technology, United States; [2]North Carolina Agricultural and Technical State University, United States

It is imperative to develop efficient CO_2 capture and activation technologies to combat the rising levels of deleterious greenhouse gases in the atmosphere. Using Quantum Mechanics methods (Density Functional Theory), we propose and evaluate several metal-free and metal-containing phosphines that provide strong CO_2 binding under ambient conditions. Depending on the electron donating capacity of the phosphine and the ability of the P-bound ligands to hydrogen bond to the CO_2, we find that the CO_2 binding can be as strong and downhill as -18.6 kcal/mol, which should be quite adequate for ambient conditions. We explore some modifications of the phosphine to improve CO_2 binding, and we elucidate which chemical descriptors correlate directly with CO_2 binding energy. Specifically, we find that charge accumulation on the CO_2 unit of the CO_2-bound adduct has the greatest correlation with CO_2 binding affinity. Finally, we probe the mechanism for CO_2 reduction to CO and methanol in aqueous media.

5:00 PM EN09.03.10

Combining Quinone-Based Cathodes with Non-Corrosive $Mg[B(hfip)_4]_2$-Electrolyte for Magnesium Batteries Sibylle Riedel, Björn Schmidt, Zhirong Zhao-Karger and Maximilian Fichtner; Karlsruhe Institute of Technology, Germany

The increasing demand for high-energy storage systems has led to intensive research into sustainable and low-cost battery technologies. A rechargeable magnesium battery system is considered as a promising approach. Magnesium (Mg) is an abundant element on Earth. Mg metal has a high theoretical capacity and can potentially be used as a metal anode.[1,2] As Mg^{2+} ion is a divalent ion and has a small ionic radius (72 pm vs. 76 pm for Li-ion), it shows strong electrostatic interactions with the classical oxide cathode materials which leads to slow kinetics and strong polarization and consequently poor electrochemical reversibility. Contrariwise, organic materials have more flexible structures, which provide energetically more favorable ion-migration pathways enabling faster ionic diffusion kinetics and improved electrochemical performance.[3] Another key factor that influences the battery performance is the electrolyte. Most of the Mg electrolytes contain chloride, which cause corrosion to the metallic cell components and can generate parasitic reactions in the cells leading to a short cycle-life of the batteries. The $Mg[B(hfip)_4]_2$ electrolyte shows important features for practical applications in terms of the high Mg deposition efficiency, high stability and non-corrosive properties.[4]

Therefore, the combination of organic redox-active cathode materials with $Mg[B(hfip)_4]_2$ electrolytes could be a promising approach for the development of Mg battery technology. On the other hand, the high solubility in electrolyte solutions and low electrical conductivity represent as the main challenges for the use of organic electrode materials. Polymerization and incorporation of a conductive carbon to prepare the organic composites are the common approaches to overcome these problems. However, a low carbon content and homogeneous dispersion of the polymer are required to avoid sacrificing energy density at the cell level and to achieve good electrochemical performance.

One approach we present here is a so-called *in situ* polymerization. The conductive carbon was directly introduced into the polymerization reaction and the polymer chains could grow within the carbon structures. Since this method ensures good contact between polymer and carbon, the carbon content can be reduced. Furthermore, this method is beneficial for preventing the dissolution of the active material in the electrolyte.

The poly-anthraquinone cathode-based Mg batteries in combination with the $Mg[B(hfip)_4]_2$/tetraglyme electrolytes showed a cycling performance for 1200 cycles with a capacity retention of 55%, and coulombic efficiency of 99%.

5:00 PM EN09.03.11

Encapsulation of Pt-based clusters in ZIF-8: Insights from First-Principles Simulations Poonam .[1], Kathrin Kollmannsberger[1], Edoardo Mosconi[2], Roland A. Fischer[1], Alessio Gagliardi[1] and Waldemar Kaiser[2]; [1]Technical University of Munich, Germany; [2]CNR-SCITEC, Italy

The reactivity of a Pt-based nanoparticle catalysts greatly depends on their size and detailed atomic structure. Recently, atom-precise nanoparticles have been generated from molecular ligand-stabilized clusters via encapsulation within a metal organic frameworks.[1,2] In this work, we aim to rationalize the underlying encapsulation mechanism of the ligand-stabilized Pt-based using first-principles simulations. Density functional theory (DFT) calculations and ab initio molecular dynamics simulations (AIMD) were carried out to understand the interaction of the Pt-based clusters with the MOF (ZIF-8) precursors in solution. By DFT, we determine the interaction of ZIF-8 precursors with the CO ligands of the Pt-clusters and reveal chemically distinct sites of all the considered clusters which favor the attraction of Zn^{2+} ions in solution. AIMD simulations of Pt-based clusters in an explicit methanol solvent model shed light on the competition between attraction of Zn^{2+} and the Pt-clusters and desorption of Zn^{2+} by solvation with methanol molecules, revealing an importance of bridging CO ligands to create a Zn-rich environment around the Pt-cluster and to guarantee the successful encapsulation.

5:00 PM EN09.03.13

Effect of Charged Polymers on Electrochemical Performance of Lithium Sulfur Batteries Using Ionic Liquids Jeong Mu Heo, Chae Yoon Lee and Keun Hyung Lee; Inha University, Korea (the Republic of)

Recently a lot of research efforts have been devoted to lithium-sulfur batteries as one of the next-generation energy storage devices because of their exceptional theoretical capacities (1675 mAh/g or 2600 mWh/g). However, migration of soluble polysulfide species through the liquid electrolyte from a positive electrode to a negative electrode, also known as the shuttle effect, often limits the performance of lithium-sulfur batteries, resulting in irreversible cycles and capacity degradation that hinder practical applications. In this study, we employed a positively charged polymer as a binder material that can attract negatively charged polysulfide species generated during the discharge cycle of the device operation to inhibit the shuttle effect and achieve stable electrochemical operation. In the case of using a conventional non-charged polymer binder, the movement and dissolution of ionic polysulfide cannot be prevented and thus stable long-term operation of the lithium-sulfur batteries was not attainable. To further improve the performance of the lithium-sulfur batteries, ionic liquids with low donor numbers compared to organic solvents were utilized to suppress the dissolution of polysulfide. Ionic liquids can also provide other outstanding characteristics such as non-flammability, negligible vapor pressure, high chemical and thermal stability, and wide electrochemical window desirable for developing environmentally stable next generation energy storage devices. The resulting lithium-sulfur batteries using the charged polymer binder and ionic liquids showed superior initial discharge capacity (> 1000 mAh/g) and capacitance retention (> 60% of its initial discharge capacity after 100 charge/discharge cycles).

5:00 PM EN09.03.14
Fast Capture and Stabilize Li-Ions via Physicochemical Dual Effects for Ultra-Stable Self-Supporting Li Metal Anode Xuzi Zhang and Ge Li; University of Alberta, Canada

Lithium (Li) metal is regarded as one of the most promising anode candidates for next-generation batteries, ascribed to its extremely high specific capacity and low redox potential. However, its application is still hindered by the uncontrolled growth of dendritic Li and huge volume fluctuation during cycles. To address these issues, flexible and self-supporting 3D interlaced N-doped carbon nanofibers (NCNF) coated with uniformly distributed 2D ultrathin $NiCo_2S_4$ nanosheets (denoted as CNCS) were designed to eliminate the intrinsic hotspots for Li deposition. Physicochemical dual effects of CNCS come from a limited surface Li diffusivity with a higher Li affinity, leading to uniform Li nucleation and a less random accumulation of Li, as proven by ab initio molecular dynamics simulations. Due to the unique structure, exchange current density is reduced significantly and metallic Li is further contained within the interspace between the NCNF and $NiCo_2S_4$ nanosheets, preventing the formation of dendritic Li. The symmetric cell with Li/CNCS composite anode exhibits a long-running lifespan for almost 1200h with an exceptionally low and stable overpotential under 1 mA cm^{-2}/1 mAh cm^{-2}. The full cell coupled with $LiFePO_4$ cathode at a low N/P ratio of 2.45 shows typical voltage profiles but enhanced performance than that of $LiFePO_4$ coupling with bare Li anode.

5:00 PM EN09.03.15
Solution Casting and Thermal Annealing of Nafion Ionomer for Fuel cell Applications Sylwia A. Sulikowski; Iowa State University of Science and Technology, United States

Fuel cells are a promising technology to produce and develop clean and sustainable energy. Nafion has been regarded as the current benchmark for polymer electrolyte membranes (PEM). The structure of Nafion plays an important role in its unique properties such as excellent thermal stability and high proton conductivity. However, researchers are seeking alternative ways to further develop PEM membranes that can have higher conductivities at higher temperatures and low relative humidity. Pre-treatments are often employed to improve the properties of PEMs by altering their microstructure. In this study, Nafion membranes were created by solution casting in Dimethylformamide (DMF) at 90 ^{O}C followed by annealing at different temperatures (140 ^{O}C and 170 ^{O}C) and rapid cooling. The microstructure of the membranes was investigated using transmission SAXS and was found that the annealing had no effect on the through-plane orientation of the Nafion membranes. However, the water uptake studies showed that when compared to unannealed membranes, membranes annealed at 170 ^{O}C had a reduced water uptake of 65.3%. This can be attributed to large structural modifications with enhanced crosslinking formed due to annealing. Heat treatment at higher temperature induces free volume in the membrane and make the molecular segments more organized. Hence it becomes harder for the water molecules to diffuse into the hydrophobic zone and water uptake and swelling decreases with increase in the annealing temperature. It is postulated that optimizing the annealing and cooling rates would induce more compact chain packing structure which would significantly impact the diffusion and proton conductivity.

SESSION EN09.04: Polymer Binders, Electrolytes and Separators I
Session Chairs: Qi Dong and Minah Lee

Cellulose Based High Performance Ion Conductors and Energy Devices Liangbing Hu[1] and Qi Dong[2]; [1]University of Maryland, United States; [2]North Carolina State University, United States

I will discuss a general design strategy for achieving one-dimensional (1D), high-performance polymer solid-state ion conductors through molecular channel engineering, which we demonstrate via Cu^{2+}-coordination of cellulose nanofibrils. The cellulose nanofibrils by themselves are not ionic conductive; however, by opening the molecular channels between the cellulose chains through Cu^{2+} coordination we are able to achieve a Li-ion conductivity. This improved conductivity is enabled by a unique Li^+ hopping mechanism that is decoupled from the polymer segmental motion. Also benefitted from such decoupling, the cellulose-based ion conductor demonstrates multiple advantages, including a high transference number (0.78 vs. 0.2–0.5 in other polymers[2]), low activation energy (0.19 eV), and a wide electrochemical stability window (4.5 V) that accommodate both Li metal anode and high-voltage cathodes. Furthermore, we demonstrate this 1D ion conductor not only as a thin, high-conductivity solid-state electrolyte but also as an effective ion-conducting additive for the solid cathode, providing continuous ion transport pathways with a low percolation threshold, which allowed us to utilize the thickest $LiFePO_4$ solid-state cathode ever reported for high energy density (Nature, Oct 22).

9:00 AM EN09.04.02
Effect of Separator Structure on Lithium Metal Batteries Hao Jia, Chao Zeng, Ji-Guang Zhang and Wu Xu; Pacific Northwest National Laboratory, United States

Rechargeable lithium (Li) metal batteries with conventional intercalation cathodes have been considered as the next-generation energy storage systems for transportation and smart grid applications because of their high theoretical energy densities. Although great successes have been reported in recent years, the two major issues related to Li metal anode, dendrite growth and low Coulombic efficiency, still hinder the practical applications of Li metal batteries. Among the components in Li metal batteries, the separator has been considered to be a relatively inert component and its effect on performances of Li metal batteries has seldom been investigated. In our recent studies, we found that the microstructure of the separator has a significant influence over the Li deposition behavior, and consequently, the cycling performance of Li metal batteries. In this talk, the effects of separator structure on Li metal anode and Li metal batteries will be discussed with the combination of experimental and simulation results.

9:15 AM EN09.04.03
Ultra-strong Nanocomposite Separators for Beyond Li-ion Batteries Ahmet Emre, Emine S. Turali-Emre, Ji-Young Kim and Nicholas Kotov; University of Michigan, United States

Multifunctional nanocomposites have been widely investigated to address challenges in next-generation energy storage applications, specifically beyond lithium-ion battery chemistries. The high theoretical specific energy density (2600Wh/kg) and high specific capacity (1675mA/g), along with the natural abundance and low toxicity of sulfur, have been attracting significant attention for the development of an alternative battery system to replace traditional lithium-ion batteries, which suffer from safety and capacity/energy density limitations. However, challenges such as polysulfide dissolution and shuttling prevent the mass commercialization of metal sulfur batteries. Inspired by biological ion transport mechanisms, we show a practical yet comprehensive approach to developing high-performance metal sulfur batteries. Aramid nanofiber (ANF) based composite ion transport membranes prevent dendrite formation and confine polysulfides on the cathode side. ANF composite battery separators provide diverse and opposing properties, including high mechanical properties, high ionic conductivity, and high thermal/chemical stability. Fabrication of such biocompatible, affordable, flexible, structural, and high energy density batteries is quite crucial in powering next-generation electronics, including but not limited to portable, wearable, implantable devices and all kinds of electric vehicles.

9:30 AM EN09.04.04
Polymer Electrolyte with Interconnected MOF Particles along Organic Nanofibers for Solid State Battery Gihwan Kim, Jeung Ku Kang and Jiheong Kang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The demand for lithium-ion batteries is greatly increasing due to the increase in demand for electronic devices including electric vehicles. Lithium-ion batteries mainly use liquid electrolytes including organic solvents, but liquid electrolytes have critical safety problems such as leakage, fire, and explosion. In order to solve this critical problem, it is essential to develop an all-solid-state battery using a solid-state electrolyte. Polymer-based solid-state electrolyte, which is a type of solid-state electrolyte, has excellent characteristics of flexibility, safety, and good interfacial contact with electrodes, but has problems with low ionic conductivity. Herein, we synthesized an enhanced ionic conductivity polymer electrolyte with interconnected Metal-Organic Frameworks(MOFs) along the organic fibers network. It provides a pathway for lithium ions to move rapidly through the interconnected MOFs pore channels. Furthermore, anions sieving effect through controlled pore size to suppress other side reactions and evenly electrodeposition of lithium ions to inhibit lithium metal dendrite formation. As a result, when the all-solid-state battery cell was operated, a lower overpotential was observed than when the conventional polyethylene oxide(PEO) polymer electrolyte was used, and stability was maintained over 1000 hours.

9:45 AM EN09.04.05
A Solvent-Anchored Non-Flammable Electrolyte (SAFE) Zhuojun Huang, Jiancheng Lai, Yi Cui and Zhenan Bao; Stanford University, United States

Lithium-based batteries are ubiquitous in modern-day energy supply systems. However, the volatile and flammable nature of the electrolytes remains a safety challenge. Solvent-free polymer electrolytes are developed to address this, yet they do not have sufficient ionic conductivity for room temperature battery operation. Although gel electrolytes address the ionic conductivity limitation, solvent molecules in them are not anchored and thus the safety feature is compromised. Here, we report that anchoring solvent molecules with salt and polymer can increase the ionic conductivity of the electrolyte without undermining its non-flammability. We name it **S**olvent-**A**nchored non-**F**lammable **E**lectrolyte (SAFE). Specifically, we developed a liquid-state polymer electrolyte composed of LiFSI salts, Dimethoxyethane (DME) solvents, and polysiloxane tethered with ion solvating moieties. DME coordinates with both the salt and the polymer, while together with the salt, they synergistically plasticize the polymer to increase the ionic conductivity. The resulting non-flammable polymer electrolyte has a room temperature ionic conductivity of 1.6 mS/cm and a wide operation window of 25 – 100°C. Benefiting from its liquid nature, SAFE is ready to use without further electrode engineering. When pairing with commercially available electrodes, SAFE demonstrated 400 cycles at room temperature without obvious capacity decay. Different from polymer or gel electrolyte, SAFE addresses the apparent contradiction between non-flammability and ionic conductivity and shows a promising design pathway for next generation safe and manufacturable electrolytes.

10:00 AM *EN09.04.06
Advanced Binder Designs for Emerging Lithium-Ion Batteries Jang Wook Choi; Seoul National University, Korea (the Republic of)

Polymeric binders have turned out to be critical for various properties of many emerging rechargeable batteries. I will summarize my group's efforts in the past ten years in developing uncommon binder designs for silicon and silicon-carbon composite anodes. They are based on supramolecular chemistries involving hydrogen bonding, ion-dipole interaction, molecular machines, etc., with the aim of activating self-healing ability. In the last part of my talk, I will also introduce recent efforts along developing advanced binder designs targeting high-nickel layered cathodes and 5-V class spinel cathodes. Albeit being contained in a small content, all the given cases coherently indicate the critical nature of binders and further opportunities for research.

10:30 AM BREAK

11:00 AM EN09.04.07
Development of a $LiMnFePO_4$ / $Li_4Ti_5O_{12}$ 2Ah Pouch Cell—An Example of the Effective Integration of New Materials Jean-Christophe Daigle[1], Martin Dontigny[1], Alexis Perea[1], Yuichiro Asakawa[2] and Karim Zaghib[3]; [1]Hydro-Québec, Canada; [2]Murata Manufacturing Co., Ltd., Japan; [3]Concordia University, Canada

One of the most promising approaches for limiting climate change is the use of alternative and greener sources of energy (wind, solar, etc.). The electricity generated from these sources fluctuates, however, and a storage solution is needed. The advent of energy storage for wind farms, solar plants, etc., requires a new generation of batteries. It is therefore imperative that a battery with high energy density, a longer life cycle and improved safety be developed.

In this paper, we describe our efforts to develop a safe and long-life cycle $LiMnFePO_4$ (LMFP)/$Li_4Ti_5O_{12}$ (LTO) 2Ah pouch cell. One of the major challenges faced in this pursuit was gas evolution during cycling. Various side reactions with active materials resulted in the generation of gas during cycling. To circumvent this, we implemented several mitigation strategies. To combat electrolyte degradation (1.0 M $LiPF_6$ in carbonate solvents) due to Mn^{2+} dissolution in LMFP, we integrated a new class of polymer as a binder in the cathode preparation, which effectively decreased the degradation during cycling. This polymer also has high voltage stability.[1] At the battery's negative electrode, we developed a new carbon coating method on LTO that minimizes electrolyte degradation and optimizes high C-rate preformances.[2] Although relatively simple, this technology made the pouch cells safer. This unique approach is versatile and can be implemented in pouch cells with any type of chemistry when gas scavenging is required. The 2Ah pouch cells did not experience any inflation during extensive cycling and aging. Cells cycled more then 500 cycles at 45^{o}C with a rate of 1C – 1C before reaching 80% retention capacity.[3]

Self-Healing Binders for Silicon-Based Electrodes Tamara Patranika, Guiomar Hernandez and Kristina Edstrom; Uppsala University, Sweden

Silicon is a promising active material for anodes in lithium-ion batteries owing to its high theoretical capacity (3579 mAh/g)[1]. However, it is well known that the compound contends with large volume changes during cycling, creating cracks in the material and therefore limiting the lifetime and capacity of the cell. To cope with these volume changes, this project aims to develop self-healing binders to improve the cycling stability of lithium-ion batteries.

Both hydrogen bonds and dynamic covalent bonds have been previously used to modify binder systems to get self-healing properties through reversible cross-linking with the binder in the electrode. While the hydrogen bonds have eminent reversibility, the dynamic covalent bonds provide high mechanical stability[2–4]. Both of which is desirable properties to implement in the polymeric binder system.

Specifically, the focus of this work has been on synthesizing borate ester bonds[5], as well as using other commercially available borate groups and coupling them with the polymer binder poly(vinyl alcohol) (PVA). Furthermore, in order to gain more knowledge of the different self-heling groups, other binder systems containing hydrogen bonds have been used for comparison.

The electrochemical performance of the cells with and without the self-healing groups has been investigated, showing an increased capacity with the latter. Besides the performance, understanding the self-healing mechanism of these binders and possible degradation reactions from these functionalities is key to further improve the system and cycle life. Therefore, the effect of the self-heling functional groups on the formation of the solid electrolyte interphase layer has been investigated with X-ray photoelectron spectroscopy. Furthermore, the electrochemical stability of the functional groups was investigated in order to compare the impact of the hydrogen bonding and dynamic covalent bonding, especially at the low operating voltages of silicon.

Recyclable Lithium Battery with Reversible Polymer Binder Chen Fang and Gao Liu; Lawrence Berkeley National Laboratory, United States

The fast growth of lithium battery market generates a strong demand for battery recycling technologies, which are critical for the sustainability of battery industry due to the limited accessibility of battery materials and the high environmental impacts of battery material mining and manufacturing. However, conventional lithium batteries are not specifically designed as recyclable units, where the commonly incorporated polymer binders, the glue-like substances that serve to maintain the mechanical integrity of battery electrode composites, on the other hand, pose significant challenge for electrode disassembly. We developed the Quick-Release Binder technology for construction of recyclable lithium batteries. This novel binder is a two-component polymer system consisting of polyacrylic acid (PAA) and polyethylenimine (PEI) that are compatible with green production and recycling, namely via water processing methods. PAA and PEI can be readily crosslinked via strong carboxy-amino ionic interaction, which is reversible depending on the pH condition of the aqueous solution. Therefore, PAA and PEI can form robust polymer binder system for battery electrode fabrication and can also be readily dissociated under alkaline condition for convenient release and thus recycling of the battery electrode materials. We have demonstrated that the Quick-Release Binder system can be applied to lithium-sulfur battery and lithium-ion battery, illustrating the universal applicability of the Quick-Release Binder system for lithium-based rechargeable batteries.

Mixed Conducting Polymer Binders for Rechargeable Batteries Pratyusha Das[1], Rodrigo Elizalde-Segovia[2], Billal Zayat[2], Charlene Z. Salamat[1], Gordon Pace[1], Yunfei Wang[3], Xiaodan Gu[3], Bruce S. Dunn[1], Sarah Tolbert[1,1], Sri Narayan[2], Barry C. Thompson[2] and Rachel A. Segalman[1]; [1]University of California, United States; [2]University of Southern California, United States; [3]The University of Southern Mississippi, United States

Conducting polymers exhibiting mixed electronic and ionic conductivity serve as excellent candidates for electrode binders due to an extension of functionality beyond simple mechanical binding. Here we present our recent work and ongoing developments in the area of mixed conductive cathode binders for Lithium-Ion Batteries (LIBs). In this regard, we have focused on electron-rich 3,4-propylenedioxythiophene-based polymers (PProDOTs), well-known to be stable in their electrochemically doped states. We have shown that dihexyl-substituted PProDOTs (PProDOT-Hx_2) display a substantial increase in electronic conductivity and a more modest increase in ionic conductivity upon electrochemical doping. This behavior has been attributed to their open and partly disordered morphology, facilitating enhanced ion transport compared to the densely packed semi-crystalline poly(3-hexylthiophene) (P3HT). As a result, we observed an improvement in the long-term stability and rate-capability with NCA cathodes relative to PVDF binder. To maximize mixed conduction, further enhancement in ionic conductivity was obtained via structural modification of the PProDOTs to incorporate oligoether side chains ((Hex:OE) PProDOTs). This aligned well with the increasing disorder and electrolyte uptake with increase in oligoether content in the polymers. Additionally, to bestow enhanced mechanical properties to the otherwise brittle conjugated polymer binders, we studied the impact of random incorporation of conjugation break spacers (CBS) to the PProDOT-Hx_2 backbone to induce deformability and ductility (PProDOT-CBS). We notice that solvent-induced swelling in the battery electrolyte results in significant enhancement in mechanical properties, reflected in the long-term cycling studies of these polymers. Our current efforts are focused on augmenting the intrinsic ionic conductivity of these PProDOT-based cathode binders. To this end, we have targeted the attachment of ionic liquid side chains such as imidazolium (Im^+) to the conjugated PProDOT backbone. We expect to gain increased cation mobility, especially Li^+ ion mobility in the resulting PProDOT-Im polymers, thereby gaining application in LIBs and emerging solid-state batteries.

Free Energy Sampling to Understand the Effect of Local Ion Coordination in Polymer Electrolytes on Transport Properties Siddharth Sundararaman, Fabrice Roncoroni, Ana Sanz-Matias and David Prendergast; Lawrence Berkeley National Lab, United States

In order to understand the success of polyethylene oxide (PEO) for lithium-ion batteries and explore possible better alternatives for salt-polymer mixtures, we study various ions at different concentrations in poly(ether-acetal) electrolytes [P(nEO-mMO), where EO is ethoxyl and MO is methoxyl]. Free-energy sampling, using metadynamics with tailored interaction potentials, elucidates the various coordination environments of ions and the energetic pathways for ion transport in these systems. Using cleverly chosen collective variables, we gain insight into: (1) the competition between cation-anion pairing and coordination by the different polymers at various concentrations, (2) the relative stabilities of single- vs. multi-chain coordination environments and (3) the impact of multi-chain coordination on the glass transition temperature and associated ion transport. We also use advanced data-mining approaches to classify the diverse set of configuration environments buried in these simulations, gaining a deeper understanding of local coordination environments that might easily have been missed with manual inspection. Armed with this insight we suggest strategies for electrolyte design to improve ion transport in battery applications.

1:45 PM EN09.05.02
Looking Beyond "Segmental Motions": A Deeper Understanding of Ion Transport in Polymer Electrolytes Through a Focus on Ion Coordination Jonas Mindemark; Uppsala University, Sweden

The traditional description of ion transport in solvent-free polymer electrolytes puts an emphasis on how the movement of ions is coupled to the polymer chain dynamics. While this is certainly correct, it neither gives a precise description of the actual mechanism of ion transfer, nor fully encompasses all the different nuances of this process that have been revealed in recent years. Since the typical ion transport process can be imagined as taking place through successive ligand exchanges within the coordination shell of a polymer-coordinated cation, it makes sense to use the coordination as a basis for the mechanistic description. It also makes sense that the coordination chemistry has a major influence on the ion transport characteristics. However, investigating this requires both a diverse set of polymer host materials with variations in coordination properties, and methods to investigate the coordination properties. Recently introduced and functionally diverse host materials, such as carbonyl-coordinating polyesters and polycarbonates, together with newly developed methods to quantify the ion coordination strength, have enabled us to demonstrate a clear link between the strength of ion coordination and the cation transference number of the system, leading to faster cation conduction in weakly coordinating systems. This is relatively straightforward to rationalize in low-salt systems, where ion clustering is minimal, but the effect also seems to be extended to high-salt systems. Through MD simulations, comparisons between the polyether PEO and the polyester PCL reveal differences in ion transport mechanisms related to coordination strength and salt clustering, which ultimately results in high cation transference numbers, thus bringing even further nuance to the mechanisms of ion transport in solvent-free polymer matrices.

High Transport Numbers in Solid Polymer Electrolytes Through Novel Lithium Salts Lorena García Maestre, Lixin Qiao, Eduardo Sanchez, Uxue Oteo, María Martínez-Ibañez, Heng Zhang and Michel Armand; CIC EnergiGUNE, Spain

It is well known the increasing demand for energy storage devices in our society. Lithium-ion batteries (LIBs) have been widely investigated over the years, although Li metal (Li^0) batteries (LMBs) are considered now a real alternative due to their lowest electrochemical potential (-3.04V vs. standard hydrogen electrode, SHE) and extremely high theoretical specific capacity (3860 mAh g^{-1}) of the Li^0 electrode.[1] In that field, solid electrolytes present advantages over liquid electrolytes due to their continuous lithium dendrite growth and concerns of flammability. More concretely, solid polymer electrolytes (SPEs) are considered now one alternative to liquid electrolytes due to their cost-effectiveness, high flexibility, ease of processing and safety, being LiTFSI/PEO, the most employed system up to now.[2] LiTFSI/PEO system possesses a very good physical and chemical stability and a very flexible sulfonamide anion center which decrease the crystallinity of the polymer matrix while the ionic conductivity is enhanced. However, although it is nowadays the most widely employed system in SPEs, it stills presents very low Li-ion conductivities (Li-ion transference number; T_{Li^+}, ca. 0.2), poor Li electrode compatibility and poor electrochemical stability against the Al current collector.[3]

The anion chemistry of lithium salts plays an important role in the determination of physicochemical and electrochemical performance of SPEs, affecting the cyclability of SSLMBs. Herein, in this work, we present three novel salt anions with the aim of decreasing the anion mobility and thus, promoting Li-ion conductivity. On the one hand, lithium(difluoromethanesulfonyl)(trifluoromethanesulfonyl)imide (LiDFTFSI), in which replacing one fluorine atom of the -CF_3 moiety by one proton (which will form H-bonds into the anionic structure of the lithium salt) will result in a higher Li-ion conductivity at a low expense of the total ionic conductivity.[4] On the other hand, we present a new *N*-ethyl-*N*-methyl functionalized sulfonimide-based lithium salt (LiTFEMSI), in which one -CF_3 groups has been replaced by a donor character group leading to a high chemical and electrochemical stability and an enhanced T_{Li^+}.[5] Benzene-based lithium salts (LiBTFSI) have been also reported which are based in the π-π stacking interaction between the pair of benzene-based anions leading to a highly selective Li-ion conductive PEs.[6]

Initiated Chemical Vapor Deposition of Anion-Conducting Polymeric Electrolytes for Macroscale All Solid-State 3D Ag–Zn Batteries Hunter Ford, Brian L. Chaloux, Joel B. Miller, Christopher Klug, Youngchan Kim, Battogtokh Jugdersuren, Jeffrey Long, Ryan DeBlock, Michelle D. Johannes, Debra R. Rolison and Megan Sassin; U.S. Naval Research Laboratory, United States

Combining two opposing battery metrics—high energy density **and** power density—in a minimal footprint requires moving away from the ubiquitous, two-century-old 2D planar or jelly-roll battery configurations to a three-dimensional, all solid-state battery (3D SSB). Microscale Li-ion 3D SSBs reported in the literature experimentally confirm the theoretically predicted energy and power enhancements of the 3D SSB configuration.[1] However, lithium-ion batteries pose several challenges including low thermal (cathode and anode) and electrical conductivities (cathode) that restrict them to microscale battery applications, as well as the strategic nature of the active materials. We posit that the demonstrated enhancements of 3D Li-ion SSBs can be extended to the macroscale with a minimal geometric footprint by swapping Li-ion active materials for non-strategic metallic active electrode materials (e.g., Ag and Zn). Three-dimensionally wired, NRL-patented zinc metal sponges serve as anode and scaffold for an interpenetrating, nonperiodic, macroscale 3D SSB.[2]

The remaining roadblock to a macroscale 3D SSB is the incorporation of a submicron-thick solid-state polymeric electrolyte/separator. Initiated chemical vapor deposition (*i*CVD) offers an ideal non-line-of-sight method to generate conformal polymer films onto (and into) complex 3D architectures. For Ag–Zn batteries, we prepare coatings of poly(dimethylaminomethylstyrene) ("pDMAMS") on both planar and complex 3D electrode architectures via *i*CVD. After deposition, the pDMAMS coatings are rendered anion conducting using vapor-phase methylation to introduce quaternary ammonium moieties, followed by solution phase incorporation of the desired anion species (e.g., OH^-, Br^-, or HCO_3^-). Characterization methods, including ATR-IR spectroscopy, X-ray photoelectron spectroscopy, and solid-state NMR spectroscopy compare the structure of the pDMAMS film before and after methylation to bulk, solution-polymerized counterparts, while atomic force microscopy and redox-probe cyclic voltammetry confirm the film is conformal and pinhole-free. Methylated pDMAMS films have an ionic conductivity of ~10^{-6} S cm^{-1} under hydrated conditions. Lastly, we probe the ability of the polymer film to support desirable Ag–Zn redox chemistry in half- and full-cell configurations. Experimental results are compared to molecular dynamics simulations of pDMAMS as a function of anion and film H_2O content.

3:00 PM EN09.05.05
Discerning the Effects of Solid Polymer Electrolyte Properties on Lithium Electrodissolution and Electrodeposition William R. Fullerton and Christopher Y. Li; Drexel University, United States

Solid polymer electrolytes (SPEs) are regarded as a promising solution to enable high energy density lithium metal batteries. While they provide a safer, non-flammable alternative to liquid electrolytes, they still suffer from low ionic conductivity and significant interfacial resistance at the electrode-electrolyte interface. During the electrodissolution process, the accumulation of vacancies can lead to void formation at the lithium-solid electrolyte interface and eventual contact loss between the electrolyte and electrode. This contact loss can increase impedance and induce high local current density upon subsequent plating, and result in dendrite propagation and accelerated impedance growth with cycling. We hypothesize that these processes are strongly dependent on SPE transport properties including ionic conductivity and transference number as well as on mechanical properties such as modulus, toughness and elasticity. To test this hypothesis, we design a series of SPEs which utilize a macromolecular crosslinker to yield a comb-chain network molecular architecture. The comb-chain architecture allows for the design of SPEs with a broad range of mechanical properties through the widely tunable network mesh size and crosslinking density. By modulating molecular structure and chemistry, we can optimize the balance between the aforementioned properties, while elucidating how these properties affect the underlying mechanism of electrodissolution and electrodeposition.

3:15 PM EN09.05.06
Li Deposition Mechanism: A Perspective Gained By Combining Imaging with Theoretical Analysis Tao Gao; The University of Utah, United States

The morphology of the Li deposit governs the performance of lithium metal anode to a large extent. Previous studies have reported many different Li deposit morphologies: hemi-sphere, granular, columnar, whisker (needle-like), Eden cluster, mossy (bush-like), and dendrite (tree-like). To address the challenge of fast-charging LIBs and LMBs, managing Li deposit morphology during battery charging is critical.Nonetheless, the formation mechanism of different Li deposit morphologies remains less studied.
To control the morphology, achieve highly reversible and compact Li deposition and prevent internal short-circuit, significant progresses have been made in engineering electrolyte compositions,SEI chemistry and substrate structures. These efforts have lead to high CE Li deposition/striping (up to 99.5%) at current densities below 1 mA cm^{-2}. To further enhance the performance of Li metal anode, fundamental understanding of the nucleation and growth of Li is necessary. In particular, these questions need to be answered:1) How do deposits develop into different morphologies and how does the morphology correlate with CE and the tendency of internal-short? 2) What governs current heterogeneity and how does it correlate with CE and the risk of internal short-circuit? Understanding these questions will provide valuable insights to guide the rational design of electrolyte and substrates for high-capacity and reversible Li metal anode (> 5 mAh cm^{-2}, > 1000 cycles), high-energy LIB capable of ultra-fast charging (>5 C), and enhanced safety for both technologies.
In this work, we reveal the mechanism of Li deposition on Si and Cu substrates by combing electron imaging, electrochemical tests with theoretical analysis. Specifically, we are interested in these questions: 1) Under what conditions will Li plating happen? 2) Once initiated, how does Li nucleate and grow? 3) How do various factors (particularly current, substrate and temperature) regulate the morphology of the deposited Li? 4) How does the morphology affect the deposition/stripping reversibility?

3:30 PM EN09.05.07
A Salt-Philic Solvent-Phobic (SP2) Interfacial Coating Design for Lithium Metal Electrodes Zhuojun Huang, Jiancheng Lai, Yi Cui and Zhenan Bao; Stanford University, United States

A key challenge to enable lithium (Li) metal batteries as next-generation energy storage devices is to stabilize the interface between Li metal and the electrolyte. A promising strategy is to promote the formation of a salt-derived solid electrolyte interphase (SEI), which has been found more robust and stable than a solvent-derived SEI. Here, we report a Salt-Philic Solvent-Phobic (SP2) polymer coating design concept for Li metal electrode that selectively transports salt over solvent and thus promotes salt-derived SEI formation. This SP2 coating approach resulted in enhanced cycling performance in several types of solvents, such as ether, carbonate, and fluorinated ether and achieved ~400 cycle life (2.5 mAh cm-2, 80% capacity retention) in 50 µm Li|NMC batteries.
My talk will cover the materials design principles for SP2 polymers and characterizations on its unique salt-over-solvent transport property.

3:45 PM EN09.05.08
Overcoming Kinetic Limitations in $LiFePO_4$ Cathodes Using an Electrostatically-Stabilized Polymer Complex Binder Gordon Pace, My Linh Le, Raphaële Clément and Rachel A. Segalman; University of California, Santa Barbara, United States

Polymer binders add critically important structural stability to all lithium ion battery cathodes, but industry standard binders, such as polyvinylidene fluoride (PVDF), are insulating to ions and electrons and therefore are detrimental to the overall charge transport kinetics. We demonstrate electrochemically stable conjugated polymer complexes that enable superior rate performance in $LiFePO_4$ (LFP) cathodes, more than doubling the rate at which the cell can be discharged while maintaining usable capacity, when compared to its PVDF counterpart. While traditional conjugated (conducting) polymer binders enhance conductivity, implementation is limited by electrochemical stability, processability, and solubility. By using electrostatics to stabilize a blend of a charged conjugated polymer with an oppositely charged polyelectrolyte, we form high solids loading, viscous solutions which dramatically improve processability. Further, the ionic crosslinks between the oppositely charged polymers prevent dissolution in the electrolytes, enabling a drop-in alternative to PVDF that dramatically reduces overpotential and increases high-rate performance.

Revisiting the Microstructures of Localized High Concentration Electrolyte Bin Li; Idaho National Laboratory, United States

Liquid electrolytes in batteries are typically treated as macroscopically homogeneous ionic transport media, despite having complex chemical composition and atomistic solvation structures, thus leaving a knowledge gap of microstructural characteristics. A promising electrolyte system design has recently been developed with the title of a localized high-concentration electrolyte (LHCE). These electrolytes are a summation of three components – a charge-carrying salt, a solvent that solvates the salt, and a diluent that is highly immiscible with the salt. This creates the perception of a high-concentration electrolyte (HCE) with high anion-cation interactions that supports a salt-derived, stable solid-electrolyte interphase, while an LHCE improves bulk electrolyte properties, such as ionic conductivity and viscosity, when compared to an HCE. Much trial by error design of this LHCE concept has been supported by simulations to confirm ionic interactions, cycling data to confirm cell stability, and post-mortem analysis to provide evidence of mechanisms. However, a systematic design to extend the capabilities of LHCEs is still to be desired. Here, we analyzed a specific LHCE mixture with the use of a ternary phase diagram to dictate the best viable mixture to extend the localization of solvation structures while maintaining viable cell-level capabilities. It was seen that the electrolyte mixture has complex mechanisms from individual ion solvation up to the solution network scale, both of which are dictated by the interactions between the three electrolyte components. With the support of both experimental and computational analysis of different electrolyte features, we have begun a methodology of formulating the most ideal LHCE mixtures for improving the cyclability of high-capacity battery chemistries.

SESSION EN09.06: Organic Active Materials
Session Chairs: Jeffrey Lopez and Jodie Lutkenhaus
Thursday Morning, April 13, 2023
Moscone West, Level 2, Room 2009

8:30 AM *EN09.06.01
Imagining Circular Organic Batteries Jodie Lutkenhaus; Texas A&M University, United States

Metals are essential ingredients in today's Li-ion batteries (LIBs), but their continued use presents economic, ethical, and environmental challenges. Projected shortages of cobalt and nickel in the coming decades may cause increased prices, and the global supply chain of these metals, lithium included, is highly localized. The last few years have brought attention to the harsh conditions of and use of child labor in the extraction of some these materials, adding social and ethical concerns. Compounded with the increasing demand for LIBs brought by the expanding electric vehicle market and rapid digitalization of society, there is an imminent need to address these issues. Society must now begin to consider the implications of a LIB's full life cycle, including the carbon footprint, the economic and environmental costs, and material access. These challenges motivate the case for degradable or recyclable batteries sourced from earth-abundant materials whose life cycle bears minimal impact on the environment. This talk imagines how polymers might contribute to the future circular battery economy. We focus first upon our work on radical-contaning polymer batteries, which offers a metal-free battery platform. These concepts are then translated to degradable metal-free organic batteries comprised of redox-active synthetic polypeptide cathodes and anodes. Specifically, the cathode polypeptide was decorated with nitroxide radicals, and the anode polypeptide was decorated with viologen groups. With the addition of an acid, the battery degraded on command, yielding amino acids and other byproducts. Although degradation offers a means to deconstruct batteries, recycling still remains a challenge. This talk closes with current and ongiong recyling approaches for polymer-based batteries and their future prospects. Taken together, polymeric materials offer a path toward the local sourcing, manufacturing, and recycling of batteries to democratize energy storage in global economies.

9:00 AM EN09.06.02
Organic Redox Mediators as Multifunctional Mobile Catalysts for Ambient Air Operational Lithium–air Batteries Sunghyun Ko[1], Yiseul Yoo[2], Jinkwan Choi[2], Hee-Dae Lim[2], Chan Beum Park[1] and Minah Lee[2]; [1]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [2]Korea Institute of Science and Technology (KIST), Korea (the Republic of)

Li-air batteries (LABs) have received considerable attention as a potential alternative to conventional lithium-ion batteries due to their exceptional energy density (~3,500 Wh/kg) enabled by the reversible conversion reaction between O_2 and Li_2O_2. However, current development of ambient air operational LABs is hindered by formation of insulating Li_2CO_3 during discharge under CO_2-containing atmosphere. Herein, we provide several p-type redox-active organic molecules that can decompose Li_2O_2 as a new class of redox mediators (RM) for Li_2CO_3 decomposition. Through systematic investigation, we successfully demonstrated that the selected RMs possessing a higher redox potential than 3.7 V (vs. Li/Li^+) can oxidize Li_2CO_3 with significantly lowered overpotential. The in situ gas analysis further supports the reaction mechanism of RM-catalyzed Li_2CO_3 decomposition. Moreover, we firstly report the suppression of highly reactive singlet oxygen ($^1O_2$) generation during RM-catalyzed Li_2CO_3 decomposition. We further showed the enhanced cycle life of RM-containing LABs under air-like atmosphere, confirming the compatibility of employing RMs under practical operating conditions. Collectively, our results provide new possibilities for designing multifunctional catalysts to promote the decomposition of major discharge products (Li_2O_2 and Li_2CO_3) during the ambient air operation of LABs.

9:15 AM EN09.06.03
Investigating the Stability of Organic Electrolytes for Lithium-Air Batteries with High-Throughput Simulations Avni Singhal, Shi Jun Ang, Yang Shao-Horn and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Lithium-air batteries have gained significant attention as a solution for applications requiring high gravimetric energy density. Currently, however, electrolyte instability remains a key challenge limiting the practical use of aprotic Li-air batteries. Common organic electrolytes are largely unstable against the oxygen electrode, experiencing degradation due to hydrogen removal, proton removal, nucleophilic attack, oxidations and reductions. Previous works have computationally screened electrolyte candidates for stability based on ground state electrolyte properties. However, the chemical processes that cause electrolyte instability are often kinetically driven and thus thermodynamics and kinetics must both be investigated in order to fully evaluate candidate stability. Computational screening for kinetic stability requires automating the determination of reaction barriers for the numerous potential reaction mechanisms.

High-throughput calculation of reaction barriers is challenging due to the difficulty of locating transition state structures. As such, transition state calculations often rely heavily on user input and chemical intuition and existing automated approaches such as double-ended string methods frequently fail for complex molecules. In this work, we present an automated pipeline for high-throughput determination of reaction free energy barriers for kinetically-controlled electrolyte decomposition processes. By integrating cheminformatics-based reaction encoding, relaxed potential energy scans, and nudged elastic band calculations, our approach enables determination of free-energy barriers for reactions of interest of candidate electrolytes at scale. In particular, cheminformatics tools are used to programmatically generate products from reactants and track reactive atoms, relaxed potential energy scans to obtain initial reaction paths, and climbing-image nudged elastic band calculations to obtain transition state guesses from these starting paths.

We apply this approach to determine reaction barriers for nucleophilic attack by superoxide, which is formed during electrochemical cycling in Li-air batteries. We screen 100+ electrolytes with 400+ potential reactions, validating expected trends in the stability of carbonate and sulfone candidates. We study the effects of chemical functionalization with electron-donating and withdrawing groups and their interplay with steric factors. Finally, we identify functional groups and other chemical modifications that could increase the stability of organic electrolytes in aprotic Li-air batteries.

9:30 AM EN09.06.04
***In-situ* Electropolymerized Metalporphyrin Cathode Materials for High Performance Organic Electrodes** Thomas Smok, Ebrahim Abouzari-Lotf, Thomas Diemant and Maximilian Fichtner; Karlsruhe Institute of Technology, Germany

The interest in organic electrode materials (OEM) for rechargeable batteries has increased tremendously over the last decade.[1] This development is caused by the inherent advantages which OEMs exhibit over commercially leading inorganic materials. Specifically, the accessibility of a broad range of redox potentials due to the molecular engineering of redox-active functionalities allows boosting the storage capacity of organics. Moreover, most materials can be easily synthesized from readily available precursors. This structural diversity leads to the application of organics in different battery cell chemistries including Li-, as well as post-lithium systems like Na-, K-, and Mg- batteries. Challenging aspects of OEM materials are high dissolution in aprotic electrolytes and therefore interlinked rapid decay in capacity.[2] Also low conductivity of OEMs remains an unresolved issue.[1]
One of the most promising representatives for organic electrode materials are π-conjugated heteroatom macrocycles like porphyrins. Using bipolar-type (*b*-type) porphyrins was considered as a conventional strategy to improve the capacity and discharge voltage of OEMs when compared to *p*-and *n*-type materials, respectively.[3] Reported porphyrin materials display good electrochemical performances combined with fast charging kinetics due to a small HOMO-LUMO gap.[4] However, like other organic electrodes, porphyrins often suffer from low conductivity and, consequently, require a significant amount of electrochemically inactive conductive carbon that occupies volume and mass without storing energy. We investigated [5,10,15,25 tetrakis(4-aminophenyl)-porphyrin] (TAPP) and its metal complexes as redox-active cathode materials to address the aforementioned issues. Interestingly, the lithium-ion cells prepared with a high content of CuTAPP active material (70 wt%) demonstrate a stable discharge capacity of ~120 mAh/g over 2000 cycles when cycling with a constant current density of 1000 mA/g. The material also showed a superior rate capability of ~ 60 mAh/g at 8 A/g. The results of DFT calculations and experimental evaluations indicate that the degree of planarity of the metalloporphyrins directly correlates to their cycling stability. On the other hand, the contribution from the central metal redox during the cycling is found to be the reason for the significantly higher performance of the Cu-complex. The findings show a general approach for facing common conductivity challenges of organic electrodes and open up a pathway for practical application in energy storage.

Recyclable Organic Radical Batteries Ratul Mitra Thakur, Ting Ma, Grant Shamblin, Suyash Oka, Suvesh M. Lalwani, Alexander Easley and Jodie Lutkenhaus; Texas A&M University, United States

Organic radical batteries are one of the possible routes for transition to a sustainable future and reducing global carbon footprint. However, focusing on the recyclability of these next-generation energy storage devices is important to achieve a circular economy. This work shows the recycling of poly(2,2,6,6-tetramethylpiperidinyloxy-4-yl) (PTMA) and poly(2,2,6,6-tetramethylpiperidinyloxy-4-yl acrylamide) (PTAm) based composite electrodes using solvent extraction technique. The electrochemical performance of the original and recycled electrodes was accessed with cyclic voltammetry (CV) and galvanostatic charge-discharge (GCD). This work identifies the associated challenges of recycling and possible changes in the recycled electrodes. One challenge is the cathode-electrolyte interphase (CEI), which is formed due to the decomposition of organic radical polymer and electrolyte, as identified from time-of-flight secondary ion mass spectrometry (Tof-SIMS). CEI formation consumes some of the active organic radical polymers which results in a decrease in the discharge capacity of the recycled electrodes. This work explores possible routes to address the issue and improve the overall capacity. This work gives valuable insights into challenges and possible solutions for recycling the next-generation electrochemical energy storage devices.

Ion-Coupled Electron Transfer of Naphthalene Diimide Derivatives for Non-aqueous Organic Redox Flow Batteries Seongmo Ahn and Hye Ryung Byon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Organic redox flow batteries (RFBs) have been investigated for future energy storage systems (ESSs). Tailoring organic redox-active molecules tunes solubility, redox potential, and chemical stability, which gives the promise to enhance energy density, cyclability, and calendar life in RFBs. Numerous studies focused on increasing molecular solubility to satisfy Econo-technical levels. In addition, introducing electron-donating and withdrawing groups to the redox-active core modulated redox potentials to negative and positive shifts, respectively. The most effective way to multiply raising energy density is to find a redox-active core undergoing multiple electron-transfer processes. Quinone is the representative one providing a single two electrons transfer in an aqueous electrolyte solution. Fast redox kinetics and chemical stability are achieved by H^+ coupling; The reduced form, hydroquinone, promoted the following electron transfer in the acidic solution. A similar concept is applied for non-aqueous electrolyte solutions and using cations of supporting electrolytes. However, such an ion-coupled electron transfer was rarely studied to date.
Here, we demonstrated naphthalene diimide (NDI) and Li^+ coupled electron transfer in acetonitrile (MeCN). The NDI is an excellent model for the

stepwise two-electron transfer process. Its low solubility by the strong p-stacking interaction was surmounted by introducing ammonium cationic substituents to the NDI via simple condensation and *N*-alkylation. As a result, two ammonium-tethered NDI and bistriflimide ($TFSI^-$) as the counter anion showed 0.9 M solubility in MeCN. Two cathodic events made an anionic radical and dianionic NDI core, respectively. The received electron is delocalized over the NDI core and also stabilized by pairing it with the cation. Cyclic voltammograms showed ~120 mV of potential difference from two cathodic waves with Li^+ of LiTFSI electrolyte in MeCN, which was narrower than ~370 mV with K^+ of KTFSI. It suggested that the Li^+ possessing high charge density was closely coupled with the anionic radical NDI, expediting the second electron-transfer process. The process was also dependent on non-aqueous solvents. High donor-number (DN) solvents widened the potential difference with Li^+ because a thick solvation shell of Li^+ weakened the ion coupling. We applied this system for non-aqueous RFBs. Unlike two distinct galvanostatic plateaus appearing with K^+, the ammonium-introduced NDI with Li^+ showed almost a single overlaid plateau caused by the rapid reduction of the anionic radical. The ammonium-tethered NDI/Li^+ in MeCN cells performed high cyclability and low crossover through an anion exchange membrane, showing a capacity fading rate of 0.0089% for 1000 cycles in RFBs.

SESSION EN09.07: Redox Flow Batteries
Session Chairs: Zheng Chen and Dawei Feng

Moscone West, Level 2, Room 2009

1:45 PM *EN09.07.01
Designs of Naphthalene Diimide for Highly Soluble and Stable Negolyte in Aqueous Organic Redox Flow Batteries Vikram Singh[1], Seongyeon Kwon[1], Yunseop Choi[2], Jongcheol Seo[2], Mu-Hyun Baik[1] and Hye Ryung Byon[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Redox flow batteries (RFBs) are intensively researched at the moment, as they are most likely to provide a solution to the global demand for grid-scale energy storage. Given the scale of the intended application, realistic solutions must be scalable, cheap, and safe. Organic molecules are ideal, in principle, and they can be derivatized to optimize their performance. Yet - clear and successful demonstrations of this advantage and rational strategies of how to guide the design of new molecules have rarely been reported.
Herein, I show that starting from naphthalene diimide (NDI) that is highly redox-active, but absolutely insoluble in water. We can rationally design a highly soluble charge carrier by tethering four ammonium functionalities to the NDI core that disrupts the long-order π-stacking that is a key feature leading to precipitation. Notably, the radical intermediate NDI^- form π-stacked dimers and tetramers during the charging process, where the radical character is nullified by antiferromagnetic coupling. It stabilizes radical intermediates without precipitation, and NDI delivers state-of-the-art performance of RFBs at neutral pH. Our approach provides a simple solution to long-standing problems in the field, i.e., solubility, radical reactivity, and operational pH, and the mechanism of stabilizing radical intermediates is generally applied to organic RFB systems.

2:15 PM EN09.07.03
Leveraging Temperature-Dependent (Electro)Chemical Kinetics to Accelerate Aqueous Organic Redox Flow Battery Characterization Eric M. Fell and Michael Aziz; Harvard University, United States

Aqueous Organic Redox Flow Batteries (AORFBs) have emerged as promising and potentially disruptive technologies for the storage of electrical energy from intermittent renewable sources for use over long discharge durations when the sun isn't shining and the wind isn't blowing. AORFBs could become preferred over Li-ion batteries for grid-scale stationary storage due to their potentially low-cost active materials made of earth-abundant elements, their inherent non-flammability, and the intrinsic decoupling of energy and power capacities in the flow battery design. Recent work has demonstrated that calendar life, rather than cycle life, limits molecular lifetimes in AORFBs due to various molecular instabilities that lead to side reactions, thus inhibiting performance [1]. To accurately determine molecular fade rates, we utilize potentiostatic cycling to avoid artifacts caused by drifts in internal resistance and employ volumetrically unbalanced, compositionally symmetric cell configurations to distinguish molecular fade from membrane crossover. Synthetic efforts have continued to improve redox-active organic molecule stability to the point that the most stable chemistries degrade at less than 1% per year [2]. With further lifetime increases, the measurement of lower capacity fade rates necessitates higher precision coulometry methods [3] and thermally accelerated degradation protocols [4] to determine which stabilizing approaches are most effective without waiting for multi-month cycling tests to quantify capacity fade.

We have developed a high-throughput setup for cycling AORFBs at elevated temperatures, providing a new dimension in the flow battery characterization space to explore. Capacity fade rates of previously published redox-active organic molecules, as functions of temperature, are evaluated in the high-throughput setup providing the ability to extrapolate fade rates to lower operating temperatures. The effect of temperature on electrochemical synthesis and recomposition [5,6] of organic molecules is also explored. Collectively, these results highlight the importance of accelerated decomposition protocols to expedite the screening process of candidate molecules for long lifetime AORFBs, which may enable massive grid penetration of intermittent renewable energy.

Improve the Kinetics of the Ketone-based Aqueous Organic Redox Flow Batteries Ruozhu Feng[1], Ying Chen[1], Xin Zhang[1], Benjamin J. Rousseau[2], Peiyuan Gao[1], Ping Chen[1], Sebastian T. Mergelsberg[1], Lirong Zhong[1], Aaron Hollas[1], Yangang Liang[1], Vijayakumar Murugesan[1], Qian Huang[1], Sharon Hammes-Schiffer[2], Yuyan Shao[1] and Wei Wang[1]; [1]Pacific Northwest National Laboratory, United States; [2]Yale University, United States

Redox flow batteries have a unique architecture that potentially enables cost-effective long-duration energy storage to address the intermittency introduced by increased renewable integration for the decarbonization of the electric power sector. Targeted molecular engineering has demonstrated electrochemical reversibility in natively redox-inactive ketone molecules in aqueous electrolytes. Yet, the kinetics of fluorenone-based flow batteries continue to be limited by slow alcohol oxidation. We show how strategically designed principles can accelerate alcohol oxidation and thus enhance battery kinetics. Rationally designed fluorenone-based flow battery electrolytes demonstrate enhanced rate capability, high battery capacity, and record-breaking long cycling. This study opens a new avenue to improve the kinetics of aqueous organic flow batteries.

3:45 PM EN09.07.05
Polymer Ion-Sieving Membranes Enable High-Performance Aqueous Organic Redox Flow Batteries Anqi Wang[1], Rui Tan[1], Chunchun Ye[2], Neil Mckeown[2] and Qilei Song[1]; [1]Imperial College London, United Kingdom; [2]University of Edinburgh, United Kingdom

Redox flow battery (RFB) technology is promising for grid-scale long-duration energy storage owing to its decoupled power and energy, long discharge duration and long cycle life. In recent years, aqueous organic RFBs based on organic redox-active molecules have attracted significant interest owing to their potential low cost compared to conventional vanadium RFBs. The widespread adoption of aqueous organic RFBs will require low-cost ion-selective membranes that could replace expensive Nafion membranes while achieving high ionic conductivity and selectivity towards redox-active materials. As yet, inexpensive ion-selective membranes are still lacking. Despite the pressing need for high-performance membranes, it remains a significant scientific challenge to develop alternative cost-effective materials and to achieve precise control over their water channels at a sub-nanometre scale for selective ionic and molecular transport.

Here, I will discuss our efforts to develop next-generation ion-selective membranes comprising sub-nanometer pores through modular synthesis of polymers of intrinsic microporosity (PIMs), whose structural diversity is controlled by choice of monomer, polymerization reaction and post-synthetic modification. The interconnected sub-nanometer pores in these functionalized PIMs allow fast, selective transport of ionic and molecular species, overcoming the conventional upper bounds of ion permeability and selectivity found in all existing membrane materials. These PIM membranes enable significant improvements in the efficiency, power density and lifetime of redox flow batteries over several thousand charge-discharge cycles in lab-scale demonstrations.

4:00 PM EN09.07.06
2-Volt All-Iron Aqueous Flow Battery Michael P. Marshak[1] and Elliott B. Hulley[2]; [1]University of Colorado Boulder, United States; [2]University of Wyoming, United States

All-iron flow batteries are attractive for use in large-scale energy storage systems due to the low cost and scalability of iron. However, iron flow batteries often use the $Fe^{2+/0}$ redox couple for the anodic reaction, which plates out iron onto an electrode during the charging process. This plating reaction limits the scalability of the all-iron flow battery for long duration because the amount of iron plated is related to the surface area of the electrode, cell, and stack, and the resulting power-energy ratio of the system cannot be scaled independently to long durations. In adddition, all-iron flow batteries usually operate at low voltages, limiting the power and efficiency of the system.

Here we show how the use of different coordinating organic ligands can modulate the potential of the $Fe^{3+/2+}$ redox couple over 2 volts in water at neutral pH. We further demonstrate the performance and cycling of an all-iron flow battery wherein both anolyte and catholyte solutions comprise iron in the +2 or +3 redox state, with different organic ligands, with an equilibrium cell potetential over 2 volts. The molecular design, bonding, and electronic structure of the organic materials will be discussed highlighting the critical requirments for organic materials to control metal-based redox reactions.

4:15 PM EN09.07.07
Neutral pH Viologen-TEMPO Based Aqueous Organic Redox Flow Battery—The Critical Role of Electrolyte Formulation on Stability and Efficiency Laura Pastor[1,2], Eduardo Sanchez[1], Maddalen Agirre[1] and Nerea Marquínez[1]; [1]CIC energiGUNE, Spain; [2]University of the Basque Country, Spain

The intermittent availably and power of renewable energy sources has become an issue, efficient energy storage systems must be introduced to overcome this obstacle.

Redox-flow batteries stand out as relevant candidates for large-scale stationary energy storage due to their many advantages, including their unique capability to decouple energy storage and power generation.[1]

In recent years, there has been a transition from redox inorganic materials to the development of water-soluble organic redox active materials owing to their low cost, high sustainability, and their structural diversity and tailorability.[2]

Redox flow batteries based on aqueous organic electrolyte have emerged as promising competitors to traditional redox flow batteries. Acidic, alkaline, and neutral AORFBs using different organic molecules/polymers as redox-active materials have been explored lately.

Despite efforts devoted to the development of new active materials, search for stable high redox potential molecules for catholyte remains a challenge, mainly limited to ferrocyanide and TEMPO derivatives which render low cell voltages[3, 4] or present uncertain stability.[5, 6]

As a solution to above mentioned problem, we have contributed to the development of neutral pH Aqueous Organic Redox Flow Batteries employing a novel anolyte-catholyte combination leading to cell voltages >1.2 V and outstanding stability and efficiency. A case of study for Viologen-TEMPO based electrolyte including synthesis, characterization and battery testing is provided.

Considering that the supporting electrolyte and the ion exchange membrane are key components in RFBs and have significant impact on the energy efficiency and power density we perform a study to understand how these factors affect the battery performance.

Several electrolyte formulations were evaluated attending to parameters such as the concentration of active materials and conductive salts. The influence of the cation on the transport phenomena, as well as the role of the anion on the stability of the solution will be discussed. Cell resistance and water transport can be modulated by wise electrolyte formulation. Moreover, different commercial CEM membranes were evaluated aiming at neutral pH systems with high RTE (>80% EE at 60 mA/cm^2) and high power densities.

Finally, with an optimized combination of membrane and supporting electrolyte, cycling test was conducted to reveal the long cycling stability with negligible capacity decay (0,001%/day) over 1000 cycles.

5:00 PM EN09.08.01
Establishing Structure-Property-Transport Relationship for PBC ionomer blends Andrew White, Thivani Senathiraja and Chris J. Cornelius; Iowa State University, United States

As the world focuses on clean and sustainable power generation without the need for fossil fuels, hydrogen fuel cell technology is becoming a leading choice due to its zero emissions. Proton exchange membranes (PEMs) are a critical part of hydrogen fuel cells, allowing protons to pass between anode and cathode, and improving their durability as well as the structure-transport-property relationship is a key part in furthering this technology. Currently, the industry standard for PEMs in hydrogen fuel cells is Nafion, a perflouronated compound that is used for many applications worldwide. However, the degradation of Nafion leads to the creation of perflourooctanoic acid, a potent environmental hazard when released into the environment, which causes much concern about the future of the compound. To remedy this concern, Nexar, a pentablock copolymer (PBC) has been proposed to serve the same function as Nafion without the environmental risks. In this study, two types of PBC (1.0 and 2.0) were blended in different ratios and solution cast in order to improve the durability and ion conductivity of PEMs created from the blend. SAXS data analysis shows sulfonic acid domain peak shifts from .0154Å to .0176Å, and .0315Å to .0369Å, indicating a change in the microstructure of the PEMs as well as a more ordered structure as a result of blending. Domain spacing between sulfonic acid groups decreases from 400Å to 355Å, resulting in a membrane that can form larger ionic clusters than the parent membrane. To study how the properties of the blended membranes changed, several tests in relation to the operation of fuel cells were undertaken. Titrations were performed on each of the blended membranes in order to observe the ion exchange capacity (IEC) of each, and results showed increasing IEC relative to the amount of PBC(2.0) in the blend. Gas permeation analysis shows a sharp decrease in the permeability of hydrogen and oxygen gasses, while the H2/O2 selectivity of the blended membranes is comparable to that of the parent membrane. Overall, the PBC ionomer blends with different ion exchange capacities shows potential in reducing the fuel cell crossover. Further studies will include thermogravimetric analysis to assess the thermal stability as well as a TEM study in order to observe the morphological changes that have been made.

5:00 PM EN09.08.02
Thermal Annealing of Solution Cast PBC Hybrid Sol-gel Nanocomposites Ionomers Thivani Senathiraja and Chris J. Cornelius; Iowa State University, United States

Tuning the interactions of solid multiblock ionomer is a cost-effective approach to target and advance specific properties for sustainable ion-conducting applications, such as fuel cells, polymer actuators, vanadium flow batteries, water desalination using electrodialysis, and water electrolysis to produce H_2 and O_2 . In this study, polystyrene based sulfonated ionomers called pentablock copolymers (PBC) were employed due to their tailorable morphology. The morphological transitions of PBC ionomer multi blocks was induced using TEOS Sol-gel nanocomposites to understand their structure-property -transport relationship. One of the previous studies portrayed that crosslinking of TEOS-TIP sol-gel network with PBC polymer chains greatly influenced the morphology and properties of multiblock ionomer such as water uptake, proton conductivity, and liquid transport, which are crucial in the fuel cell, lithium-ion battery, or vanadium flow battery applications. However, it was found that the morphology of hybrid membranes transitioned from ordered to random morphology as more TEOS-TIP components were introduced. Hence it was postulated that thermal annealing can be a probable route to further drive the TEOS-TIP network and assemble hybrid PBC membranes into ordered structures as thermal annealing of ionomers leads to the development of interconnectivity between the adjacent ionic channels. The PBC membranes were solution cast using Tetrahydrofuran and were annealed at 80^{o}C and 100^{0}C. The transmission SAXS analysis revealed that the thermal annealing of an unmodified PBC membrane led to the disappearance of their characteristic peaks. This may be attributed to the formation of loose clusters with higher temperature. However, the PBC incorporated with sol-gel shifted towards the lower scattering angle, indicating the formation of large sulfonic acid group clusters. This shows that thermal annealing significantly alters the microstructure of the membranes. Moreover, it was found that thermal annealing and higher TEOS content in the PBC membrane significantly reduced the water uptake by 17% but increased methanol uptake by 22.22%. Due to the enhanced crosslinking between the polymer chains with temperature, it was observed that the gas permeability of the unmodified membranes reduced significantly however the gas selectivity of hydrogen gas and carbon dioxide increased by 30%. While incorporation of sol-gel decreased both permeability and selectivity of the PBC membranes. Future study will incorporate proton conduction, mechanical durability and thermal stability of these PBC hybrid nanocomposite membranes.

5:00 PM EN09.08.03
Protective Interfacial Coating of Polydopamine Layer for Inhibiting Electrolytes Decomposition in Extremely Lean-Electrolytic Lithium Secondary Batteries Myeong Gyun Nam and Pil Jin Yoo; Sungkyunkwan University, Korea (the Republic of)

To meet the rising energy demands, secondary battery systems based on diverse metal ions with a high energy density have been developed. Nevertheless, highly capacitive anode materials, such as Li metal and silicon, typically result in the depletion of the electrolyte and the excessive formation of solid electrolyte interphase (SEI) layers during cell operation. Especially for commercial pouch cells, the amount of electrolyte utilized in cells is significantly less than that used in laboratory-scale coin cells, making the cycle life of pouch cells is significantly more susceptible to electrolyte depletion conditions.

Therefore, to mitigate the issue of electrolytes decomposition, surface passivation strategies involving coating layers are extensively studied. The coatings act as electrolyte-blocking layers to keep the electrolyte away from the surface of the electrode materials, thereby selectively permitting the passage of Li ions. As such, these blocking layers confer the advantageous properties of selective Li-ion conductivity, good insulation, and ample mechanical durability against external stress while simultaneously passivating the surface of the active materials and inhibiting electrolyte decomposition.
Among various candidates for the passivation layer, polymers containing Li-conductive functional groups have also been identified as potential electrolyte-blocking layers. In particular, due to their outstanding coating properties and high Li-ion conductivity on a variety of substrate types, phenolic species could be considered as one of the most promising candidates. Typically, dopamine is the first seeding material in phenolic species to be used as a complexing agent. In the structure of dopamine, the electron-donating amine group has excellent adsorption properties on a variety of surfaces. In addition to other types of interactions, such as hydrogen bonds, van der Waals interactions, and π- π interactions, the indole-transformative nature of amine groups enables the homogeneous adsorption of charges on surfaces, regardless of their type or hydrophilicity.
In this presentation, we introduce polydopamine (PD) as a protective layer to alleviate electrolyte degradation by effectively separating solvent molecules from Li ions. To prove the feasibility, an extremely lean electrolyte testing (ELET) method is proposed as a standard cell testing technique for quantitatively investigating the recyclability of electrolytic species during cell cycling. In this proposed technique, a small coin cell with an extremely small amount of electrolyte (less than 2 μl mAh^{-1}), which is similar to that employed on a commercial scale, is employed to enable the direct and intuitive assessment of cell cycle life taking into account the effect of the relieved electrolyte decomposition. In addition, contour maps to precisely evaluate and estimate the cell performances were successfully constructed using equations derived from the ELET performance and cell configurations, such as electrolyte usage. Consequently, using the ELET technique, we demonstrated that the incorporation of a marginal fraction of the PD layer (~ 4 wt%) significantly reduced the electrolyte consumption of the Si–C composite by 150% relative to that of the parent material. Furthermore, the PD coating inhibited the excessive growth of the SEI, which further confirms the retardation of the electrolyte impregnation. We anticipate that our findings will contribute to the development of high-capacitive materials with superior cycle life and a connection between academic research and practical applications by means of this practical evaluation method that can be applied to a wide range of battery systems.

5:00 PM EN09.08.04
Organic Redox Electrolytes for Continuous Desalination and Li-Recovery System Byeongkyu Kim, Yong Seok Kim, Taeyup Jeong, Doonyapisut Dulyawat and Chan-Hwa Chung; Sungkyunkwan University, Korea (the Republic of)

Capacitive deionization (CDI) has been developed to alternative desalination technology because of its good energy efficiency. In conventional CDI system, ions from the saline are adsorbed on the electrode surface. To improve desalination performance, solid-phase electrode materials with a high specific surface area and electrical conductivity are required for the system. Although recent studies show high specific capacity, these systems require a complex design to scale up due to only the surface of the electrode can contribute to ion removal mechanism. Various approaches, such as membrane CDI, flow-electrode CDI, and desalination batteries, have been tried to solve these issues, but they have not been evaluated to be suitable for designing large-scale and continuous systems.
In the present work, we suggest a system based on the Faradaic reaction of organic redox electrolytes to store the salt in the liquid phase. Considering that a redox flow battery (RFB) generally stores electrical energy as chemical energy in the redox electrolytes via the Faradaic reaction of redox-active materials (RAMs), a hybrid system is designed in which salt removal is performed by CDI, but ion storage occurs in the redox electrolytes rather than the surfaces of electrode materials. In this design, the whole electrolyte volume can be used to store the removed salts. Also, it is believed that the system can maintain its high stability due to electrodes have not participated in the operation.
For continuous desalination system, a desalination- and RFB-cell is fabricated, respectively. An anion- and cation-exchange membrane separates the ion removal region from the anode and cathode in a desalination cell. To maintain charge balance throughout the Faradaic reaction of the redox electrolyte, sodium and chloride ions have been exchanged across each ion-exchange membrane. Therefore, desalination occurs throughout the charging process, in other words. After desalination, the reacted RAMs and salt ion flows continuously into RFB-cell, where the stored energy is discharged. This entire reaction happens repeats with no additional control. Especially, the developed system uses organic material as RAMs (2-phenyl-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide, PTIO) and organic solvent for redox electrolyte. The organic state of the electrolyte has various benefits, including the possibility to apply a high voltage of 2.4 V to overcome water splitting limits, scaling of desalination capacity, and sustained desalination performances due to NaCl insolubility in organic solvent. The continuous desalination system based on these designs shows a high desalination capacity value of 80 mg g^{-1} at a desalination rate of 0.11 mg cm^{-2} min^{-1} with the energy consumption value of 109.6 kJ mol^{-1}. Furthermore, the system can be operated continuously over 38 hours without additional control to desalinate a much larger volume of saline.
Moreover, this study suggests an advanced system for collecting Li while desalination. λ-MnO_2 is deployed as an ion-sieve materials in the system to selectively adsorb Li-ion from the solution. The ion-sieve material is installed in the anolyte tank to collect Li-ion while the desalination-cell is operating. Oxidized PTIO aids in the intercalation of Li-ion into the ion-sieve, resulting in the formation of $Li_xMn_2O_4$ in the anolyte tank. The Li recovery process achieves a high selectivity of 57.7 from K^+ and 12.2 from Na^+ while maintaining desalination performances.

Molecular Dynamics Simulations of the Polymer Electrolyte-Electrode Interface Aysha Siddika Asha, Justice Nkemakolam Iroegbu, Benjoe Rey B Visayas, Maricris Mayes and Caiwei Shen; University of Massachusetts Dartmouth, United States

Electric double-layer supercapacitors (EDLCs) based on polymer electrolytes are widely studied for flexible, wearable, and multifunctional energy storage applications. However, EDLC electrode materials often present significantly lower capacitances in polymer electrolytes than in liquid electrolytes. This phenomenon has been frequently reported but not systematically studied and understood. Here we present the molecular simulation of a representative polymer electrolyte-based EDLC to reveal the polymer electrolyte-electrode interface at the atomic scale for the first time. The molecule insights combined with experimental verifications provide explanations for the performance disparities between EDLCs using polymer electrolytes and liquid electrolytes.
The simulation model of polymer electrolyte-based EDLC is built with polyethylene oxide (PEO) and lithium perchlorate ($LiClO_4$) between two pieces of single-layer graphene electrodes and compared with an aqueous electrolyte-based EDLC consisting of the same salt except that the PEO molecules were replaced with the water molecules. All simulations were performed using the molecular-dynamics simulation code LAMMPS using the CHARMM force field. We simulated the polymer electrolyte at both melted and solid states under various electrical potentials using the constant charge method. For the experimental part, thin films of PEO-$LiClO_4$ electrolyte were prepared by the solution casting method. Both polymer and aqueous electrolytes (1 M $LiClO_4$ solution) were tested using electrochemical impedance spectroscopy and cyclic voltammetry.
We find from time evolutions of ion concentrations that the polymer systems take longer time than the aqueous system to establish stable EDL structures due to the ionic conductivity discrepancy. After the EDL structures reach equilibrium, the polymer systems show thick inner Helmholtz layers (IHLs) formed by polarized PEO molecules, and similar outer Helmholtz layers (OHLs) and diffuse structures to that seen in liquid electrolytes. Interestingly, unlike ions in typical liquid electrolytes with small solvent molecules, the ClO_4^- ions in polymer electrolytes form OHLs that are inside IHLs near the positive electrodes. The Li^+ ions in polymer electrolytes also form double OHLs that are unseen in other liquid electrolytes. Moreover, the simulation results show that the intrinsic interfacial capacitances of the polymer systems are very close to the values of the aqueous system. Our designed experiments verify that polymer electrolytes can form much better interfaces with electrodes when melted and achieve capacitances approaching that measured with the aqueous electrolyte. The improved interface can be preserved during heating and cooling cycles. These results prove that EDLCs using polymer

electrolytes can potentially achieve capacitances that are comparable to those using liquid electrolytes, which provides guidance for the design and optimization of various flexible, wearable, and multifunctional supercapacitors.

Carbon Bio-Waste Eletrocatalyst for Seawater Batteries João P. Ferreira, Tiago Salgueiro, Joao Ventura and Joana Oliveira; University of Porto, Portugal

Humanity is reaching a tipping point where new sustainable energy solutions are needed. Rechargeable sodium seawater battery (SWB), assume the world leadership of high voltage batteries in marine environment. With natural seawater as the active material, the SWB can be supplied infinitely with Na cations. Because of their open structure cathode, the performance of the battery is dependent on the characteristics of the cathode material, such as its specific surface area, porosity, functionalization, and wettability. The redox reactions involved in SWBs are slow electrochemical processes. With increased surface area, a much faster capacitive mechanism arises with an important contribution of the electric double layer (EDL) formed at the cathode interface.
Therefore, in this work, we studied how the performance of a seawater battery cell depends on four different cathode current collectors, commercial, heated and activated carbon felts and a peanut shell derived activated carbon electrode. Their associated performance was evaluated through galvanostic charge and discharge cycles and cyclic voltammetries. Their surfaces were analysed by scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS) and their wettability was measured. The performed electrochemical characterization allowed to observe a gradual improvement of the cathode performance with the increase of the specific surface area due to an enhancement of the capacitive behaviour contribution. Thus, the activated carbon felt showed the highest capacitive behaviour contribution. Nevertheless, the peanut shell derived material (synthesised through a carbonisation and activation using potassium hydroxide method) revealed a voltage gap similar to that of the activated carbon, being even smaller for the highest current. The cyclic voltammetry showed a great capacitive effect and the calculated gravimetric capacitance of the full seawater battery cell employing the peanut shell derived electrode was close to that of the activated carbon. The obtained voltage gaps and gravimetric capacitance demonstrate that the peanut shell derived electrocatalyst coated carbon felt shows good performance. This is caused by highly porous structure of the electrocatalyst with macroporous cores that act as secondary ion-buffering reservoirs, mesoporous walls that provide pathways with low resistance, and micropores that can afford the electric double layer capacitance, and also by a highly functionalized surface where oxygen functional groups. This work opens a new path for the integration of bio-waste in seawater batteries towards a more sustainable future.

5:00 PM EN09.08.07
Forming an Inorganic-Organic Bi-Layered on Li Metal with Reduceable Li Salt@Polymer Layer for High Energy Density Li Metal Batteries
Seungcheol Myeong, Jiseok Kwon, Keemin Park, Yongmin Jung, Taeseup Song and Ungyu Paik; Hanyang University, Korea (the Republic of)

Lithium(Li) metal is considered a promising anode for high energy density batteries. However, lithium dendrite growth during Li plating/striping causes low columbic efficiency and safety issues. The above problems can be controlled by the engineering of an interface between Li metal and electrolytes for better Li-ion kinetics and interface stability. In this study, we form inorganic/organic bi-layer, composed of 200nm thick inorganic (LiF, Li_3N, Li_2S) inner layer (Li metal side) and outside porous PTFE polymer layer (electrolyte side), on Li metal surface. The robust inorganic layer prohibits dendritic Li growth. The flexible and porous polymer layer retains the protection layer structure with high Li-ion flux. In a symmetric cell test, Li metal with the bi-layered protection layer shows stable cycle over 600hours under $1mA*cm^{-2}$ with $5mAh*cm^{-2}$. Full cell cycle test, 20μm lithium metal with bi-layered protection layer anode paired with capacity of $5mAh*cm^{-2}$ high-nickel contents nickel manganese oxide (NCM811) cathode, shows stable cycle performance over 200cycles with the Li anode efficiency of 99.6% calculated by average Coulombic efficiency.

5:00 PM EN09.08.08
3D-Structured Fiber-Mesh Supercapacitors Based on Graphene Oxide/Carbon Nanotube Core and PEDOT:PSS Sheath Fibers Minju Choi[1,2], Il-Young Jo[1], Bon-Cheol Ku[2] and Myung-Han Yoon[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Due to mechanical flexibility, lightweight, and excellent electrochemical performance, conjugated polymer-based pseudocapacitive materials such as poly(3,4 ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) have been regarded as a promising active component for fiber-shaped supercapacitors. However, it has been known that they exhibit several practical issues such as high voltage drop and considerable capacitive degradation for the purpose of relatively long fiber-type supercapacitors. Herein, we developed long-range fiber-type supercapacitors based on graphene oxide-carbon nanotube (GO-CNT; core) and conjugated polymer (PEDOT:PSS; sheath) fibers. The GO-CNT fibers which exhibit very high electrical conductivity over 40,000 s/cm played an important role as a current collector by reducing the voltage drop even in the case of meter-scale long fiber devices. The enlarged volume of PEODOT:PSS sheath was successfully fabricated on the surface of water-wettable GO-CNT core fiber by direct wet spinning of PEDOT:PSS followed by PEDOT:PSS fibers' twisting and self-fusion. The resultant core-sheath fibers showed large length-normalized capacitances of 7.37 and 31.66 F/cm for one and eight strands twisted/self-fused sheath, respectively (volume-normalized capacitance of 120 F/cm^3) while the full cell showed superior energy (2.22 Wh/kg) and power densities (65.5 W/kg). Furthermore, 3-dimensional fiber mesh-type supercapacitors could be fabricated in the form of a hemisphere or cylinder which showed large scalable charge storage capacity under multiple series connections for more practical usage.

5:00 PM EN09.08.09
Preparation of PEDOT:PSS Fibers MXene Based Composite Film for Electrochemical Energy Storage Zuwang Wen, Youngseok Kim and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Herein, we report on 2D Ti_3C_2Tx MXene and PEDOT:PSS conducting polymer fiber-based composite films with alternating layer structures for electrochemical energy storage application. In the proposed alternating layer structures, the highly-conductive crystallized PEDOT:PSS fibers were self-fused to form porous fibrillar networks to facilitate electrical conduction and enhance mechanical strength. In parallel, PEDOT:PSS fiber layers function as spacers to minimize MXene flakes restacking which shorten electrolyte transport pathway and take advantage of MXene's large electrochemically active surface areas. The resultant composite electrodes were able to deliver large gravimetric capacitances over 400 F/g, and showed minimal capacitance degradation with film thickness. Furthermore, excellent mechanical strength and flexibility of the composite films allowed for folding to arbitrary shapes without apparent electrical/electrochemical damage. We expect this work will pave the way for designing high performance MXene and PEDOT:PSS-based composite materials for their application to energy storage, electrical catalysis, and flexible electronics.

5:00 PM EN09.08.10
Stretchable Gas Barrier Film using Liquid Metal Towards a Highly Deformable Battery Nyamjargal Ochirkhuyag, Yuuki Nishitai, Satoru Mizuguchi, Yuji Isano, Sijie Ni, Koki Murakami, Masaki Shimamura, Hiroki Iida, Kazuhide Ueno and Hiroki Ota; Yokohama National University, Japan

Highly deformable batteries that are flexible and stretchable are important for next-generation wearable devices. Several studies have focused on the stable operation and lifespan of batteries. On the other hand, there has been less focus on the packaging of highly deformable batteries. In wearable devices, solid-state or pouch lithium-ion batteries (LIBs) packaged in aluminum (Al) laminated films, which protect against moisture and gas permeation, are used. Stretchable elastomer materials are used as the packaging films of highly deformable batteries; however, they are extremely permeable to gas and moisture. Therefore, a packaging film that provides high deformability along with gas and moisture barrier functionalities is required for the stable operation of highly deformable batteries used in ambient conditions. In this study, a stretchable packaging film with high gas barrier functionality is developed successfully by coating a thin layer of liquid metal onto a gold (Au) deposited thermoplastic polyurethane film using the layer-by-layer method. The film exhibits excellent oxygen gas impermeability under mechanical strain and extremely low moisture permeability. It shows high impermeability along with high mechanical robustness. Using the proposed stretchable gas barrier film, a highly deformable LIB is assembled, which offers reliable operation in the air. The operation of the highly deformable battery is analyzed by powering LEDs under mechanical deformations in ambient conditions. The proposed stretchable packaging film can potentially be used for the development of packaging films in advanced wearable electronic devices.

5:00 PM EN09.08.11
Design of Carbon-Modified Separators and Current Collectors for Long-Lasting Li Metal-Based Batteries Patrick J. Kim[1], Junghwan Kim[1,2], Kihwan Kwon[1,2], Kwanghyun Kim[1,2] and Junghyun Choi[2]; [1]Kyungpook National University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Metallic lithium (Li) has drawn a huge attention from battery industries and academia investigating next-generation anodes, due to its excellent properties: high specific capacity (3860 mAh g^{-1}), the most negative potential (close to -3.04 V vs. SHE), and low density. Unfortunately, inherent challenges associated with inhomogeneous Li plating/stripping and poor Coulombic efficiency impede the pragmatic use of Li metal anode for conventional batteries. As one of the promising approaches, carbon-based nanomaterials have been widely applied to the modification of battery separator and current collectors. By utilizing carbon-based materials (e.g., graphene powder, carbon nanotubes, carbonized materials and so on), most of the major problems originated from the material properties of polymer separator can be dramatically addressed. In addition, safety problems resulted by the growth of Li dendrites can be significantly improved. Apart from the separator modification, it also has the analogous effects on stabilizing the Li deposition when carbon-based nanomaterials are used for the modification of current collectors. Throughout this talk, we are going to give a talk about our research results and research direction in detail.

5:00 PM EN09.08.13
Unveiling the Microstructure Effect of CNT-Based Current Collector on Li Deposition Behavior Junghwan Kim[1,2], Kihwan Kwon[1,2], Kwanghyun Kim[1,2], Han Seung Min[1], Patrick Joohyun Kim[2] and Junghyun Choi[1]; [1]Korea institude of ceramic engineering and technology, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of)

In order to develop a post-modern battery, Li metal batteries (LMBs) has been referred owing to its high specific capacity (3860 mAh g^{-1}) and lowest operating potential (-3.04 V vs SHE). However, LMBs have intrinsic problems related with the poor coulombic efficiency and the formation of dendritic Lithium. These unnecessary phenomena impede the commercialize of Li metal anodes. Among various strategies to overcome these severe challenges of Li metal anodes, the utilization of three-dimensional (3D) current collectors has shown very interesting results in terms of electrochemical performance. In this work, we evaluated two different carbon nanotubes (i.e., double-walled nanotube [DWNT] and multi-walled nanotube [MWNT]) to identify how the microstructure of carbon nanotube current collectors affects the electrochemical performances of LMBs. As MWNT has a more reversible Li$^+$ storage structure than DWNT, it can induce the homogeneous and stable Li deposition over the entire surface of MWNT matrix. This effect suppresses the growth of dendritic Li and directly attributes to the cycle stability of Li metal half-cell at high current density. Moreover, it has proven a possibility in full-cell application when the MWNT current collector was assemble with the LiCoO2 cathode. The MWNT@LiCoO2 cell showed the high coulombic efficiency (99 %) with notable cycle retention (97 % at 50 cycle). This work suggests that application of carbon-based material and structure would be desirable route toward enhancing the cycle stabilities of LMBs.

5:00 PM EN09.08.14
Prussian Blue Coated Separator to Alleviate Transition Metal Cross Over in High Nickel Cathodes Changhyun Park, Min-Ho Kim and Hyun-Wook Lee; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Transition metal layered oxides ($LiNi_xCo_yMn_{1-x-y}O_2$, NCM) have been considered as one of the most promising cathode materials for lithium-ion batteries used in long-mileage electric vehicles and energy storage systems. Despite its potential interests, NCM cathodes are likely to be degraded during the persistent cycling due to the generation of hydrogen fluoride (HF), which is often produced by decomposition of $LiPF_6$, giving rise to severe transition metal (TM) dissolutions into electrolytes. Especially, it was reported that dissolved TM ions tend to cross the separator and deposit on the anode surface with reduction reactions. The TMs can catalyze parasitic reactions such as electrolytic decomposition and dendritic Li growth, ultimately leading to catastrophic safety hazards. In this study, we demonstrate that Prussian Blue nanoparticles (PBNPs) anchored to a commercial polyethylene (PE) separator successfully mitigates such problematic TM crossover toward anode sides. Prussian Blue (PB, $Fe[Fe(CN)_6]$) and its analogues (PBAs) are cubic-type metal-organic frameworks (MOFs) with cyanide ligands around transition metal cations. It is known that its large interstitial sites can host various monovalent ions, divalent ions, and zeolitic water molecules. We found that PB nanolayers embedded in the upper and bottom regions of PE separator improve electrolyte wettability and ion selectivity of separator, effectively reducing cell resistance. In addition, they also significantly suppress TM crossover during cycling, even under harsh conditions (high cutoff potential of 4.6V) that would accelerate TM dissolution. When using a PB coated separator under a harsh condition, NCM||graphite full cells maintain 50.8% of their initial capacity at the 150th cycle. Therefore, we propose that through scalable production of PB-coated PE separator via facile synthesis method, our strategy can help establish and new research direction for the design of high-energy-density batteries in both academic and industrial field.

5:00 PM EN09.08.15
Universal Organic Anodes for Advanced Alkali Ion Batteries Using Halogenated Contorted Hexabenzocoronene Derivatives Seokhoon Ahn; Korea Institute of Science and Technology, Korea (the Republic of)

Contorted hexabenzocoronene (cHBC) derivatives, small organic semiconductors with nanographene were designed and synthesized for alkali-ion batteries such as Li-ion batteris, Na-ion batteries, and K-ion batteries. The aromatic core of cHBC is distorted away from planarity by steric congestion in its proximal carbon atoms. This unique structure of cHBC allows to form self-assembled molecular wires through pi-pi interactions. Lithium ions could be intercalated into the columnar structures of cHBC and stored with facile insertion and desertion advantages compared with graphite anode. Furthermore, when halogen atoms such as fluorine and chlorine are introduced into the outer shell of cHBC, larger alkali ions than lithium ion could be stored in the outer shell through interactions between halogen atoms and alkali ions, supported by simulation. Especially, chlorinated cHBC showed satisfactory cycling performance for NIBs and KIBs owing to the pseudocapacitive behavior with reversible specific capacities of approximately 175 and 260 mAh/g, respectivley.

A Prelithiated Silicon-Sulphur High-Capacity Battery with Promising Cycle-Life—A Micelle-Like Electrolyte Additive Suppresses the Polysulfide Dissolution Faiz Ahmed, Defu Li and Gao Liu; Lawrence Berkeley National Laboratory, United States

Prelithiated Si-S batteries are promising storage systems due to their high safety, low cost, and high energy density. However, the practical application of these batteries is limited because of the significant capacity decay as a result of active sulfur loss after charge-discharge cycling, and unstable solid-electrolyte interphase (SEI) on the Si anode [1-3]. Especially the loss of sulfur cathode is caused by the severe shuttle effect of dissolved polysulfide [3]. Several strategies have been reported to suppress the active sulfur loss, but the outcomes are far away from the commercial application of Li-S batteries [4-5]. To simultaneously solve the aforementioned problem, this work report on a novel prelithiated SiOx composite-S/C composite full-cell battery system. Herein, we have used an excellent strategy to suppress polysulfide dissolution using a micelle-like fluorinated ether-based additive with lithium bis(trifluoro-sulfonyl)imide (LiTFSI) electrolyte salts for Li-S battery applications. S/C composite is used as cathode material and prelithiated SiOx composite anode is used as an anode instead of Li-metal in order to avoid side reactions. The LiTFSI imide electrolyte with fluorinated ether-based additive exhibits better electrochemical stability, cycling stability, and a high specific discharge capacity of ca. 1318 mAhg^{-1} with the battery configuration of S/C composite//electrolytes//SiOx composite at 0.1 C. Furthermore, the results demonstrate that the 0.5M LiTFSI electrolyte with fluorinated micelle-based electrolyte additive shows excellent cycling performance by suppressing polysulfide dissolution with excellent capacity retention and coulombic efficiency (99.80%) after 1000 charge-discharge cycles. The newly developed prelithiated SiOx composite-S/C composite full cell achieves a high reversible capacity (924, and 914 mAhg^{-1} at 0.3 and 0.4 C, respectively), and long cycle life (capacity decay only 10% after 500 charge-discharge cycles). Scanning Electron Microscope (SEM) and X-ray photoelectron spectroscopy (XPS) are used to better understand the surface morphology of the cycle electrodes.

9:00 AM *EN09.09.01
An Ultrafast, Durable, and High-Loading Polymer Anode for Aqueous Zinc-Ion Batteries and Supercapacitors Xiaolei Wang; University of Alberta, Canada

With high theoretical capacities (820 mAh g^{-1} and 5855 mAh cm^{-3}), suitable electrochemical potential (−0.763 V vs standard hydrogen electrode), low cost, and rich abundance of component materials, aqueous zinc-ion batteries (ZIBs) and capacitors (ZICs) have exhibited great promise for grid-level energy storage and other stationary applications. Zn metal as excessive Zn are often used to compensate for the uncontrollable dendritic growth, corrosion behaviour, and low Coulombic efficiency (CE) of the Zn metal. As such, most of the ZIBs and ZICs developed using these electrode materials exhibited actual device energy and power densities that were significantly lower than the corresponding theoretical values. Another key performance metric that needs to be improved in ZIBs is their high-rate charge and discharge. In addition to the dendrite-derived problems commonly experienced in batteries based on other metal anodes, ZIBs are disadvantaged by hydrogen gas evolution from water decomposition especially under high-rate charge/discharge, leading to poor cycle life.
Herein, an ultrafast, stable, and high-loading polymer anode for aqueous Zn-ion batteries and capacitors (ZIBs and ZICs) is developed by engineering both the electrode and electrolyte. The anode polymer is rationally prepared to have a suitable electronic structure and a large π-conjugated structure, whereas the electrolyte is manufactured based on the superiority of triflate anions over sulfate anions, as analyzed and confirmed via experiments and simulations. This dual engineering results in an optimal polymer anode with a low discharge potential, near-theoretical capacity, ultrahigh-loading capability (≈50 mg cm^{-2}), ultrafast rate (100 A g^{-1}), and ultralong lifespan (one million cycles). Its mechanism involves reversible Zn^{2+}/proton co-storage at the carbonyl site. When the polymer anode is coupled with cathodes for both ZIB and ZIC applications, the devices demonstrate ultrahigh power densities and ultralong lifespans, far surpassing those of corresponding Zn-metal-based devices.

9:30 AM EN09.09.04
First Principle and Machine Learning Study to Elucidate the Behavior of Vanillin for Enhancing the Coulombic Efficiency of the Zn Anode in Aqueous Zinc Ion Batteries Yaqiong Li[1], David Hoang[2], Xiulei (David) Ji[2] and Peter A. Greaney[1]; [1]University of California, Riverside, United States; [2]Oregon State University, United States

Zinc metal batteries have been widely researched due to their low-cost, low toxicity, and high theoretical capacity advantages. However, the problem of corrosion of the zinc metal anode (ZMA) has not yet been solved. In this project, we focus on the effect that adding small quantities of vanillin has on improving the Coulombic efficiency of plating Zn from a highly concentrated Water-in-Salt Electrolyte. Specifically, we use molecular dynamics (MD) simulations and ab initio calculations to understand the role that vanillin and its derivatives play in displacing water from the solvation shell of Zn ions at the ZMA surface. To achieve this, we have used Gaussian process regression and Bayesian inference to accelerate our exploration of these solvation structures on the Zn substrate.

Environmentally Friendly Phytic Acid Additive Enabling Simultaneous Optimization on Electrode Interface and Coordination Environment for Stable Aqueous Zinc-Ion Batteries Yimei Chen and Xiaolei Wang; University of Alberta, Canada

Despite with advantages of water compatibility, low cost, high safety and capacity, aqueous zinc ion batteries (ZIBs) are facing challenges from zinc dendrite, side reactions and low coulombic efficiency, which limits their broad application and mass production. In this paper, phytic acid (PA), an inositol polyphosphate, is introduced as an additive in 1M ZnSO$_4$ electrolyte to suppress zinc dendrite and H$_2$ evolution. The simulation and experimental results show that the phytic acid additive can absorb on the zinc anode surface, covering the active sites for H$_2$ production and guiding the uniform diffusion and deposition of zinc ions. Besides, PA has six phosphate groups, with each phosphorus atom bounding to 4 oxygen atoms. The electronegative oxygen atoms have a strong affinity to Zn^{2+}, and can compete with water molecules in the Zn (H$_2$O)$_6$$^{2+}$, changing the coordination environment of zinc ions. With PA additive, the zinc dendrite and side reactions are suppressed, and a high coulombic efficiency of 99.4% and long cycling stability of more than 1200cycles can be obtained at the current density of 1mA cm^{-2} and capacity of 1mAh cm^{-2}. When coupling with I$_2$/AC cathode, the full cell with PA additive delivers a high capacity of 120mAh g^{-1} at current density of 1A g^{-1}, and can stably cycle for more than 3000cycles, while the battery using 1M ZnSO$_4$ failed at 1300cycles. This work provides a simple but promising approach to the development of high-performance aqueous ZIBs.

10:30 AM EN09.09.06
Modeling to Reveal the Synergistic Effect from Organic Additives that Enhance the Coulombic Efficiency of Zn metal batteries Yanke Fu[1], Heng Jiang[2], Longteng Tang[2], Chong Fang[2], Xiulei (David) Ji[2] and Alex Greaney[1]; [1]University of California, Riverside, United States; [2]Oregon State University, United States

Aqueous zinc metal batteries are a promising technology for safe, cost-effective, and sustainable grid-scale energy storage. However, their commercialization has been stymied by the hydrogen evolution reaction (HER) which parasitically corrodes the active mass of the Zn metal anode during plating/stripping. We have developed a highly concentrated aqueous electrolyte that all but eliminates the HER and enables dendrite-free Zn plating/stripping with 99.9% Coulombic efficiency under the low current density operating conditions where the HER is most problematic. The electrolyte is a highly concentrated "water-in-salt-electrolyte" with two organic additives. This talk will present the results of our *ab initio* molecular dynamics simulations that, when interpreted in conjunction with the results from careful NMR and femtosecond stimulated Raman spectroscopy, reveal the synergistic way in which these organic additives alter the Zn^{2+} solvation structure, and enable formation of a protective organic solid electrolyte interphase (SEI) layer. This electrolyte opens the door to commercially viable rechargeable aqueous zinc metal batteries.

10:45 AM EN09.09.08
Evaluating Li Ion Storage Mechanism In Carbon Nanotube (CNT) Anodes For High Energy Density Li-Ion Batteries: An Atomistic Perspective
Aniruddha M. Dive, Kathleen E. Moyer-Vanderburgh, Francesco Fornasiero and Liwen Wan; Lawrence Livermore National Laboratory, United States

Current Lithium-ion batteries (LIBs) are limited to energy densities of ~150 Wh/kg and pose safety issues associated with dendrite formation and the use of flammable liquid electrolytes that can result in the common battery failure known as thermal runaway and explosion. Lithium metal is an ideal anode for high energy density LIBs due to its high theoretical capacity (3860 mAh/g) but is dangerous due to its propensity to form dendrites. Carbon nanotubes (CNTs) with superior electronic, mechanical, and structural properties provide an exciting alternative as anode for high energy density LIBs. LIBs with vertically aligned CNTs forest help achieve the capacity retention > 80% and superior efficiency over 1000 charging-discharging cycles. However, a fundamental understanding of Li$^+$ ion storage within CNT anodes is largely unexplored and lacking.

Experimental characterization of Li$^+$ ion storage in CNT anodes is expensive and challenging. Previous theoretical studies have evaluated storage mechanism for isolated Li$^+$ ions within small diameter CNTs (< 1.5 nm) forest. In common organic liquid electrolytes, Li$^+$ ions prefer to be solvated and therefore isolated Li$^+$ ions cannot accurately describe the Li$^+$ storage mechanism especially in large diameter CNTs. In the current study, we carefully investigated the de-solvation mechanisms for Li$^+$ ions in EC: EMC (3/7 w/w) 1.2 M LiPF$_6$ liquid electrolytes both inside and outside of pristine CNT. The calculated de-solvation energies for Li$^+$ ion adsorption onto the outside surface (~0.4-0.5 eV) of CNTs show relatively lower energies as compared to inside surface (~ 0.9-1.0 eV) of CNTs. We therefore claim that the Li$^+$ ion storage strongly occurs on the outside surface of pristine defect-free CNTs. We further employ classical molecular dynamics simulations to investigate the Li$^+$ ion storage on the outside of CNTs. The classical molecular dynamics simulations reveal a capacitive-type storage mechanism for pristine CNTs forest. Recent experimental reports suggest a large fraction of storage mechanism in CNT anode to be capacitive type (> 55 %) which supports the findings from atomistic modeling. Introducing structural defects (n-membered C-C rings), functional groups (-OH, =O, -COOH) etc… can lead to intercalation or plating-type Li ion storage in CNT forest which would result in higher capacity as well as energy density. However, for pristine CNTs we report the Li$^+$ ion storage mechanism to be purely capacitive and therefore would serve as potential supercapacitor rather than battery.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

11:00 AM EN09.09.09
Catalysing the Performance of Li-Sulfur Batteries with Two-Dimensional Conductive Metal Organic Frameworks Preeti Bhauriyal and Thomas Heine; Technische Universität Dresden, Germany

At present, the efficiency of high energy density Li-sulfur (Li-S) batteries is being narrowed by the limited strategies to deal with the shuttling effect, sluggish redox kinetics and poor ionic and electron conductivities of the cathode hosts. Recently synthesized triphenylene based two-dimensional conductive metal organic frameworks (2D MOFs) hold the promising characteristics to overcome the limitations with suitable pore and anchoring sites along with the desired electron conductivity.1 In this study, we use density functional theory calculations to investigate 2D honeycomb MOFs with hexa-substituted triphenylene linkers with pairs of varying metal ions (Cu, Ni, and Co) and functional groups (N, O, and S) (M3(2,3,6,7,10,11-hexaiminotriphenylene)2 (M3(HITP)2), M3(2,3,6,7,10,11-hexahydroxytriphenylene)2 (M3(HOTP)2) and M3(triphenylene-2,3,6,7,10,11-hexathiol)2 (M3(THT)2)) to be the potential cathode hosts in Li-S batteries and analyse their structure-activity relationship. The detailed study of structural-electronic characteristics followed by analysis of triangle of catalytic activity conclude that M3(HOTP)2 can deliver higher anchoring efficiency, but it suffers low redox reactivity with high Li diffusion and Li2S decomposition barrier, whereas M3(HITP)2 MOFs appear insubstantial with the possibility of Li polysulfide shuttling resultant of the lower anchoring. Co3(THT)2 not only has superior anchoring efficiency (-1.40 to -2.68 eV) but also shines in facile Li+ diffusion (0.68 eV), small Gibbs free energy requirement of 0.68 eV for Li polysulfide reduction and moderately low Li2S decomposition barrier (1.06 eV) that simultaneously contribute to the performance of Li-S batteries. Our study concludes that the combination of Co and S in Co3(THT)2 make the most suitable cathode host and provides a basis for the designing and screening of new materials having such active components to achieve high performance Li-S batteries.

11:15 AM EN09.09.10
Different Electrochemical Reaction of Metal Hexacyanometallate According to the Electrode Kinetics Ahreum Choi[1], Taewon Kim[1], Min-Ho Kim[1], Seok Woo Lee[2], Young Hwa Jung[3] and Hyun-Wook Lee[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Nanyang Technological University, Singapore; [3]Pohang Accelerator Laboratory, Korea (the Republic of)

Na-ion batteries (SIBs) have received considerable interest owing to the abundance and even distribution of Na compared to those of Li. Metal hexacyanometallates, known as Prussian Blue analogues (PBAs), have been considered as the promising cathode materials for SIBs, because of the inherent advantages of PBAs involving large channel sizes that allow accommodating Na ions. Manganese hexacyanomanganate shows the highest capacity (~200 mAh g^{-1}) among PBAs, accompanying the abnormal insertion of two Na ions in a sub-unit cell. However, the structural distortion by strong Jahn-Teller effect of high-spin Mn(III) aggravates the cyclability of manganese hexacyanomanganate. Herein, we report that manganese hexacyanomanganate shows different electrochemical reaction according to its kinetic properties. Under the sufficiently fast reaction rate, the charge redistribution can be triggered (low-spin Mn^{III} + high-spin Mn^{III} → low-spin Mn^{II} + high-spin Mn^{IV}) instead of Jahn-Teller effect. The relation between kinetic property and the electrochemical reaction of manganese hexacyanomanganate is supported by the analysis through X-ray absorption near-edge spectroscopy (XANES) and X-ray photoelectron spectroscopy (XPS). Moreover, different crystal structures reported by using postmortem synchrotron X-ray diffraction analysis (synchrotron XRD) provide a clue to the mechanism of charge redistribution. The long bonding length between transition metal and ligands in the orthorhombic structure could activate charge redistribution based on the superexchange rule. In this work, we report the charge redistribution mechanism which is the new electrochemical reaction of manganese hexacyanomanganate under the fast kinetics environment. As a result, the unstable redox reaction of high-spin Mn(III) can be stabilized, improving cycle performance of manganese hexacyanomanganate. These results can pave the way for high-performance Na-ion batteries.

Melanin and Polypyrrole Coated Nanocellulose Hydrogel Networks for Energy Storage Noah Al-Shamery, Tobias Benselfelt and Pooi See Lee; NTU Singapore, Singapore

Melanins are black-brown pigments of a specific class of poly indolequinones found in nature and inside the human body. [1] They are responsible for processes like photoprotection, radical scavenging, and metal ion chelation. More recently, there has been significant interest in eumelanin as a functional material due to its macromolecular structure and the exploitation of the quinone-hydroquinone redox equilibrium. [1] While eumelanin can be used in many promising applications for environmental, health, energy storage, and sensor devices, melanins are insoluble in most solvents, limiting their processing into homogenous materials and coatings. [2] One avenue that has shown promise for providing a stable network substrate for eumelanin devices is incorporating cellulose nanofibrils (CNFs), a nanoscopic material that originates from plant biomass. [3] In this work, a flexible network consisting of CNFs coupled with conductive polypyrrole (PPy) is utilized to form a functional eumelanin hydrogel material for energy storage applications. The resultant energy densities and conductivity values measured against Zn as the counter electrode in a 0.1M $ZnSO_4$/0.9M Na_2SO_4 aqueous electrolyte surpass those in other synthetic eumelanin composite materials using polyvinylidene fluoride (PVDF) and carbon black. According to scanning electron microscopy and electrochemical impedance spectroscopy, the improved energy densities can be attributed to reduced internal resistance due to the conductive pathways afforded by the conductive PPy vapor-phase polymerized on top of the eumelanin interacting with the CNFs, thus creating a core-shell structure with a PPy concentration gradient decreasing to the inside of the material. A hypothesis for this behaviour is that due to the amphiphilic nature of PPy, this structure has increased hydrophobicity on the outside but is permeable for charges by offering hopping sites to the core where more redox centers are available from the eumelanin. Under atmospheric pressure, this reduces the amount of water from outside conditions penetrating the structure and competing with the electrolyte, thus decreasing the inactive mass in the material significantly. Together with the added redox centers provided by the eumelanin, this could be the reason for the increased energy density. This material was then tested in aqueous electrolyte zinc coin cells, where it was shown to have charge/discharge stability for over 1300 cycles, showcasing this composite material type as a promising eumelanin-based composite energy storage material.

10:35 AM EN09.10.02
Aqueous Organic Redox Flow battery for Grid Energy Storage Dawei Feng; University of Wisconsin--Madison, United States

An increasing amount of renewable energy sources are being integrated into the electric grid in the US and around the world. However, as intermittent wind and solar begin to approach more than a quarter of grid energy production, significant energy storage technology must be employed as well to mitigate the unbalanced energy production and demand in the grid. To meet the emission targets in an economically viable manner, low-cost grid-scale energy storage technology must be developed. This talk will compare different battery technologies and describe our efforts in development of new generation of inexpensive redox active species for redox flow batteries (RFB) that can offer extraordinary energy density and cycling stability. This involves identification of critical needs for redox couple design in RFB and development of simplest yet effective synthetic routes towards redox active molecules with desired performance.

10:50 AM EN09.10.03
High-Donor Electrolyte Additive for Stable Aqueous Zinc Batteries Wenjing Deng and Xiaolei Wang; University of Alberta, Canada

As one of the emerging secondary batteries, rechargeable aqueous zinc-ion batteries (AZIBs) are prevailing over conventional lithium-ion batteries counterparts in terms of low cost, environmental benignity, and intrinsic safety. Metallic zinc anode is highly prized due to its low redox potential, high theoretical capacity, earth-abundance, and water compatibility. Despite these attractive merits, critical issues of unstable Zn chemistry in conventional aqueous electrolytes such as dendrite growth, hydrogen evolution and side reactions would inevitably provoke surface corrosion and damage the anode-electrolyte interface during battery operation. electrolyte engineering *via* introducing additives may become one of the most expedient solutions to achieve anti-side reactions and smooth deposition simultaneously. For parameter, Gutmann donor number (DN) reflects the intrinsic capacity of electron-donating, which can be used to indicate the solubility of intermediate products and the variation of the hydrogen-bonding network in aqueous electrolytes. A unique and facile strategy to improve Zn reversibility in aqueous batteries by tailoring electrolyte solvation structure with high-donor-number N, N-dimethyl acetamide (DMA) solvent additive. it is demonstrated that high-donor DMA additive with strong electron-donating ability can confine free water activity, replace the water in Zn2+ solvation sheath, and reshape hydrogen-bonding network of water, which is highly conducive to reducing the reaction activity. DMA additive is proven capable of replacing coordinated water molecules and participating in the solvated Zn^{2+} sheath, contributing to the restraint of dendrite growth and side reactions. The DMA-modified electrolyte enables remarkable suppression of water-involved hydrogen evolution and severe corrosion, which contributes to preferentially uniform deposition and ultralong cycling life of 4500 h at current density of 1 mA cm^{-2} in symmetric cell, and high Coulombic efficiency of 99.6% in asymmetric cell. Besides, with solvation modulation, full batteries of Zn//VO_2 exhibit long-term cycling performance of 500 cycles and withstand subzero temperature condition. This regulation strategy employing high-donor solvents as additives thereby verifies the effectiveness of aqueous batteries.

11:05 AM EN09.10.04
Abstract Presented (ON-DEMAND ONLY) Low Concentration Sulfolane-based Electrolyte for High Voltage Lithium Metal Batteries Pengcheng Li and Ge Li; University of Alberta, Canada

Electrolyte engineering is crucial for the commercialization of lithium metal batteries. Here, lithium metal is stabilized in highly reactive sulfolane-based electrolyte under low concentration (0.25 M) for the first time. Inorganic-polymer hybrid SEI with high ionic conductivity, low bonding with lithium and high flexibility enables dense chunky lithium deposition and high plating/stripping efficiency. LCE also enables excellent cycling stability of NCM523/Li cells at 1 C (90.7% retention after 500 cycles) and 0.3 C (83.3% retention after 1000 cycles). Even with a low N/P ratio (~2), the capacity retention for NCM523/Li cells can achieve 94.3 % after 100 cycles at 0.3 C. The exploring of the LCE is of paramount significance because it provides more possibilities of the lithium salts selection, especially reviving some lithium salts that are excluded before due to their low solubility. More importantly, LCE has the significant advantage of commercialization due to the cost effectiveness.

11:20 AM EN09.10.05
A Fast, Stable, and Thick Polyimide Anode for Aqueous Zinc Batteries and Capacitors Zhixiao Xu and Xiaolei Wang; University of Alberta, Canada

Zn metal has shown promise as an anode material for grid-level energy storage, yet is challenged by dendritic growth and low Coulombic efficiency. Herein, an ultrafast, stable, and high-loading polymer anode for aqueous Zn-ion batteries and capacitors (ZIBs and ZICs) is developed by engineering both the electrode and electrolyte. The anode polymer is rationally prepared to have a suitable electronic structure and a large π-conjugated structure, whereas the electrolyte is manufactured based on the superiority of triflate anions over sulfate anions, as analyzed and confirmed via experiments and simulations. This dual engineering results in an optimal polymer anode with a low discharge potential, near-theoretical capacity, ultrahigh-loading capability (≈50 mg cm^{-2}), ultrafast rate (100 A g^{-1}), and ultralong lifespan (one million cycles). Its mechanism involves reversible Zn^{2+}/proton co-storage at the carbonyl site. When the polymer anode is coupled with cathodes for both ZIB and ZIC applications, the devices demonstrate ultrahigh power densities and ultralong lifespans, far surpassing those of corresponding Zn-metal-based devices.

From Waste to Energy—Extraction of Mesoporous Nanocomposites from Spent Li-Ion Batteries for High-Performance Supercapacitor Devices with Ultra-High Stability Yasmine I. Mesbah; American University in Cairo, Egypt

Lithium-ion batteries (LIB) are one of the most significant energy storage devices used nowadays. However, a huge number of spent batteries bring harmful resource waste and environmental hazards due to heavy metals and organic electrolytes. Consequently, recycling spent LIB has become a hot topic lately, where researchers are actively working to develop a plethora of methods to extract valuable metals and components. In this study, mesoporous Li-Ni-Mn-Co oxide nanoparticles have been successfully extracted from spent Li-ion batteries using a simple microwave/precipitation method. The extracted Li-Ni-Mn-Co oxides were used to construct functional supercapacitor devices. However, the extracted oxides showed poor stability and low conductivity. To enhance cycling stability and conductivity, fullerene (C76) is used as a carbon additive to form Li-Ni-Mn-Co oxide/C76 nanocomposite material. The morphological, structural, and compositional analyses were performed using FESEM, HRTEM, XRD, and XPS techniques. The Li-Ni-Mn-Co oxide/C76 nanocomposite exhibits high conductivity and high wettability with an enhanced gravimetric capacitance of ~357 Fg-1 at 1.0 Ag-1. The asymmetric supercapacitor devices deliver specific energy as high as ~21.3 Wh/kg at a specific power of ~800 W/kg and a superior retention rate of ~115% after 20,000 cycles with ~100% Coulombic efficiency.

Study of Alternative Eco-Friendlier Wood-Plastic Composites of Recycled HDPE Enhanced with Hemp Fibers Iouliana Chrysafi, Eleftheria Xanthopoulou, Alexandra Zampoulis and Dimitrios Bikiaris; Aristotle University of Thessaloniki, Greece

Plastics are the most widely used materials that can be found in almost every human made object and often replace traditional resources such as wood, metal and glass. High-Density Polyethylene (HDPE) replaces many natural resources, due to the low cost and easy processing, but its ever-increasing wastes make it harmful to the environment. Thus, many processes are used to recycle it. On the other hand, the continuous consumption of natural resources that causes a downgrading of the sustainability of the natural environment led the scientific community to study alternative products as a replacement for natural wood. Such alternative materials can derive from agricultural crop residues. Hemp is an ideal replacement for wood due to its lightweight, hydrophobic characteristics, and excellent long-term mechanical stability, with the lowest carbon emissions footprint.

The aim of this research is to use alternative products for the construction of wood-plastic composites (WPCs), as an eco-friendlier solution, that can be used in the construction of floor surfaces, objects, in the interior or exterior spaces, in the construction of frames, and door leaves, but also in the automotive industry in the interior of the car. So, the main goal is the use of recycled HDPE and the replacement of wood with hemp crop residues. In the present work, HDPE was recycled through mechanical and thermal processes (r-HDPE). More specifically, HDPE waste plastics were grinded through a mill and thereafter, extruded through a Haake-Buchler Rheomixer. The thermal and mechanical properties of r-HDPE have been tested compared to HDPE and it was found that after recycling the properties of r-HDPE are not affected so the enhancement with the hemp fibers followed. Composites containing 10, 20, 35 50 and 75% wt. of hemp fibers were prepared also by melt mixing. To improve the adhesion between the fibers and the polymer matrix Joncryl ADR-4400 (JC) and propylene grafted-maleic anhydride (PPgMA) compatibilizers were used.

In this study the chemical, structural, thermal, and mechanical properties of the r-HDPE-hemp fiber composites are examined and the composites with the different compatibilizers are compared. Testing the structural properties of the composites by X-Ray Diffraction (XRD), it is found that the samples are semicrystalline, and their crystallinity decreases with the increase of the hemp fibers content, while there is a shift in the peaks due to the expected disruption of the arrangement of the polymer chains by the addition of the fibers. From the Fourier Transform Infrared Spectroscopy (FTIR) it is concluded that the addition of compatibilizers does not change the chemical structure of the materials. Thereafter, the thermal properties of composites are measured by Thermogravimetric Analysis (TGA) and Differential Scanning Calorimetry (DSC). So, it is concluded, that the compatibilizers do not affect the thermal properties of the composites and the decrease on thermal stability will not affect their application in WPCs. Moreover, the decomposition steps were separated dur to the degradation of hemicellulose, cellulose, lignin and rHDPE, respectively. Finally, the mechanical properties are examined by tensile and impact strength experiments. A decrease in tensile and impact strength as the content of the fibers increases due to the higher creation of crack points in the polymeric matrix is observed. However, the enhanced elongation at break is encouraging for their application at WPCs.

All in all, the results of this study are positive and in conjunction with other tests concerning the degradation of the samples, the construction of different WPC-based objects will be feasible in the near future.

Acknowledgments: This research has been co-financed by the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship and Innovation, under the call RESEARCH-CREATE-INNOVATE (project code: T2EΔK – 00008).

Editing Degradable Polycarbonates from Waste Resources Fabiana Siragusa, Thomas Habets, Bruno Grignard and Christophe Detrembleur; University of Liege, Belgium

Designing new polymers from wastes while making them intrinsically degradable has become a new challenge to overcome the plastic waste accumulation in the environment and the associated pollutions. Recently, we engineered a novel synthetic pathway to create polycarbonates[1] by the room temperature step-growth copolymerization of highly reactive CO$_2$-sourced exovinylene biscyclic carbonates with various diols derived from biomass[2] or waste commodity plastics. These innovative low carbon footprint polymers are thermally stable, isolable and processable. On the path to circularity, their unique microstructural features offer competitive depolymerization scenarios, enabling the formation of new value-added organic scaffolds that can serve as organic building blocks in medicinal chemistry and organic synthesis, or as monomers for producing new polymeric materials[3,4]. In this talk, we will discuss how these polycarbonates can be easily depolymerized, with a special emphasis to describe the mechanism and the selectivity of the depolymerization process.

Poly(oxazolidone)s as the Next Generation of Non-Isocyanate Polyurethanes—A Facile Access to Recyclable Advanced Materials Thomas Habets, Bruno Grignard and Christophe Detrembleur; University of Liege, Belgium

Polyurethanes (PUs) are world-class relevant materials entering in the conception of multiple daily life applications such as elastomers, foams, adhesives, paints, medical devices… Among them, poly(oxazolidone)s, i.e. polymers characterized by cyclic carbamates repeating linkages, display unique thermal and chemical stabilities making them valuable options for designing the next generation of high performances materials. However, these polymers are commonly prepared by reacting in harsh conditions epoxides with harmful and nasty isocyanates, which utilization is now regulated by REACH legislation. Recently, we engineered a novel sustainable approach toward poly(oxazolidone)s by the valorization of CO_2 and readily available synthons[1–5]. The labile behavior of new discovered bonds was studied at the model molecule level before being implemented to polymeric materials. This novel approach quickly gives access to diversified CANs (covalent adaptable networks) with tunable properties by virtue of monomer design. The so-produced materials can be easily recycled upon thermal reprocessing such as thermoplastic materials while benefiting from the properties of thermosets in working conditions. Besides, chemical recycling of these materials delivers starting building blocks that might re-enter the loop or benefit as valuable building blocks in various fields.

9:30 AM EN10.01.05
The Role of Plastic-to-*x* Technologies in a Circular Economy for PET Bottle Resin Taylor Uekert, Tapajyoti Ghosh, Julien Walzberg and Alberta Carpenter; National Renewable Energy Laboratory, United States

The United States generates the most plastic waste of any country and is a top contributor to global plastic pollution. A portfolio of end-of-life strategies must be implemented to minimize environmental impacts and retain valuable plastic material, but it can be challenging to determine how these options compare, especially when they generate products of different values and lifetimes. Here, we use a material flows model equipped with consequential life cycle assessment (LCA) to estimate the circularity, economic cost, and environmental impacts of polyethylene terephthalate (PET) down-cycling by mechanical recycling, closed-loop recycling by glycolysis, up-cycling to fiber-reinforced resin, and conversion to non-plastic products (electricity, oil) on a United States economy-wide basis with annual time resolution. The framework can implement PET end-of-life pathways over time, and uses the resulting trends to predict an optimal sequence of technology phase-in (or phase-out) that maximizes PET circularity while minimizing overall greenhouse gas emissions and cost. This analysis enables consistent comparison of plastic-to-*x* processes on an “apples-to-apples” basis, thereby facilitating prioritization within the ever-growing PET recycling research space.

10:15 AM EN10.01.06
Molecular Cages for Automated Chemical Separation in Continuous Flow System Jiratheep Pruchyathamkorn; University of Cambridge, United Kingdom

Chemical separation is essential for several industrial processes, waste water purification, air cleaning, drug synthesis and synthetic research in laboratory. The challenges we are facing now such as global warming and limited oil supplies mean that we must use resources more wisely. To solve these problems, new strategies are required that are more efficient, more environmentally friendly and less energetically costly than those currently employed, as well as economically worth for applying to industry. Metal-organic coordination cages provide new opportunities to address the need for improved separation technologies. Recent work in this field has demonstrated that these containers can encapsulate specific guest species and act as vehicles for targeted molecular transport and separation.

We synthesised $Fe^{II}_4L_4$ water-soluble cage via ‘subcomponent self-assembly’ technique, based on a diamino terphenylene subcomponent, bearing chiral glyceryl groups. The aqueous solution of this cage was used as a liquid membrane in a triphasic U-shaped tube system, separating two organic layers, the feedstock and receiving phases. The cage is able to encapsulate specific guest compounds from a mixture in the feedstock phase and release them in the receiving phase. We could separate naphthalene from larger aromatic compounds such as triisopropylbenzene, as well as ferrocene from its larger derivatives. Within the U-tube system, the transport of compounds was monitored by NMR, GCMS and UV-Vis spectroscopy. To understand the system better, we proposed a kinetic model that can be used to explain the guest transport process, and studied the effect of competing guests on the rate of transport of the selected compounds.

We demonstrated that there is need to improve the bulk liquid membrane separation system to facilitate faster transport, in order to allow it to be used for extraction in industries. It took over 50 days in the U-shaped tube setup for the transport of ferrocene through the cage solution to reach equilibrium. Hence, we designed and optimised a slug flow system to obtain the conditions that offer best extraction efficiency. The continuous flow system gave significantly greater contact areas between phases with better mixing caused by the chaotic internal circulation within the flow, resulting in faster transport (within hours), less amount of solvents needed and less energy required for extraction. The cage could be automatically recycled, and the extraction progress could be monitored in real time by UV-Vis spectroscopy. Further work is being done to precipitate out ferrocene after the guest release, shifting the equilibrium toward the completion of the extraction process in continuous flow system.

This finding is highly industrially relevant, and the main goal is to open up new opportunity for industries requiring novel chemical separation technique.

10:30 AM EN10.01.07
Closed-loop Recycling of Topochemical Polymer Single Crystals Zitang Wei, Xuyi Luo and Letian Dou; Purdue University, United States

Plastics play crucial rules in almost every aspect of life. Unique properties of plastics like chemical and light resistant, strong, moldable, and low cost make plastic materials useful in many aspects of our global society. However, largely relying on feedstock resources like fossil fuels, plastics production is not sustainable. Thus, plastic recycling could be an efficient alternative to save feedstock resources as well as to reduce production cost.
Recently, a series of polymer materials synthesized via topochemical polymerization are considered as strong candidates for next generation recyclable plastics. It is well-known that topochemical polymerization has high efficiency and environment-friendly features, such as solvent-free and catalyst-free reaction conditions, high reaction yield without side reactions, and atom economy. Yet, there exist few studies on depolymerizing and recycling those polymers. In 2014, Dou et al synthesized a topochemically polymerizable polyindenedione derivative [2,2'-Bi-1H-indene]-1,1'-dione-3,3'-diyl dialkylcarboxylate (BIT) system. In this study, high-quality polymer single crystals can be obtained by shining visible light and the polymerization yield is quantitative. Interestingly, in the polymer single crystal structures, a newly formed elongated carbon-carbon bond with length of 1.59Å was discovered, which is longer than normal carbon-carbon single bond (~1.54 Å). Inspired by this discovery, we demonstrate a topochemical approach for creating elongated C–C bonds with a bond length of 1.57~1.63 Å between repeating units in the solid state with decreased bond dissociation energies. 12 distinct polymers from three different classes exhibit rapid depolymerization via breakage of the elongated bond within a desirable temperature range (140~260 °C) while otherwise remaining remarkably stable under harsh conditions. Additionally, one-dimensional polymer single crystals can be processed into two-dimensional thin films and can be melt processed for 3D printing. Processed polymers can maintain a high depolymerization yield with tunable mechanical

properties. This work provides a unique strategy of solving plastic recycle issue by novel molecular design, careful single crystal analysis and innovative material processing.

10:45 AM EN10.01.08
Intrinsic Activity of Silica-Alumina for the Conversion of Polyethylene into Tunable Aromatics Below Pyrolytic Temperatures Makenna Pennel and Matteo Cargnello; Stanford University, United States

Plastic waste is a growing catastrophe that lacks global strategy, largely due to inadequate recycling capabilities. The search for a superior recycling process has spanned decades and disciplines, but recently, low-temperature hydroconversion reactions have gained increasing attention. These reactions typically produce fuel-range alkanes using moderate hydrogen pressures, but questions surround the economics of such conversions given the products are of relatively low monetary value. Other low-temperature reactions that produce value-added products have been proposed. One prominent example is the hydrogen-free tandem hydrogenolysis/aromatization reaction pioneered by Zhang et al., which converts polyethylene into alkylaromatics using a Pt/Al_2O_3 catalyst at 280 °C. These compounds are valuable as lubricants and are currently produced through more energy-intensive routes. A techno-economic assessment for this type of polymer conversion has not been published, but the catalyst will undoubtedly be a cost driver given the low polymer/catalyst ratios and energy-intensive catalyst regeneration procedures detailed in the literature. Lowering catalyst costs and increasing efficiency are paramount to moving the technology forward.

In a preliminary step to address these problems, we examined the intrinsic activity of nominally metal-free, mesoporous silica-alumina mixed oxide materials (SiO_2-Al_2O_3) for the conversion of polyethylene into aromatic compounds. Herein, we demonstrate that SiO_2-Al_2O_3 deconstructs polyethylene into smaller, aromatic molecules under identical conditions as those used by Zhang et al. during reactions with Pt/Al_2O_3. Yields are comparable, the catalyst can be reused without regeneration, and product selectivity can be tuned by altering reaction conditions or the acidity of the SiO_2-Al_2O_3. Notably, the fraction of polyaromatic products increases with the Brønsted acidity of the catalyst, as does the degree of polymer deconstruction. Preliminary work on the mechanism of the reaction suggests that acid sites are responsible for initiating depolymerization and aromatization reactions in analogy to previous work in the literature. This work showcases the intrinsic activity of SiO_2-Al_2O_3 for polyolefin deconstruction/aromatization at sub-pyrolytic temperatures and lays the foundation for future studies involving solid acid and bi-functional catalysts.

11:00 AM EN10.01.09
Consumer Gatekeeping in Sustainable Materials Streams—An Application in Cellulose Nanomaterials Nasreen Khan, D. Cale Reeves and Blair K. Brettmann; Georgia Institute of Technology, United States

U.S. consumers spent 4.5 trillion dollars on goods while generating 292 million tons of municipal solid waste in 2018 – and trends in both spending and waste generation are increasing. Packaging and containers made of paper and paperboard (6.4 million tons) and plastic (10 million tons) are the greatest proportion of landfilled tonnage. Displacing plastic-based materials with bio-sourced materials may be consistent with green chemistry and engineering design principles but does not truly improve the circular economy if the bio-sourced materials travel straight to landfill. Consumers act as gatekeepers in a circular economy, determining which products and materials end up in landfill or are diverted back to post-consumer manufacturers. By understanding consumer behaviors around product acquisition and disposition, products can be manufactured to ensure that the value of materials is retained.
Here we develop a framework for incorporating consumer behavior into circular economy. We advance the green chemistry principle of F-factor by incorporating manufacturing efficiency and consumer behavior into the lifetime functionality of material mass. We demonstrate the framework using cellulose nanomaterials (CNMs) in packaging – a new bio-based material with the dual potential to be a "good citizen" in landfill and to contribute to post-consumer product manufacturing. The framework highlights how increased functionality, and thus the preservation of economic value, arises from the recirculation of material streams that pass through multiple sequential phases: from the manufacturing phase – where green chemistry principles can be applied - to product acquisition - where manufacturing decisions meet consumer decision-making – to product disposition – where consumer behavior dominates – and back to manufacturing. This approach reassesses the impact of sustainable manufacturing practices and showcases new strategic opportunities for high-impact policy interventions – targeting both manufacturers and consumers – to reduce wasted resources and improve the circularity of *function*.

11:15 AM EN10.01.10
Reactive Crystallization via Metal-Organic-Framework Formation Enables Separation of Terephthalic Acid from Textile Impurities Abigail K. Nason, Ronald Jerozal, Phillip Milner and Jin Suntivich; Cornell University, United States

Polyethylene terephthalate (PET) fibers are among the largest plastics in production. Used commonly in textiles, PET fibers are often blended with non-PET components such as cotton, dyes, and additives. As these non-PET components generate impurities during depolymerization, extracting high-purity terephthalic acid (TPA) monomer from the chemical recycling of textiles is challenging. Here, we demonstrate the extraction of high-quality TPA from the impure crude digestion mixtures containing depolymerized PET fibers and non-PET components. Our approach uses reactive crystallization to turn TPA into a metal-organic framework (MOF). As TPA is the only component in the mixture capable of forming an extended, crystalline structure, TPA monomers are separated from impurities as MOF crystallizes. We demonstrate this concept on recycled TPA (rTPA) extracted from a polyester-cotton blend textile through alkaline hydrolysis, where the impure rTPA was used as an organic linker to prepare MOF MIL-53(Ga). This MOF crystallization removed the trapped impurities. After MOF disassembly, colorless TPA, reminiscent of virgin-grade monomer, was obtained. These results demonstrate self-assembly-induced crystallization as a new strategy to selectively recover monomers from complex mixtures.

SESSION EN10.02: Decomposing Materials Wastes—Physical, Chemical and Biological Approaches II

Upcycling of Cotton-Based Textile Waste Using Different Recycling Strategies Following the Principles of Circular Economy Varvara Apostolopoulou Kalkavoura, Maria-Ximena Ruiz-Caldas, Natalia Fijol and Aji Mathew; Stockholm University, Sweden

To move from linear towards circular economy model several attempts to close the loop are necessary in every sector. The overconsumption of textiles threatens the environment due to the large land, water and pesticides use for cotton production, the dependance on the fossil-based resources for the production of synthetic fibers, including the release of microplastics during their repeating washing cycles, at the same time as the waste textiles are piling up in landfills or burned in incineration facilities. The challenges in the recycling of textiles are multiscale including the poor sorting, the lower post-consumer fiber quality or the difficulty to separate the pure constituents from blended fabrics.

Here we present and compare few recycling strategies mainly targeting the cotton. By acid hydrolysis using sulfuric or citric acid we are able to obtain cellulose nanocrystals (CNC) and separate them from the synthetic fibers. To identify what impacts the sustainability, we combined our experiments with a life cycle assessment following a cradle-to-cradle approach. One important outcome that increased the sustainability was the recovery of citric acid which had a purity over 90%. Another recycling route that allowed us to further compare the quality of the final products was to perform TEMPO mediated oxidation on cotton and blended fabrics. All processes were then compared to conclude which parameters affect the product yield, the potential for scaling up and the process sustainability.

The efficient recycling of cotton allows us to manufacture waste-based cellulose/nanocellulose materials which have the potential to be used in various applications such as thermal insulation, packaging and water purification. For instance, in our previous work cellulose nanomaterials foams from wood cellulose showed superinsulating properties even at moist conditions, thus recycled nanocellulose has the potential to be used in such applications too, paving the way to upcycle textile waste into high-performance materials.

2:00 PM EN10.02.02

Network Polyesters Enable Circular Uses of Important Petrochemicals and Materials Chen Wang; University of Utah, United States

The life cycle of today's polymer materials is linear. Globally, ~380 million tons/year of plastics are produced, of which only 16% are repurposed, and 67% are discarded in landfill and the environment. Unmanaged waste plastics have become a dire environmental crisis. Innovations are urgently needed to develop tomorrow's materials that are recyclable-by-design. In this presentation, I will discuss redesigning polyester materials for durable goods.

2:15 PM EN10.02.03

X-ray Studies to Elucidate the Effect of Substrate Morphology on Deconstruction Sarah A. Hesse[1,2], Christopher J. Takacs[1,2], Erika Erickson[3,2], Gregg T. Beckham[3,2] and Christopher Tassone[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]BOTTLE Consortium, United States; [3]National Renewable Energy Laboratory, United States

Plastics are becoming a pollution problem worldwide. Among those plastics is poly(ethylene terephthalate) (PET), one of the five most widely produced and used polymers today. Efforts are underway to create chemical and biological deconstruction pathways for PET, but challenges still remain. While the polymer conformation and morphology appear to play a significant role on the deconstruction of PET, this role is poorly understood. This talk aims to establish how morphology affects the deconstruction of PET, in particular PET deconstruction using PET hydrolases.

PET hydrolases are part of a small number of enzymes that have shown promise in facilitating PET deconstruction, catalyzing hydrolysis of the ester bonds in this ubiquitous synthetic polymer. While one can measure product release resulting from these enzymatic deconstruction reactions, very little is known about the interactions between the enzyme and the polymer during the interfacial biocatalytic reactions.

The current state of the art in characterizing the enzyme-to-substrate interaction relies upon computational chemical modeling and X-ray crystallography, where model PET oligomers (i.e., dimers and trimers) are docked or posed within the enzyme active site. These approaches do not take into consideration the various morphologies of different non-model PET substrates, or how the polymer chain is accessed by the enzyme in the first place. However, it is particularly the morphology and crystallinity of a given PET substrate that dictate the level of deconstruction activity of a particular PET hydrolase. We have used *in-situ* and *ex-situ* X-ray scattering techniques at the Stanford Synchrotron Radiation Lightsource to probe the nano (~1-100 nm) to atomic (<1 nm) length scales of polymers. Understanding the effects of polymer morphology on the enzyme activity will enable expansion to other polymer systems and deconstruction pathways.

Hydrothermal Liquification of Mixed Food and Plastic Waste from Supermarkets Panagiotis Evangelopoulos; RISE, Sweden

Every year in Sweden, more than 70 000 tonnes of expired food with the packaging from the supermarkets are discarded without passing through proper sorting[1]. Separating plastic packaging and food waste from retailers requires a lot of effort, is time consuming and thus costly. Therefore, in most of the cases the waste is not separated and plastic packaging together with the expired food ends up on the same waste fraction. The hydrothermal liquefaction (HTL) is a promising technology that can be applied into such heterogeneous waste fractions. This mild temperature thermal treatment process can be used for treating food waste together with the plastic packaging without sorting.

The proposed recycling route of HTL is aiming to introduce a new alternative recycling towards the concept of circular economy. Thermochemical processes are the foundation for recirculation of secondary raw materials. Chemical recycling decomposes organic matter into lower molecular weight compounds, leaving no microplastics preventing them from escaping to the aquifer. So, it can stop the occurrence of plastic debris in the environment. The products of HTL are hydrocarbon rich bio-oil that can be used for production of secondary raw materials and combustible gas that can supply the process with the energy needs.

The Hydrothermal Liquification (HTL) has been tested for several applications in the past with positive results. The main advantage of this process is that it can tolerate high moisture content of the feedstock, so no time and energy consuming drying of the feedstock prior to the process is needed[2]. In the case of mixed food waste with plastic packaging, the moisture content of the waste fraction is expected to be high, which makes HTL an attractive option. Another advantage is rather low temperature of the process, which results in lower energy consumption compared to other thermochemical processes. Using these processes, the part of waste that goes to energy recovery can be minimised, leading to lower CO_2 emissions. Moreover, the dependency from virgin raw materials can be reduced since less fossil resources would be needed for production of plastics.

[1] Food waste volumes in Sweden Reports, (n.d.).

3:45 PM EN10.02.05

Library of Sustainable, Functional Biocomposites Sabrina Shen, Nicolas A. Lee and Markus Buehler; Massachusetts Institute of Technology, United States

Conventional engineering materials often have poor degradation mechanics or recyclability, resulting in accumulation of solid waste that leads to the deterioration of ecological processes. Furthermore, there is significant confusion surrounding recycling infrastructure and concepts of biodegradation and compostability, especially amongst the general population. Rather than improving degradability or recyclability of conventional materials, here we present an alternative approach that uses abundant natural materials to create functional biocomposites that are suitable for conventional or additive manufacturing methods. By combining various organic "binders" and "fillers" with diverse physical,

mechanical, and chemical properties, we create a library of materials that are fully nontoxic and biodegradable in ambient conditions. With sufficient understanding of the behavior of complex biocomposites, functional degradable materials can be tailored toward unique applications.

4:00 PM EN10.02.06
Enabling Circular Polymers Through Computational Design Alexander R. Epstein[1], Xiaoxu Ruan[1], Jeremy Demarteau[2], Eric A. Dailing[2], Rishabh D. Guha[2], Orion Cohen[1], Ryan Kingsbury[2], Brett A. Helms[2,2,2], Stephen J. Cox[3] and Kristin A. Persson[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of Cambridge, United Kingdom

Monomer-to-monomer recycling is a promising solution to the global plastic pollution crisis but is not feasible for most conventional plastics due to the difficulty of selectively cleaving a carbon-carbon backbone. One solution is to design polymers to incorporate bonds that can be selectively broken in specific chemical processes. This work demonstrates how computational tools can be used to develop mechanistic insights into how bond chemistry enables monomer-to-monomer recycling. Specifically, we used both classical and quantum methods to simulate the acid-catalyzed hydrolysis mechanism that enables recycling of a new polymer platform, poly(dikeotenamine)s (PDKs), which have been shown to display chemical circularity with >90% monomer yield. We find that the depolymerization rate of PDKs can be greatly varied through heteroatom and functional group substitutions on the monomer and crosslinker. This variance in depolymerization rate arises from unique mechanisms depending on the type and location of chemical substitution; thus, we used simulations across a range of length and time scales in order to examine a range of effects. By understanding how chemical bonding affects PDK recycling, we design the chemistry of PDKs to target specific properties while retaining recyclability. We discuss several cases in which computational and experimental design worked in close collaboration to develop diverse PDK formulations.

4:15 PM EN10.02.07
Illuminating Catalytic Polymer Deconstruction Processes to Understand Effects Beyond the Reaction Center Christopher Tassone[1,2], Gregg T. Beckham[2,3], Nicholas A. Rorrer[3,2], Sarah A. Hesse[1,2], Anjani K. Maurya[1,2], Robert Allen[3,2], Christopher J. Takacs[1,2], Gorugantu Sri Bala[4,2], Linda J. Broadbelt[4,2], David Brandner[3,2], Katrina Knauer[3,2], Kevin Sullivan[3,2] and Bonnie Buss[3,2]; [1]SLAC, United States; [2]BOTTLE, United States; [3]NREL, United States; [4]Northwestern University, United States

Over the last several years the development of catalytic deconstruction approaches has been extremely successful. Homogeneous catalytic approaches have resulted in high selectivity to specific products, with high activity. Thus far development of these chemistries has been focused on achieving chemio-selectivity, as a means of controlling product distributions. However, in general these catalytic reactions occur in solutions in which the polymer is not solubilized, leading to either a solid-liquid phase separated mixture, or an immiscible liquid-liquid phase separated mixture in cases where the reaction temperature is above the melting point of the polymer. In this heterogeneous mixture, the diffusion of catalyst into the bulk of the polymer, as well as the accessibility of catalyst to the desired polymeric bonds of interest become incredibly important in determining the activity of the catalyst, as well as the potential inhibition of the reaction. Here we present detailed structural characterization of the polymer using a combination of x-ray scattering, x-ray spectroscopy, and electron microscopy to understand the molecular and mesoscale structure of the polymer, how this is perturbed by the reaction conditions, and how this evolves over the course of the reaction. We find that the ability of a catalyst to diffuse into the bulk of the polymer, and turn the reaction from a surface limited to a bulk deconstruction process, as well as the interconversion between the amorphous and crystalline fractions facilitated by the production of monomeric products is a crucial design consideration for highly active and selective deconstruction chemistries.

4:30 PM EN10.02.08
Biodegradability Study of Thiol-ene Photopolymers Amelia Heiner, Jeffrey S. Bates and Chen Wang; University of Utah, United States

Polymer materials are used in many commodity single-use applications, including adhesives, over-print varnishes (OPV), packaging materials, and contact lenses. However, these materials are hydrophobic, contain no nutritional value to microorganisms, and include many additives to enhance their performance, making them non-biodegradable. This study examines the synthesis and end-of-life scenarios of thiol-alkene (thiol-ene) films using click photopolymerization. We propose that because of their multifunctionality and the presence of ester groups in their backbones, these polymers may provide nutrients for microorganisms that will enable the biodegradation and disintegration of the material after disposal in non-standard and non-specified environmental conditions. The degradation of the material is investigated through biochemical oxygen demand testing and material characterization. Biodegradability will enable the replacement of non-biodegradable materials in single-use applications.

4:45 PM EN10.02.09
Controlling Polymer Deconstruction to Monomer via Solvation Free Energy Mutian Hua, Jeremy Demarteau, Alexander R. Epstein, Kristin Persson and Brett A. Helms; Lawrence Berkeley National Lab, United States

Polydiketoenamine (PDK) elastomers are circular replacements for difficult-to-recycle polyurethanes used in a wide range of consumer products. The materials, time, and energy efficiency of recycling PDKs back to monomer will be discussed here from two vantage points: the bonds undergoing hydrolysis in strong acid and the solvation of polymer chains in the reaction medium. Specifically, PDKs undergoing depolymerization by hydrolysis in strong acid are insoluble, but swell in the reactive medium, aided by the ionization of diketoenamine bonds. Since both acid and water are required for hydrolysis, solvation emerges as a critical factor governing PDK depolymerization rates at length scales beyond the bond. Understanding the impacts of solvation on depolymerization rates is challenging due to: (1) the high concentration of acid used (~5 M); (2) the collective influences of monomer polarity, MW, crystallinity on the solvation free energy; and (3) the evolution in composition and polymer hierarchies during depolymerization. We will discuss how monomer polarity, crystallinity, and crosslinking density influence the fraction of activated bonds, degree of swelling, and self-diffusion of acid and water, resulting in faster macroscopic rates of chemical depolymerization.

SESSION EN10.03: Poster Session: Decomposing Materials Wastes—Physical, Chemical and Biological Approaches

5:00 PM EN10.03.01
Molecular Engineering of a Synergistic Photocatalytic and Photothermal Membrane for Highly Efficient and Durable Solar Water Purification
Kun Fang[1], Cui Du[1], Junliang Zhang[1], Shengyang Yang[1] and Chen Zhou[2]; [1]Yangzhou University, China; [2]U of Central Missouri, United States

In recent years, the solar-driven interfacial evaporation system (SIES) has obtained a lot of interest as a potential solution to freshwater scarcity. However, the organic pollutant residues affected the practical application of the distillate generated by SIES. Herein, a solar interfacial membrane (AuNPs@g-C_3N_4/CMF) (AMF) for desalination and removal of multiple water pollutants was prepared by generating Au-doped carbon nitride (AuNPs@g-C_3N_4) directly on the carbonized melamine (CMF) through a co-calcination process. The designed membrane features excellent light absorption, efficient water supply, and low thermal conductivity. All the above advantages of the AMF membrane contributed to an outstanding evaporation rate (1.675 kg m^{-2} h^{-1}) and high photothermal conversion efficiency (94.03%) under 1 sun irradiation. For seawater desalination, the membrane performed well in removing ions from simulated seawater and demonstrated good stability during long-term desalination. Meanwhile, the membrane still exhibits a high evaporation rate (1.24 kg m^{-2} h^{-1}) even in a 10% salt solution environment. Owing to the photocatalysis capability of AuNPs@g-C_3N_4, the AMF membrane also performs effectively in the removal of organic dyes and formaldehyde.

5:00 PM EN10.03.02

Optically Transparent, Mechanically Tough, Spray-Coatable Waterborne Polyurethane Composites Reinforced with Natural Polymer-Derived Nanofibrous Fillers Jungho Jin[1,2]; [1]Univ of Ulsan, Korea (the Republic of); [2]BIOQIT Co., Ltd, Korea (the Republic of)

Waterborne polyurethane (WPU) has emerged as an environmentally benign alternative to conventional PU owing to its low VOC (volatile organic compound) content, low toxicity, non-flammability, and ease of handling. Despite such advantages, WPU in general tends to show inferior mechanical properties compared to conventional PU.

In this work, we introduce an optically transparent, mechanically tough waterborne polyurethane (WPU) nanocomposite incorporating succinylated cellulose nanofibers (SCNF) and chitin nanofibers (SChNF) as the reinforcing fillers. Both a commercially available WPU, as well as, a typical anionic WPU synthesized using poly (tetrahydrofuran) (PTMEG), isophorone diisocyanate (IPDI), and dimethylol propionic acid (DMPA) as the internal emulsifier is used. Aqueous colloidal suspensions of the SC(h)NF nanofillers are prepared via the aqueous counter collision (ACC) method. A simple blending of the two waterborne materials renders homogeneous WPU/SC(h)NF (1–10 wt%) nanocomposite that simultaneously achieves an outstanding mechanical toughness and high optical transparency (>90%). We also demonstrate an environmentally benign aerosol-spray coating of the WPU/SC(h)NF using dimethyl ether (DME) as the aerosol propellant.

5:00 PM EN10.03.04

Raw Biomass Electroreforming to Formic Acid Li Quan Lee[1,2]; [1]Nanyang Technological University, Singapore; [2]Nanyang Environment and Water Research Institute, Singapore

Biomass is widely recognized as a CO_2-neutral, abundant, and renewable resource replacement for fossil fuels. However, the biomass energy extraction still strongly depends on thermal conversion of woody biomass. Without proper carbon capture and storage, this thermal conversion process generates CO_2 emissions. A greener and sustainable method to fully utilise biomass would be much more appealing. At ambient condition, biomass derivatives could be employed into water electrolysis to reform into valuable chemicals. Nevertheless, due to the rigid polymeric structures of biomass, they often require energy-intensive and harsh pre-treatment processes before refining. Herein, we electrooxidized glucose, the monomer from abundant cellulose and achieved high selectively of up to 88% of potassium formate in less than 4h at 1.58V vs. RHE. A simple dilute acid hydrothermal pre-treatment was employed to depolymerize cellulose and hemicellulose of glucose-containing waste sugarcane bagasse without any separation steps. Then, this mixture of sugars with mono- and oligo- saccharides were electro-reformed into organic acid salts dominated by potassium formate. Techno-economic analysis and life cycle assessment was also conducted to evaluate this new process. The coupled carbon-negative green hydrogen generation to raw biomass electroreforming driven by solar renewable energy was also demonstrated, holding great promise to make significant contribution towards a sustainable energy future.

5:00 PM EN10.03.09

Degradation of Organic Molecules by Tribovoltaic Mechano-Chemistry Leqi Lin and Jun Liu; University at Buffalo, The State University of New York, United States

The presence and accumulation of organic pollutants in water systems is a significant threat to the health of humans and aquatic ecosystems. Herein we demonstrate a new pathway for high-efficient degradation of organic molecules based on the tribovoltaic effect. The method does not require photo-irradiation nor electrochemistry, but only use mechanical energy to generate electron-hole (e-h) pairs at dynamic metal-semiconductor contacts. The e-h pairs excited by collision between metal and semiconductor particles in the water are capable of generating highly reactive free radicals and driving dye molecule degradation. Such mechano -catalysis mechanism is proved to be a versatile strategy with a broad range of material selection and mechanical stimuli, which has great implications for cost- and energy-effective water treatment, as well as potential applications in green chemical synthesis.

5:00 PM EN10.03.10

Potential of Polymer Electrolysis for Plastic Materials Takahiro Saida, Kazuma Hisazaki and Takahiro Maruyama; Meijo University, Japan

Plastic waste is conscious of one of the global problems. Most plastic recycling is thermal recycling by incineration; that percentage is 63% of plastic waste in Japan. All know thermal recycling is not sustainable for plastic material and generates greenhouse gas emissions. Material recycling, which is reused by remolding, is 21% in Japan. And thermal recycling also has problems that cannot fully recover the monomer, separate the pigments and dyes, and degrade the quality of plastics. Therefore, we focused on chemical recycling with depolymerization. Chemical recycling is in the minority to the high cost, although it is known that PET can be depolymerization. We aim to develop new chemical recycling by electrolysis with a relatively low cost and small scale.

In general, plastic materials are insulators and are expected to be hard to electrolyze. However, two reports demonstrated the decomposition of polymers. [1, 2] Thus, polymer electrolysis may be possible, but its potential has not been understood correctly. In this study, primary and secondary alcohols with different carbon-chain lengths as the model molecule were electrolyzed to understand the electrochemical behavior of polymer decomposition. In addition, the electrolysis of PVA, PEG, and Nylon 66 was conducted as the first step of depolymerization into monomers.

The electrochemical cell was composed of a working electrode, a carbon counter electrode, a reversible hydrogen electrode (RHE) as a reference electrode, and 0.2 M NaOH. This study employed platinum and iron plate as the working electrode. Cyclic voltammetry (CV) was conducted at room temperature in an inert atmosphere. 1, 3, 5, 7, and 9 carbon atoms (linear) of a primary alcohol and 3, 5, 7, and 9 carbon atoms (linear) of a secondary alcohol were used as the model molecule. Primary and secondary alcohols were added 1mL to the electrolyte to investigate the electrochemical behaviors. PVA and PEG were also added to the electrolyte. Nylon 66 was polymerized on the working electrode directly.

The oxidation currents were observed at addition of primary and secondary alcohols. Their oxidation currents probably meant the decomposition of a model molecules. But their oxidation currents decreased with increasing the carbon-chain length. Therefor polymer, has long carbon chain, was expected to hard to electrooxidation.

The electrooxidation behaviors of PVA and PEG were different. In PVA, the CV shape was almost no change. In contrast, the oxidation current was observed in PEG. The oxidation of polymer may favor the presence of other atoms, such as oxygen, at the main chain rather than the functional group at

the side chain. Nylon 66 oxidation, which had nitrogen atoms at the main chain, also showed oxidation currents. However, the oxidation current of Nylon 66 was only observed in the case of the iron plate as the working electrode. This phenomenon suggests that the suitable catalyst for polymer oxidation likely depends on the presence of elemental species in the carbon chain.
The results of this study demonstrated the realization potential of polymer electrolysis. At the same time, these indicated two issues: all polymers cannot electrolyze, and the electrocatalyst probably depends on the polymer species. Hereafter, it is necessary to develop the electrocatalyst to oxidize or reduce polymers with other atoms in the carbon chain.

5:00 PM EN10.03.11
Use of Waste Plastics in the Reduction of Iron Oxides Wenceslao a. Jaimes, Samane Maroufi and Veena Sahajwalla; University of New South Wales, Australia

The unpacking of huge amounts of electronic waste (e-waste) in the world is no longer surprising, since almost 50 million tons were discarded between 2018 and 2019 alone [1]. What is even more surprising is that only 20% of this waste was given a second use other than disposal in open dumps. Within electronic waste, there is a vast variety of plastics, which include polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinylchloride (PVC), and acrylonitrile butadiene styrene (ABS), and it is the latter which it is more commonly found in electronic waste, due to its ease of transformation and low production costs. In order to properly recycle this waste, the purity of the material must be high and of the same material, if it is sought to reuse and produce other by-products; however, this is not necessarily a requirement in the metal and steel industry [2], where the high temperature environment in the process provides a great opportunity to use complex plastic waste, as a reducing agent for recovery of metals (e.g. Iron), and as fuel or as a source of energy in reactions.

The trend to replace natural fuels in the steelmaking process has increased in recent years, following the IPCC waste hierarchy, which says that waste must first be reused, followed by recycling, recovery of energy from it, and finally discarded. In this way, recent works on the implementation of the so-called secondary carbon resource have been reported, one of these is the recycling of 100% end-of-life materials with a high carbon content, such as melamine, or more recently, the potential of using auto-reducible waste toner to recover metallic iron (98% purity) has also been reported. These proposals to partially replace coke as a source of carbon in steel production, has recently been categorized as the new technique of micro recycling, within the alternative sources of carbon include e-waste from printers at the end of life, monitors, discs hard or plastic Although recent studies on tablets based on epoxy resins and their thermal transformation for the manufacture of Fe-Si nanostructures, have broadened the path towards a more sustainable (or colloquially called green) metallurgy. Until now, the extent to which iron oxides are reduced by using e-waste plastics such as ABS or toner has been limitedly explored.

Therefore, at the Centre for Sustainable Materials Research and Technology (SMaRT), the study of the use of non-conventional materials as a replacement for coal in the manufacture of steel is being carried out. Materials such as plastic waste (ABS), and toner residue, have been used to evaluate their effectiveness as fuels and reducing agents in the reactions of iron oxides in the presence of carbon sources. For this, characterisation techniques, such as XRD, XRF, SEM, Gas IR analysis, have been carried out in order to understand materials and interactions at high temperatures, by preparation of different blends of these waste materials and EAF Slag, the degree of reduction was studied by exposing them at 1550 °C under an inert atmosphere in a customised designed furnace. The reduction reactions were confirmed for both waste materials by the detection of CO, CO_2 and H_2 gases. Finally, the observation of the self-reducing toner at high temperatures, i.e., 500-1600 °C, confirmed the reduction of iron oxide via H_2 enabled reactions. Where the studies revealed that ABS-PC and Toner waste materials can act as reducing agents in the reduction of iron oxides from EAF slag and exhibited a degree of reduction of 100% for a Slag/Toner blend, and 99% for a Slag/Plastics blend.

5:00 PM EN10.03.13
Bioplastics From Unprocessed Spirulina Paul Grandgeorge, Hareesh Iyer, Ian Campbell, Kuotian Liao, Mallory Parker, Andrew M. Jimenez and Eleftheria Roumeli; University of Washington, United States

The increasing global materials consumption and the long-lasting detrimental effects of polluting manufacturing industries urgently call for innovative and sustainable new materials. Plastics, in particular, albeit ubiquitous and useful in an enormous range of applications, are associated with un-sustainable sourcing, manufacturing as well as end-of-life fates. During the past decades, various biodegradable plastics with properties comparable to those of commodity plastics have been pioneered. However, despite being biodegradable, these plastics were designed to degrade in aerobic environments, not in general landfills which is the place they usually end up in. As a result, even biodegradable plastics degrade at an unsustainably slow rate.
In this work we discuss the plasticization mechanism, as well as mechanical and thermal properties of bioplastics produced from selected plant and algal biomass. The biomass-based bioplastics are prepared by introducing various amounts (1-40 wt%) of low-carbon sugars as plasticizers and compounding the mixtures. We use a design of experiments to guide the formulations and processing conditions for each mixture. Specifically, we vary heating time, temperature, and shear stress in the extrusion process. The effects of varying the plasticizer amount and altering the processing parameters on the micro-morphology, mechanical and thermal properties of the produced bioplastics are characterized. We study the biomass particle morphology before compounding, through scanning electron microscopy (SEM). After the extrusion process, the bioplastic films are evaluated in terms of micro-morphology again through SEM, and their crystalline features are examined through X-ray diffraction (XRD). Tests are conducted to characterize the mechanical properties of the bioplastics (modulus, strength, elongation to break) and thermal stability is assessed through thermogravimetric analysis (TGA). The processing parameters as well as composition of the prepared bioplastics are correlated to the measured mechanical properties. Finally, a biodegradation assessment of the prepared bioplastics is conducted through characterizing their mass loss profiles during soil burial tests.

10:30 AM *EN11.01.01
All-Day Passive Radiative Cooling for Future Clean Energy Technology Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

With the ever-increasing consciousness of the energy crisis and global warming issues, passive cooling methods that use free and renewable energy sources have been pursued recently. Radiative cooling is an efficient passive cooling strategy that dissipates excessive heat to the universe through thermal radiation. In particular, all-day passive radiative cooling has offered an even larger spectrum of energy-saving applications by suppressing solar absorptivity under solar irradiation. In this talk, we present our recent research progress on all-day passive radiative cooling for practical applications as well as for improved cooling performance. Firstly, we discuss the inverse design of daytime radiative cooling for high performance [1]. The design of a selective multilayer emitter was optimized by a genetic algorithm, and we achieved highly suppressed solar absorption, thereby, high-performance radiative cooling under direct sunlight. We then discuss the efforts to promote the implementation of radiative cooling for real-world applications. We first discuss the realization of all-day radiative cooling devices on a large scale to address practical issues [2-4]. By using silica-coated porous anodic aluminum oxide, we developed a centimeter-scale radiative cooling device demonstrating a maximum cooling of 6.1 °C below ambient during the daytime [2]. We also developed large-scale radiative cooling devices in particle mixture coating format [3]. By further analyzing the effect of each particle on radiative cooling performance, we report a large-scale paint-format radiative cooling device with high performance [4]. Such particle-based devices allow the use of facile one-step and cost-effective fabrication methods, providing the potential for large-scale production and applications. Finally, we present radiative cooling devices with practical functionalities, including transparency [5] and switchability [6]. We discuss a transparent radiative cooling device that transmits visible light reflects near-infrared light and radiates thermal energy to lower the temperature during the daytime while maintaining transparency [5]. Such a transparent can be used for eco-friendly cooling windows in vehicles or buildings. We then discuss a switchable radiative cooling device according to temperature [6]. By exploiting the changeable material properties of vanadium dioxide in response to temperature, we achieved a temperature-adaptive radiative cooling device that radiates thermal energy only when the temperature is above the phase transition temperature.

Hierarchically Patterned Self-Cleaning Polymer Composites for Daytime Radiative Cooling Kai Zhou[1], Xiao Yan[1], Seung Oh[2], Gabriela Padilla-Rivera[2], Hyunjung Kim[2], Donald Cropek[2], Nenad Miljkovic[1] and Lili Cai[1]; [1]University of Illinois at Urbana Champaign, United States; [2]Army Construction Engineering Research Laboratory, United States

Exposure to outdoor heat stress threatens the health of humans taking outdoor physical activities, while the open nature of outdoor activities makes it impractical to use traditional electrical cooling methods. Passive daytime radiative cooling (PDRC), which uses intrinsic optical properties to achieve passive cooling without consuming electricity, has been proposed and developed to tackle outdoor cooling challenges in recent years. PDRC selectively achieves high solar reflectivity and utilizes the fact that the thermal emission can go through the sky window (in the wavelength range of 8—13 µm) into the cold universe (~3 K). However, outdoor PDRC materials are susceptible to environmental contamination, including solid microparticles and water accumulation. Such surface contaminants severely decrease the cooling efficacy, requiring routine cleaning to recover; also, for the PDRC textile worn by humans, aesthetic purposes make the daily dust cleaning necessary. In order to minimize cleaning labor, self-cleaning has been integrated with PDRC. However, commonly used methods to combine self-cleaning with PDRC materials involve adding fluorinating chemicals like polytetrafluoroethylene (PTFE) into the radiative coolers, and their fabrications are usually complex and expensive. A simple, cost-effective strategy to combine self-cleaning with radiative cooling is needed. Here, we develop a hierarchically patterned nanoporous composite (HPNC) using a facile template molding fabrication method to integrate PDRC materials with self-cleaning and antibacterial functions. The HPNC design decouples multifunctional control into different characteristic length scales that can be optimized simultaneously. Using a nanoscale porous polymer matrix and tunable particle fillers to tailor the radiative cooling properties, the HPNC samples enable >7.8°C temperature reduction for outdoor cooling of the human body and 4.4°C sub-ambient cooling for building applications under intense solar irradiance. Meanwhile, a micro-scale pillar array pattern integrated into the HPNC enables superhydrophobicity with self-cleaning and anti-soiling functions to mitigate surface contamination. Moreover, the HPNC design allows for the incorporation of nanoparticles for additional functionality. Here, we embed and coat photocatalytic agents to generate effective photoinduced antibacterial effects. The scalable fabrication and multifunctional capabilities of our HPNC design offer a promising solution for practical daytime radiative cooling applications with minimal maintenance needs.

A New Instrument for Angularly and Spectrally Resolved Radiative Emission Measurements of Radiative Cooling Structures Magel Su[1], Gunnar Nelson[2], Himashi Andaraarachchi[2], Parker Wray[1], Uwe Kortshagen[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]University of Minnesota, United States

Research on terrestrial radiative cooling has yielded a large volume of theoretical and experimental results for many designs, including thin film multilayer stacks, nanoparticles, and metaphotonic structures, which are capable of passive radiative cooling. However, the most widespread method of characterizing radiative cooling is in an uncontrolled and poorly calibrated outdoor ambient. Direct measurement of the spectral and angular distributions of radiative emission simultaneous with sample surface temperature measurements are thus urgently needed by the community to facilitate inter-comparisons between radiative emission measurements and radiative cooling performance.
Here, we report measurements obtained using a calibrated and extensively modeled custom-designed radiative emission apparatus capable of simultaneous measurements of surface temperature and spectral- and angular-resolved radiative emission. This instrument enables simulation of outdoor ambient environments under well-controlled laboratory conditions. In terrestrial radiative cooling, surfaces are cooled by radiating thermal heat from the terrestrial ambient environment to the cold ambient of space directly through the atmospheric transmission window (8 – 14 µm), while also reflecting sunlight (0.3 – 2 µm) to prevent parasitic solar heat absorption. To simulate an outdoor ambient environment exposed to the clear sky our design utilizes a cryoshroud to simulate the cold ambient of space (2.7 K), a solar simulator, thermoelectric heating elements to control the ambient sample temperature under high vacuum (<1e-9 Bar) as well as ambient conditions, and insulating stage design to reduce convective/conductive heat loss mechanisms. COMSOL thermal and radiation modeling was used to validate our test apparatus design simulating closely outdoor ambient conditions.
We also present thermal and radiative emission results for a nanoparticle-based radiative cooling structure in this instrument, comparing silicon dioxide (SiO_2) and/or silicon nitride (Si_3N_4) nanoparticle films with planar thin film multilayer structures for application in large-scale terrestrial radiative cooling. Nanoparticle films exhibit radiative cooling powers of over 60 W/m^2 at 300 K.

SESSION EN11.02: Radiative Cooling II

Hybrid Evaporative Radiative Cooling for Large Energy Savings Zhengmao Lu[1,2], Arny Leroy[2], Lenan Zhang[2], Jatin J. Patil[2], Evelyn Wang[2] and Jeffrey C. Grossman[2]; [1]EPFL, Switzerland; [2]MIT, United States

Passive cooling technologies can be a game changer for addressing global cooling demand, where standalone evaporative or radiative cooling methods have already shown much promise. However, they often face challenges associated with water consumption, solar absorption, parasitic heating, low cooling power, and humidity constraints. Here, we present a hybrid evaporative-radiative cooling architecture that addresses these previous shortcomings. The structure consists of a solar reflector, a water-rich and IR-emitting evaporative layer, and a vapor-permeable, IR-transparent, and solar-reflecting insulation layer. We showcased this concept with the enhanced specular reflector, the polyacrylamide hydrogel, and the polyethylene aerogel as the three layers, respectively. In Cambridge, MA, USA, we demonstrated 9.3 °C below the ambient under direct sunlight. With minimal water expenditure, our sample consistently stayed below the wet bulb temperature, which is not possible with pure evaporation. Under the same weather condition, we showed 300% enhancement over a state-of-the-art radiative cooler in daytime cooling power. Further, we show that hybrid evaporative radiative cooling offers large energy-saving opportunities in food storage and building thermal management applications for a wide range of climate conditions.

2:00 PM EN11.02.02
Design Transparent Radiative Cooler using Quantum Computing-Assisted Active Learning Seongmin Kim[1], Wenjie Shang[1], Seunghyun Moon[1], Trevor Pastega[1], Eungkyu Lee[2] and Tengfei Luo[1]; [1]University of Notre Dame, United States; [2]Kyung Hee University, Korea (the Republic of)

Passive radiative coolers, which allow emitting radiation through an atmospheric window ($8 < \lambda < 13$ µm), have attracted much attention as a solution to climate change issues, owing to their potential in energy- and refrigerant-free cooling capability. In particular, transparent radiative cooler (TRC) that has high transmission in visible light and high emission in the atmospheric window has been developed for energy-saving windows. However, it is difficult to design a high-performance TRC with high visible transparency along with high ultraviolet and near-infrared reflection and high cooling capability. In this work, we design a visibly transparent radiative cooler using a quantum computing-assisted active learning design scheme that combines machine learning, quantum annealing, optical simulation, and on-the-fly dataset acquisition in one iteration. The optimally designed cooler has high visible light transmission and low ultraviolet and near-infrared light transmission to maximize cooling performance, and high emission in the atmospheric window range. We experimentally demonstrate the optical properties of the designed cooler and demonstrate its passive cooling ability under dynamic environments by field experiments. The field testing results show a temperature reduction of up to 6.1°C when using our fabricated TRC compared with common glass. In addition, we calculate the energy saving for cooling when a standard room uses our designed cooler instead of normal windows, and the results show that the cooler can lead to a potential energy saving of ~86.3 MJ/m^2 annually in hot regions. We believe that the designed TRC can be applied for energy-saving windows and the quantum computing-assisted active learning scheme can be efficiently used for functional material design in general.

2:15 PM EN11.02.03
Superhydrophobic Hierarchical Polymer Film for All-day Passive Radiative Cooling Atmospheric Water Harvesting Zhizhong Cheng[1], Yaerim Lee[1], Ahmet A. Günay[1,2], Jiang Guo[1], Sivasankaran Harish[1] and Junichiro Shiomi[1]; [1]The University of Tokyo, Japan; [2]Middle East Technical University, Turkey

Passive radiative cooling atmospheric water harvesting (PRC-AWH) is a promising alternative to overcome water scarcity issues as an energy-saving technique. However, it is a challenging task to ensure all-day PRC-AWH operation. Here, we report a self-cleaning, scalable, flexible, and optically effective hierarchical polymer film to achieve continuous (all-day) PRC-AWH which exhibits high solar reflectivity, high emissivity, and a high water uptake performance. Owing to its unique hybrid photonic and hierarchical structured surface, the polymer film exhibits high solar reflectivity and ideal infrared emissivity, and achieves superb average subcooling throughout the day. Outdoor tests demonstrate that daytime PRC-AWH is realized in natural weather conditions to collect large amounts of water from the atmosphere. Controlled environment tests further elucidate the droplet capture mechanisms that contribute to the performance enhancement with the use of hierarchical structures at both micro and macro scales. Besides, the hierarchical structures ensure the surfaces to achieve superhydrophobic surfaces where the dust collected on the surface is cleared out by the condensed droplet to keep it clean at all times. Our results demonstrate that such a hierarchical polymer film shows great potential of all-day PRC-AWH that can at least double the yield of water, while removing and collecting water passively and efficiently.

2:30 PM *EN11.02.04
Integration of Radiative Roof Cooling Coating into Buildings as a Zero-Energy Cool Roof Strategy in Hot and Humid Region Lin V. Lu; The Hong Kong Polytechnic University, Hong Kong

Radiative sky cooling has attracted worldwide attention due to its passive cooling potential with zero energy input. Daytime cooling materials with outstanding spectral properties are developing rapidly. Using these new cooling materials as roof coatings can become one of the most prominent radiative cooling methods integrated with buildings. Current existing models and numerical tools are not able to incorporate the spectral selectivity of radiative cooling materials and local precipitable water vapor, thus failing to accurately predict roof thermal performance. Therefore, we newly develops a spectral selectivity-based passive radiative roof cooling model to integrate full spectral properties of emerging cooling materials and consider precipitable water vapor-induced atmospheric radiation for precise evaluation of roof cooling performance. A field experiment was carried out to validate the developed model. The new spectral selectivity-based radiative roof cooling model can be widely employed to accurately evaluate the utilization of daytime radiative coolers as a rooftop strategy in improving building thermal and energy performance. The energy consumption assessment of buildings with radiative roof cooling coating as a zero-energy cool rooftop strategy in hot and humid region, such as Hong Kong, is conducted. Findings can help local policy makers implement cool roof scheme into low-energy building strategy.

3:00 PM EN11.02.05
Radiative Cooling Walls with Asymmetric Emissivity for Building Envelope Qilong Cheng and Yuan Yang; Columbia University, United States

Passive daytime radiative cooling (PDRC) is an attractive electricity-free approach to reducing energy consumption of buildings by reflecting sunlight [wavelengths (λ) ~ 0.3 to 2.5 μm] and emitting infrared radiation (IR) through the atmospheric transparency window (ATW: λ ~ 8 to 13 μm) to the cold sky. Current PDRC research focuses on roofs, but limited attention has been paid to the walls, which occupy a major portion of building envelopes. Unlike the roofs, the walls face both cold sky and hot ground, so either high emissivity or low emissivity is not the best solution. Here we develop a scalable cooling wall with asymmetric emissivity. The wall can simultaneously reflect the thermal radiation from the hot ground and remain emissive to the cold sky, to achieve further building cooling and even sub-ambient cooling, which are demonstrated by simulations and experiments. Such asymmetric emissivity leads to further cooling of ~100 W m^{-2} than conventional walls at a ground temperature > 50 °C, and shows temperature drops of 3.1 °C (peak) / 2.3 °C (daily average) compared to the control wall in the field tests. Taking the United States as an example, the proposed zigzag wall can work effectively over 29% area and benefit 45% population, providing up to 27 MJ m^{-2} year-round saving per wall area for a typical midrise apartment building.

3:45 PM EN11.03.02
Moisture Thermal Battery with Autonomous Water Harvesting for Passive Electronics Cooling Jian Zeng[1,2], Renkun Chen[3] and Ravi Prasher[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]University of California, San Diego, United States

Electronics will consume ~ 20.9% of global electricity by 2030, all of which will end up as heat. Data center alone requires ~ 2.1×10^{11} kWh of cooling load and ~ 1591 billion gallons of water yearly. Passive cooling of high-power electronics with minimum energy and water input is thus critical for the global water-energy nexus but has been challenging due to the large fluctuation in heat loads between the on-/off-peak hours. The thermal fluctuation could be mitigated by latent heat cooling. In this work, we develop a moisture thermal battery (MTB) by coating superabsorbent hydrogel on to a pin fin heat sink with large surface. The MTB leverages large latent heat and high thermal conductance of water evaporation for electronic cooling during on-peak hours and importantly, autonomously harvest atmospheric moisture and store the water during off hours. The MTB provides thermal capacity up to ~ 200 kWh m^{-2} for evaporative cooling with a record-high effective heat transfer coefficient up to ~ 1000 W m^{-2} K^{-1} for a passive device (no external power). The MTB was also demonstrated to suppress temperature fluctuation of a high-power field effect transistor and a computer CPU between the on- and off- peak hours by ~ 15 K, indicating its potential broad applications for autonomous water harvesting and cooling for a wide range of electronic devices with high heat loads.

4:00 PM EN11.03.03
Temperature and Humidity Control Using Lower Critical Solution Temperature (LCST) Mixtures Jordan Kocher and Shannon Yee; Georgia Institute of Technology, United States

Traditional air conditioning systems contribute significant greenhouse gas (GHG) emissions throughout their lifetimes, with roughly one third coming from the refrigerant, one third coming from energy consumption for temperature control, and one third from energy consumption for humidity control. There exists a need to create air conditioning systems that consume less energy and do not use high global warming potential (GWP) refrigerants. Aqueous mixtures that possess lower critical solutions temperatures (LCSTs) will mix with water when below the LCST and separate into a two-phase mixture above the LCST. This allows for the creation of a new air conditioning cycle. The first process in this cycle uses low-grade heat to cause the LCST mixture to separate into a phase that is water-rich and a phase that is water-scarce. Those two phases are then physically separated and cooled back down to ambient temperature. Due to its high chemical potential, the water-rich phase can desorb water into the outdoor air, which produces indirect evaporative cooling that can be provided to a building. Meanwhile, the low chemical potential of the water-scarce phase allows it to absorb moisture from building air, thereby providing dehumidification. After this, the two phases are reheated to once again induce phase separation and repeat the cycle. We have performed a step-wise demonstration of this new cycle with several different LCST mixtures and regeneration temperatures less than 100 C. We rank the LCST mixtures based on their effectiveness in this particular application. However, all of the mixtures fall short of reaching the conditions required for building thermal comfort; namely, the water-scarce phase is unable to dehumidify air to sufficiently low humidities. This demonstrates the need to discover new aqueous LCST mixtures that can provide superior performance when used in this cycle. In particular, we show that more effective LCST mixtures would have more negative enthalpies and entropies of mixing. The discovery of these new mixtures would enable an air conditioning cycle that is driven by inexpensive, low-grade (i.e., solar) heat, consumes no water and very little electricity, and uses no high GWP refrigerants.

4:15 PM EN11.03.04
Passive Freezing Desalination driven by Radiative Cooling Xin Huang and Aaswath Raman; UCLA, United States

With global temperature rises posing fundamental economic, health, and security risks to human civilization, maintaining habitable built environments has emerged as one of our times' most pressing challenge. Passive radiative cooling in particular has emerged as a promising technology, driven by a net radiative heat loss to cold outer space via the atmospheric transmission window in the long-wave infrared (LWIR) wavelengths. However, its potential for generating and remediating water remains an open frontier for research. Indeed, with increasing water scarcity there is now significant interest in finding lower-cost ways to generate fresh water. At the same time, many industrial processes, including oil and gas production, produce high-salinity wastewater that requires remediation.

Conventional desalination processes, including membrane-based and thermal desalination approaches, require large energy inputs which can become prohibitive as salinity increases. Alternatively, the most commonly used passive thermal desalination method is solar desalination which uses the sun as the heat source in an evaporation-condensation cycle. However, weather conditions and solar insolation limit its applicability throughout the year.

Here, we propose a passive approach to a more thermodynamically attractive phase change that can also enable desalination: freezing. In particular, we use radiative cooling to enable passive freezing desalination for the first time. We experimentally demonstrate passive desalination of 37.3 g/L salt water to 1.88 g/L after two radiative cooling-driven freezing desalination stages, with 50% recovery and 17.5 g/L salt water to 0.7 g/L after two radiative cooling-driven freezing desalination stages, with 65% recovery. We develop and validate a thermal model that accurately predicts the performance of the system and extend it to probe the theoretical limits of performance. These results demonstrate that passive freezing desalination driven by radiative cooling could fundamentally enable new technological possibilities for desalination. Further, this could be a complementary method to solar desalination to enable 24-hour, year-round passive thermal desalination.

SESSION EN11.04: Poster Session I
Session Chairs: Sungyeon Heo and Po-Chun Hsu
Tuesday Afternoon, April 11, 2023

5:00 PM EN11.04.01
Comprehensive Design Characterization Towards Optimization of Microparticle-Polymer Composite Radiative Cooling Paint Jooyeong Yun[1], Dongwoo Chae[2], Heon Lee[2] and Junsuk Rho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Passive daytime radiative cooling (PDRC) technology achieves cooling effect by reflecting incoming solar flux and enhancing thermal radiation in the atmospheric transmission window. The trait to operate without any consumption of energy offers great potential as a future energy-saving technology and has attracted substantial interest in many research communities. Among many PDRC structures, random dielectric particles or paint-like coatings have shown powerful radiative cooling performances with excellent scalability and easy fabrication. In this work, we provide a rigorous analysis of the optical properties and radiative cooling performances of PDRC paints comprised of two-material particles, SiO_2 and Al_2O_3 by using 2D FDTD simulation study. We investigate the effects of design variables of particle size parameters, size distribution, binder volume ratio and coating thickness. We then conduct an outdoor cooling measurement of the fabricated PDRC devices to show the radiative cooling potential of our PDRC paint and to analyze and understand its performance based on our numerical investigations. The fabricated PDRC paint exhibited high solar reflectance of 0.958 and strong long wave infrared emission of 0.937 in the atmospheric transparency window achieving maximum temperature drop of 9.1°C. This comprehensive study provides understanding of complex physical relations of materials and structure parameters of the PDRC paint system. This will be an intuitive guidance for researchers to find the optimal design conditions of PDRC paints and to engineer them to be applicable to various environment.

5:00 PM EN11.04.02
Nano-to-Macro Design of Ultra-scalable Hygroscopic Hydrogels for High-Performance Water Capture Carlos D. Diaz, Zhengmao Lu, Kezia Hector, Miles Roper, Xinyue Liu, Gustav Graeber, Leon Gaugler, Evelyn Wang and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Hygroscopic hydrogels have recently emerged as low-cost and scalable sorbent materials for a wide range of applications including passive cooling, thermal energy storage, building dehumidification, and atmospheric water harvesting. Despite extensive efforts in the synthesis of novel hydrogels, their performance, as quantified by their a) water uptake and b) sorption kinetics, remains limited. Moreover, the rational engineering of hygroscopic hydrogels has been largely unexplored, hindering their optimization for sorption applications. In this work, we leverage physical models we have developed to enable the hydrogel design across different length scales, ranging from the polymer network scale to the macroscopic material scale, for high-performance water sorption. Specifically, we demonstrate a) high water uptakes of 1.74 g/g at 30% RH, exceeding by 15% previous state-of-the-art hydrogels, achievable by maximizing the salt content during synthesis, and b) the impact of polymer nanostructure on sorption kinetics, providing a path to fast kinetics by adequately engineering the polymer network. By simultaneously improving uptake and kinetics, our results demonstrate superior hygroscopic hydrogels which can enable high-power density thermal energy storage, efficient passive cooling, and large-scale water harvesting.

Solar-Thermal Hybrid Concept of Energy Harvesting in Rural Africa Derick C. DeTellem, Sarah Abdallah, Christian Coris, Clayton Baker and Sarath Witanachchi; University of South Florida, United States

In this paper we are reporting the results from an experimental project conducted in Africa to combine the energy harvested with solar cells with energy harvested from waste heat to charge a 12V battery to provide portable electricity for day-to-day use in rural Africa. Communities in rural Africa burn wood for their cooking needs. Most of the heat generated is wasted to the environment. While silicon solar cells have the potential to generate significant currents based on the solar radiation intensity, voltages generated by a single solar cell is limited. On the other hand, thermoelectric modules that convert heat into electricity generates high voltages, but the current is limited by the intrinsic properties of the thermoelectric materials. Under the new hybrid concept, thermoelectric modules generated high voltages from waste-heat while silicon solar cells generated high currents. The hybrid of the combination in a unique configuration has resulted in power outputs that are much higher than the added output of the individual devices. The circuit design, the IV-characteristics, and the conditions for optimum power generation in the hybrid configuration will be presented. The project was supported by an NSF IRES grant.

5:00 PM EN11.04.05
A Unified Multiscale Understanding of Sorption-Based Atmospheric Water Harvesting Yang Zhong, Lenan Zhang, Xiangyu Li, Bachir El Fil, Carlos D. Diaz, Chenyang Li, Xinyue Liu, Alina LaPotin and Evelyn Wang; Massachusetts Institute of Technology, United States

Sorption-based atmospheric water harvesting (SAWH) is the extraction of water vapor in the atmosphere using sorbent materials to deliver point-of-use drinking water directly from the air. With the advances of materials innovations, SAWH devices can operate in a broad spectrum of relative humidity, which opens new avenues to address water scarcity faced by two-thirds of the world's population. Although substantial progress has been made to enable sustainable SAWH, there is still a giant barrier between fundamental studies and real-world applications. Here, we develop a unified multiscale understanding to develop SAWH technologies by bridging the material insights to device optimization. First, we elucidate fundamental water sorption mechanisms, key material properties, and vapor diffusion regimes. To fill the gap between the materials and devices, the physical insights gained at the material level are translated into the optimization principles through heat and mass transfer at the device level. Then, we show the interplay of material and device design can lead to new opportunity space toward the thermodynamic limits of SAWH systems. Finally, we perform a techno-economic analysis to evaluate the economic feasibility of SAWH technologies and envision the impact of large-scale SAWH on the worldwide water economy and environment. Our work provides a unified understanding of SAWH technologies, which can lead the way to the practical development of SAWH at different length scales and its broader global impact.

Physical Interpretation of Role of Optical Constants in Thermal Insulation and Heat Shielding Coating Hidefumi Odaka; AGC Asia Pacific Pte Ltd, Singapore

Zero Energy Building (ZEB) is a building with net zero energy consumption, meaning the total amount of energy used by the building on an annual basis is equal to the amount of renewable energy created on the site. In this realization, thermal insulation and heat shielding throughout window are considered to be one of the important factors to realize it. Depending on the climate and environment where the buildings are built, appropriate glazing windows are designed to decrease the energy usage. For example, low U value and low Solar Heat Gain Coefficient (SHGC) are required in in the regions with large differences in summer and winter temperature. Low Overall Thermal Transfer Value (OTTV) is necessary in the land of everlasting summer to save the energy consumption by air conditioner. In addition to it, the designing of visible transmittance is attracting much attention to save the lighting energy of building especially in the green building rating of Leadership in Energy and Environmental Design (LEED) and Thai's Rating of Energy and Environmental Sustainability (TREES).

In order to meet the above requirements, many coating technologies have been invented. Atmospheric pressure CVD is used for making transparent conductive film, mainly composed of tin oxide, to make heat shielding window. Sputtering method is applied for making not only Ag-based Low-E with thermal insulation window but also reflective coating for heat shielding, where many stacks are used to control interference of light from visible to infrared region. As a result, optimized window is made, which meet the requirement of customer.

In this presentation, representative products for thermal insulation and heat shielding are reviewed, which is used in business. Then, some physics that determine optical constants, common to Ag, transparent conductive materials and TiN, are discussed from the standpoint of band structure of these materials. It is shown that the inter-band and intra-band transition can explain the origin of optical constants, with the only difference being the contribution of these transition. Finally, optical property of Ag-based Low-E and reflective coating made of TiN are discussed using matrix formalism of electric field intensity of light. In the anti-reflection coating for lens, dielectric materials with large difference in optical constant are stacked to achieve low reflection. On the other hand, both real and imaginary part of the optical constant play an important role to control the light in Ag-based Low-E and reflective coating made of TiN. The meaning of optical constant will be discussed relating to SHGC and OTTV. These phenomena are also discussed using electric field intensity in the multi-layer stack of in Ag-based Low-E and reflective coating made of TiN.

SESSION EN11.06: Dynamic Building Envelopes I
Session Chairs: Sungyeon Heo and Po-Chun Hsu
Wednesday Morning, April 12, 2023
Moscone West, Level 2, Room 2005

9:00 AM *EN11.06.01
Light and Thermal Management by the Kirigami-Based Dynamic Shading Envelopes Heesuk Jung[1,2], Miaomiao Hou[3], Byungsoo Kang[2], Zherui Wang[1], Hyo-jeong Choi[4], Phillip Lee[2], Dorit Aviv[1], Hyeok Kim[4] and Shu Yang[1]; [1]University of Pennsylvania, United States; [2]Korea Institute of Science and Technology (KIST), Korea (the Republic of); [3]Tongji University, China; [4]University of Seoul, Korea (the Republic of)

Conventional heating, ventilation, and air conditioning (HVAC) systems in buildings not only consume substantial energy but increase the heat-trapping gases in the atmosphere, which further aggravates global warming. To improve building energy efficiency and thus reduce negative environmental impacts, we investigate kirigami structures as adaptive building envelopes as a promising alternative to manage building heating and cooling. Numerical simulations are performed to study the mechanisms of light and thermal modulation by the kirigami-based dynamic envelopes by taking into consideration of building locations and occupants needs. We then design outdoor test chambers with thermo- and lux- sensors installed outdoor to demonstrate the effect of kirigami structures with variable cut dimensions on light modulation and temperature inside of chambers. By comparing experimental results and simulation, we gain insights to optimize indoor light and heat management by fine-tuning kirigami designs.

9:30 AM *EN11.06.03
Versatile Electrochromic Platforms for Energy Applications Hong Chul Moon; University of Seoul, Korea (the Republic of)

Multifunctional systems serving simultaneously as two or more devices have attracted significant attention owing to the high integration of electronic devices in cutting-edge technologies. In this work, we introduce the versatile use of electrochromism including thermal management and energy storage. In particular, we are going to describe all-in-one type, single-layer device platforms based on solid-state ionic conductors. It also covers effective strategies to tune electrochromic performance.

Using Reversible Metal Electrodeposition in Windows to Improve Energy Efficiency and Control Natural Lighting Michael D. McGehee[1], Andrew Yeang[1], Yuchun Cai[1], Gabriel McAndrews[1] and Christopher Barile[2]; [1]University of Colorado, United States; [2]University of Nevada, Reno, United States

Dynamic windows with adjustable tint give users control over the flow of light and heat to decrease the carbon footprint of buildings and improve the well-being of the people inside them. Despite the benefits of dynamic windows, they are deployed in less than 0.004% of commercial building space because the existing technology cannot achieve fast and color-neutral tinting at an agreeable cost. Reversible metal electrodeposition (RME) is a promising approach to solve the problems plaguing the current generation of dynamic glass. Here, we demonstrate the use of polymer inhibitors to reversibly deposit metal films with controlled morphology in dynamic windows. The dynamic windows that employ the polymer inhibitor can readily tint to below 0.001% visible transmittance in less than 3 minutes and exhibit high infrared reflectance (>70%), color-neutral transmittance ($C^* < 5$), and a wider range of optical and solar modulation than any existing technology. The polymer inhibitors also increase efficiency and improve the durability of the windows and enable construction of 1 ft.^{2} dynamic windows with fast response and excellent uniformity.

10:45 AM EN11.06.05
Bioinspired Building Envelop with Lightweight, Unltra Thermal Conductivity, High Energy Dissipation and Fire Resistance Fengyin Du[1,2], Tian Li[2] and Changwen Miao[1]; [1]Southeast University, China; [2]Purdue University, United States

Multiple hazards including impact load, heat damage and fire shock arising from extreme weathers usually bring life-threatening problems to residents. To prevent these threatens, expecially those caused by mechanical-thermal-fire coupled damage, urgently needs the construction of versatile preotective building materials. Herein, we develop an effectvie approach to engineer a bioinspired cement wood with a hierarchical structure through self-assembling cement in polymeric solution. This emerging cement wood demonstrates a unique combination of light weight, high stiffness, superior thermal insulation, remarkable energy dissipation and good fire resistance. When appied as building envelop, the prepared cement-based material can dissipate impact energy and block heat diffusion to block the spread of fire, therefore significantly reducing the risk of property damage or bodily injuries.

Dynamically Synergistic Solar and Mid-Infrared All-Season Radiative Thermoregulation Based on Reversible Metal Electrodeposition Chenxi Sui and Po-Chun Hsu; The University of Chicago, United States

The coldness of the deep universe and the hotness of the sun have been considered renewable thermodynamic resources for sustainable thermoregulation. How to utilize both resources showed drastic improvement in the past decade, enabled by the plasmonic and nanophotonic research. Remarkably, the rational photonic and thermal design has pushed forward the power and efficiency of daytime radiative cooling. In this presentation, we will introduce our recent research progress on electrochemical devices that can electrically switch between solar heating and radiative cooling states, by reversibly electrodepositing metal on graphene. Such a non-trivial and opposite spectral tuning requires the fabrication of the ultra-wideband transparent conductive electrode, which is transparent in both solar and mid-IR regimes, and the precise control of the plasmonic nanoparticles' morphology during the reversible metal electrodeposition. With the optimization of every device component, this device can maximize its solar reflectivity at the cooling state and minimize its thermal emissivity at the heating state, and thus can serve as the smart building envelope for year-round HVAC energy saving. Ideally, the device can help buildings save 19.2% of HVAC energy across the United States, based on the building energy simulation results. The durable electrodeposition and broad-band spectral tuning are confirmed by the DFT simulations and effective medium theory. In addition to the synergistic solar and mid-IR dual-band tuning, our electrochromic device can tune the thermal emissivity with 0.85 contrast based on non-volatile and reversible metal electrodeposition, bringing vast opportunities for applications in space heat management, and thermal camouflage.

11:15 AM EN11.06.07
Progress in Energy Saving Thermochromic Smart Window Yi Long; The Chinese University of Hong Kong, Hong Kong

Thermochromic material responds to solar spectrum differently at the stimulus of heat which makes it attractive in the energy saving smart windows application due to its rational response, simple set up and passive response. The most studied inorganic VO_2 has the intrinsic problems of low luminous transmission (T_{lum}) and low solar modulation (ΔT_{sol}) the transmission difference between high and low temperatures). Numerous efforts such as employing dopings, nanoparticle-based composites, and nano-porous structuring have been widely studied. Our group have developed five new approaches to tackle this veritable challenge, namely, biomimetic nanostructuring including photonic structure and moth eye gridded structures tunable plasmonic structures organic and hybrid structures. In addition, new active controls has also been applied to thermochromic material to generate a new electro-thermochromics or mechanical-thermochromic materials. A very recent new liquid window and RC regulation smart windows will be presented.

Infrared Metamaterials from Plasmonic Metal Oxide Nanocrystals Delia Milliron; The University of Texas at Austin, United States

Metal oxide nanocrystals doped with a few percent of aliovalent dopants become electronically conducting and support strong light-matter interactions in the infrared due to localized surface plasmon resonance (LSPR). At the same time, they remain wide bandgap semiconductors, so they are transparent to visible light, offering unique opportunities to selectively control lighting and manage thermal energy. In nanocrystals of the prototypical material tin-doped indium oxide (ITO), for example, the strength and spectrum of light absorption are tunable across the mid- and near-infrared by varying the amount of tin incorporated during synthesis and, secondarily, the nanocrystal size. These nanocrystals are ideal building blocks for optical metamaterials, where the spectra of the components and the nature of the coupling between them determine the effective optical response. Two different assembly strategies illustrate the potential. First, thermoreversible gel networks of nanocrystals are fabricated where LSPR coupling controls the infrared optical spectrum and distribution of near-field hot spots. Second, superlattice films of ITO nanocrystals exhibit tunable epsilon-near-zero (ENZ) spectral windows depending on the mixing ratio between two components with distinct tin doping concentrations. An efficient computational method has been developed to interpret the optical spectra and enable design of metamaterials with targeted optical response.

Temperature Adaptive Solar and Radiative Coating for Thermal Management of Terrestrial and Space Objects Jiachen Li, Kaichen Dong, Derick Tseng, Kai Xu and Junqiao Wu; University of California, Berkeley, United States

The sky is a natural heat sink that has been extensively used for passive radiative cooling of households. Materials with minimized solar absorption and maximized infrared emission have been realized for daytime radiative cooling. To further improve the overall energy saving of radiative roofs, we developed a mechanically flexible solid film that adapts its thermal emittance to different ambient temperatures at zero energy consumption. Our recent efforts have led to the fabrication of the temperature adaptive radiative coating (TARC) at large scale and low cost. Experiments and simulations show TARC outperforms existing roof coatings for energy saving in most climates. A similar, temperature adaptive solar coating (TASC) could be also envisioned that adapts its solar absorptance to ambient temperature. The TARCs and TASCs may also find broad applications in other markets such as vehicles, spacecraft/spacesuits, textiles, and electronics, the benefits of which have been confirmed by our simulations.

2:00 PM *EN11.07.02
Phase-Changing Copolymers for Thermoresponsive Transmittance Modulation Qibing Pei; University of California, Los Angeles, United States

Thermoresponsive materials exhibiting switchable transmittance via temperature change are useful for smart window applications. We have introduced solid-state thermoresponsive phase-changing copolymer films with large transmittance modulation between room and elevated temperatures. The copolymer films comprise two phase-separated co-monomers. By controlling the domain size and the crystallinity of the phase-changing domain, two distinct transmittance modulation modes are made possible. The first mode undergoes opaque-to-transparent transition from room to elevated temperatures, while the second has the opposite transition. The copolymer films are investigated for either electrically controlled opacity change or autonomous and climate-adaptable solar modulation.

Facile Manufacturing of Breathable, Washable and Fabric-Integrated Squid-Inspired Thermoregulatory Composites Sanghoon Lee, Mohsin Ali Badshah, Erica M Leung, Panyiming Liu, Aleksandra A. Strzelecka and Alon Gorodetsky; University of California, Irvine, United States

Effective thermal management is critical for the operation of many modern technologies, such as smart clothing and food packaging. By leveraging the static infrared-reflecting design of the space blanket and drawing inspiration from the dynamic color-changing ability of squid skin, we have developed composite materials with tunable thermoregulatory properties specifically for these applications [1, 2]. Our composites demonstrated an on/off switching ratio of ~25 for the transmittance, regulate a heat flux of ≥ 30 W/m^2 with an estimated mechanical power input of ~ 3 W/m^2, and feature a dynamic environmental setpoint temperature window of ~ 8 °C [1]. Such composites moreover could be sustainably manufactured over large areas of ~ 0.3 m^2 at a low estimated starting material cost of around $ 0.1 m^{-2} [2]. We have now developed washable, breathable, and fabric-integrated variants of our composites that demonstrate the ability to withstand multiple wash cycles, feature air and water permeabilities similar to common fabrics, and maintain their desirable tunable thermoregulatory functionalities, respectively [3]. Due to their state-of-the-art figures of merit, our bioinspired composite materials hold potential as a platform technology for next-generation sustainable and wearable thermal management systems.

Visibly Transparent and Infrared Reflective Coatings for Personal Thermal Management and Thermal Camouflage Ho Kun Woo[1], Kai Zhou[1], Su-

Kyung Kim[2], Adrian Manjarrez[1], Muhammad Jahidul Hoque[1], Tae-Yeon Seong[2] and Lili Cai[1]; [1]University of illinois, United States; [2]Korea University, Korea (the Republic of)

Tailoring thermal radiation using low-infrared-emissivity materials has drawn significant attention for diverse applications, such as passive radiative heating and thermal camouflage. However, the previously reported low-infrared-emissivity materials have the bottleneck of lacking independent control over visible optical properties. Here, we report a novel visibly transparent and infrared reflective (VTIR) coating by exploiting a nano-mesh patterning strategy with an oxide/metal/oxide tri-layer structure to realize. The VTIR coating shows simultaneously high transmittance in the visible region (> 80% at 550nm) and low emissivity in the mid-infrared region (< 20% in 7 – 14 µm). Our VTIR coating not only shows a radiative heating effect of 6.6 °C for indoor conditions, but also enables a synergetic effect with photothermal materials to keep human body warm at freezing temperatures for outdoor conditions, which is 10 – 15 °C warmer than normal cotton and Mylar film. Moreover, it demonstrates an excellent thermal camouflage effect at various temperatures (34 °C – 250 °C) and good compatibility with visible camouflage on the same object, making it ideal for both daytime and nighttime cloaking. With its unique and versatile spectral features, this novel VTIR design has great potential to make a significant impact on personal heat management and counter-surveillance applications.

3:30 PM EN11.08.03
Sweat-Responsive Continuous and Wide-Range Infrared Chromism in MXenes for Adaptive Textiles Keqiao Li, Yang Li and Baoling Huang; The Hong Kong University of Science and Technology, China

The dynamic control of infrared (IR) radiation from surfaces is highly desired in a variety of areas. In particular, smart textiles, which can passively cool/warm the human body by regulating the radiative heat exchange with the environment, have aroused significant interest. Unlike air conditioners, such smart textiles can locally regulate the skin temperature without heating/cooling the entire building interior space, which is more efficient and energy-saving. In addition to the modulation of IR emissivity (ε) in a continuous manner over a wide range, adaptive textiles need to satisfy other requirements in flexibility, wearability, and water/air permeability, making it challenging to realize. Here, we report an infrared chromism phenomenon found in stacked $Ti_3C_2T_x$ MXene nanosheets, where the emissivity varies in a wide range of 0.12 to 0.68 as the adsorption/desorption of physisorbed water within the interlayers of stacked nanosheets. This emissivity modulation is a continuous and reversible process without the assistance of any external device and energy input. By intercalating cellulose nanofibers into the $Ti_3C_2T_x$ interlayers, the stability of water adsorption is significantly enhanced, making the dynamic process highly repeatable. Based on this water-induced emissivity modulation, we demonstrate a sweat-responsive adaptive textile that can help the human body adapt to fluctuations in personal heat load. When the human body feels cold and keeps dry, the textile is in low-*ε* modes where thermal radiation of the human body outwards can be suppressed to keep warm; otherwise, the textile can switch to wet states and high-*ε* modes. The radiative heat dissipation is enhanced significantly for cooling the human body. Besides the application in personal thermal management, this strategy may also find opportunities in other scenarios requiring adaptive IR emissivity regulation, including IR camouflage and IR anti-counterfeiting.

3:45 PM EN11.08.04
Noninvasive Measurement of Core Body Temperature from the Human Forearm Gimin Park[1], Seungjai Woo[1], Kyomin Kim[1], Jiyong Kim[1], Sang Kyu Kim[2], Kogsoon Kwon[2], Hotaik Lee[2], Soyoung Lee[2], Sungho Kim[2], Hongsoon Rhee[2] and Woochul Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of)

The human core body temperature (CBT) is one of the most fundamental indications for determining a subject's health condition [1]. The traditional invasive method of measuring CBT is inserting a temperature probe into specific sites of the human body (*e.g.*, esophagus, rectum, axilla, and tympanic membrane). To overcome the downsides of invasive methods like discomfort and poor standards of hygiene, researchers have developed noninvasive CBT sensors including the zero-heat-flux sensor and the double sensor. The major drawback of these noninvasive CBT sensors is that they hinder the subject's operative capabilities as they must be attached to regions close to the internal organs (*e.g.*, forehead and thorax). In this study, we present a noninvasive method of determining the subject's CBT by gathering certain thermophysical data at the forearm (*i.e.*, the skin temperature, heat flux, and blood perfusion rate). Under a thermoneutral state, experimental data show that the CBT region extends out to the extremities, which includes the large arteries at the forearm. We have measured the surface temperature and heat flux with a resistance temperature detector and a thermopile heat flux sensor, respectively. Also, we have incorporated a way to measure the blood perfusion rate thermally *via* sinusoidal heating. With the measured data, solving the Pennes' bioheat equation in a heterogeneous medium to account for variability in tissue layers allows for the estimation of CBT within a few degrees. The study was performed on human subjects for a period of approximately forty minutes. One subject showed promising results with estimated average range of CBT of 0.73°C. For periods where the subject's actual CBT (axillary temperature) did not fall within the estimated range, the average deviation away from the actual CBT was only 0.24°C. This study leaps towards a more convenient way of gaining the subject's health condition.

Non-dispersive Production Strategy of Binder-Free Boron Nitride Slurry via Differentiation of Exfoliation, Amorphization and Functionalization Yujin Han, Hanhwi Jang and Yeon Sik Jung; KAIST, Korea (the Republic of)

Miniaturization and high-power consumption of modern electronic devices have led to local heat generation and accumulation issues, and as a result, demand for thermal dissipation technology has increased recently. Hexagonal boron nitride (BN) is recently highlighted as a material for thermal regulation due to excellent thermal conductivity ($750 Wm^{-1}K^{-1}$) with electrical insulation and thermal stability. In spite of the great advantages of superior thermophysical properties, poor interfacial interaction between BN nanosheets often degrades the collective functionality, and conventional approaches inevitably used an additive to compensate for the formability, but this severely diluted the BN's thermophysical properties. In this study, we report a highly effective non-dispersive binder-free BN slurry production method. The method is totally conversive without loss of materials, immediately applicable, and shows wide morphology variability by virtue of excellent dispersity and rheological characteristics. By adjusting hydrodynamic stress regimes and mechanochemical reaction conditions, we strategically differentiate the functionality of BN nanosheets into a physically exfoliated BN (p-BN) as a thermal conductive component and a mechanochemically treated BN (m-BN) as an interfacial adhesive component. Via finding an optimal ratio of p-BN and m-BN that maximize the thermophysical functionality and mechanical stability, the casted BNs exhibit excellent thermal conductivity (> $40 Wm^{-1}K^{-1}$,) with high adhesion energy over $3.8 J/m^2$ without any additive incorporation. Owing to systematically ordered microstructures with rich hydrogen bonding component, the casted BN is well-adhered to the heat exchange unit and successfully reduce working temperatures of the various device modules including high power LED, central processing unit (CPU) and Peltier module. Furthermore, confirmed by high temperature combustion and neutron radiography, the binder-free characteristic with rich boron contents in the casted BN film gives superior flame retardancy (> 900°C) and thermal neutron absorption ($>1.3x10^3 cm^{-1}$).

5:00 PM EN11.09.01
Enhanced Thermal Performance of Selenides Compounds Synthesized by Ball Milling or the Pack Cementation Process Evangelia Tarani[1], Dimitrios Stathokostopoulos[1], Dimitris Karfaridis[1], Ioanna Sfampa[2], Fani Stergioudi[1], Nikolaos Michailidis[1], Konstantinos Chrissafis[1] and George Vourlias[1]; [1]Aristotle University of Thessaloniki, Greece; [2]KLEEMANN, Greece

The operation of the elevators inside and/or outside the buildings requires the installation of additional functions in the cabin. However, the use of conventional air conditioners has a detrimental effect on the construction level, energy consumption, noise level in the cabin, and the environment. An innovative method that can be applied alternatively in order to overcome most of these problems is the use of suitable thermoelectric air conditioners. In this direction, thermal storage plays a key role to lower building energy consumption. The thermoelectric materials community has made significant progress on nanostructured and process able materials to improve efficiency and flexibility, reducing manufacturing costs. Selenide compounds, such as Ag_2Se and Cu_2Se, have received a lot of attention because of their promising capabilities in thermoelectric applications. Additionally, Ag, Cu, and Se are less toxic than Bi, Pb, Sb, and Te, while Se is about 10 times more abundant than Te.
Two different methods for the synthesis of Ag_2Se and Cu_2Se compounds have been used. The first one is the high-energy ball milling (HEBM) process, which is a powerful solid-state synthesis/powder mechanical alloying method, using different milling times (1-20 hours). The second one is the simple, cost-effective, and eco-friendly technique of pack cementation. The structural and morphological characterization of the synthesized selenides was studied by Fourier Transform Infrared Spectroscopy, X-ray Diffraction, X-ray Photoelectron Spectroscopy and Scanning Electron Microscopy. The thermal stability of the prepared samples was examined by Thermogravimetric analysis (TGA).
The synthesis of samples with the pack cementation method is the result of a reactive diffusion process due to the reaction of the donor materials with the products of the halide activator.

Real-Time Manipulation of Multiphase Fluids Using Photo-Responsive Surfactants Xichen Liang, Kseniia Karnaukh, Lei Zhao, Serena Seshadri, Sophia J. Bailey, Michael Haggmark, Matthew Helgeson, Michael Gordon, Paolo Luzzatto-Fegiz, Javier Read de Alaniz and Yangying Zhu; University of California, Santa Barbara, United States

The manipulation of multiphase fluids has been identified as a crucial process for a variety of applications, including thermal management of buildings and electronics, power generation, desalination and bio-medical devices. While most previous works rely on passive control of fluid through artificial micro-/nanostructured surfaces, active methods using an electric, magnetic or thermal stimuli to control multiphase fluids offer real-time tunability and multi-functionality. However, existing methods typically rely on a high voltage (10-1000 V), a strong magnetic field (0.1 T), or a high temperature gradient generated by a high power source such as lasers. Here, we demonstrate dynamic control of liquid droplets in a multi-phase fluid system using light-sensitive surfactants that can induce large changes in the interfacial tension thereby exerting a photo-Marangoni force on a droplet. The surfactants are activated by visible light whose intensity is 1-2 orders of magnitude lower than the laser intensities used in thermal-capillary actuation. We characterize the magnitude and rate of change in interfacial tensions of various fluid-fluid systems. We also demonstrate fast and programmable movement of liquid droplet on liquid-infused-surfaces, inside microchannels, and on liquid substrates. Furthermore, we present a theoretical framework underlying the key parameters that contribute to the droplet motion. The results demonstrated in this work opens exciting doors for the use of photo-sensitive surfactants for dynamic manipulation of multiphase fluid systems for energy, building, thermal management and microfluidics applications.

5:00 PM EN11.09.04
Encapsulation and 3D Printing of Salt Hydrates for Thermal Energy Storage Sarah Lak, Patrick Shamberger and Emily Pentzer; Texas A&M University, United States

Thermal energy storage technologies are crucial for the growth of sustainable energies due to the intermittent nature of many renewable energy resources. Salt hydrates, a class of phase change materials (PCMs), are promising as low-cost, high volumetric energy density media for latent heat storage. However, their inherent limitations such as undercooling and incongruent melting render them unstable for extended thermal cyclability. Microencapsulation can mitigate some of these challenges, enhance heat transfer efficiency, and minimize moisture loss/gain from the external environment to improve PCM performance. We demonstrate the use of non-aqueous Pickering-type emulsions, stabilized by alkylated graphene oxide (GO) nanosheets, as templates for subsequent precipitation of commodity polymers to access core-shell microcapsules loaded with salt hydrates. These microcapsules are robust to thermal cycling, exhibit minimal undercooling in comparison with the bulk salt hydrate, and have a high loading (~90 wt%) of pristine core material. Further, this single-step, highly tunable approach is amenable to different salt hydrates as cores and different polymers as shell materials, making it suitable for tailoring capsule properties. Alternatively, we have formulated functional inks containing salt hydrate PCM particles as rheological modifiers in polymer solutions; eliminating the need for prior microencapsulation of the PCM. These inks are then 3D printed into complex hierarchical structures using a direct ink writing technique. This approach affords excellent passive thermoregulation properties to the fabricated composites, representing a significant advancement in developing materials aimed towards energy management and sustainability.

5:00 PM EN11.09.05
Facile Synthesis of High Thermal Conductive h-BN Microspheres/Paraffin Wax Shape-Stabilized Phase Change Materials for Intelligent Heat Storage System Hyung Jin Mun, Ye-Ji Lee, Hyunji Kang, Minseob Lim, Hong-Baek Cho and Yong-Ho Choa; Hanyang University, Korea (the Republic of)

The entire humanity is experiencing a severe energy consumption dilemma. As a result, increasing the efficiency of energy utilization and avoiding its depletion as a critical solution has gained increasing global attention. Thermal energy storage technology plays a significant role in reducing the disparity between energy demand and supply as a highly efficient technique for management of energy [1]. Among all the materials, phase change materials (PCMs) have garnered the most attention in numerous fields such as building and temperature control equipment due to their ability to capture and release a large amount of thermal energy during their melting and freezing processes, with superb advantages of storing or releasing the thermal energy at a constant temperature or within a narrow temperature range. Among a wide spectrum of prospective organic and inorganic PCMs, paraffin wax (PW) is particularly attractive because of their low price, large latent heat, chemical stability, no toxicity, and lack of phase separation. However, one of the main undesirable drawbacks of PW is low thermal conductivity, which decreases the efficiency of heat transfer. Moreover, the leakage of the PCMs when the application temperature exceeds the melting point hinders the direct application to numerous fields. In order to tackle the challenges, a method of encapsulation or shape stabilization of PCMs using supporting materials was considered, which allows the solid state to be maintained during the phase-change process of PCMs.

In this work, we utilized a spray-dry strategy to fabricate thermally conductive hexagonal-boron nitride microspheres (sph-BN) as a shape-stable porous support using the as-synthesized nano-BN (nano-BN) powders. Sph-BN was assembled with polyvinylpyrrolidone (PVP) as an organic binder during the process followed by calcination to form porous structures in sph-BN after elimination of PVP between nano-BN. High thermally conductive sph-BN/PW shape-stabilized PCMs (SSPCMs) composites were successfully obtained by simple solution process that PW is incorporated into the pore sites in sph-BN at above of melting temperature of PW followed by mold-pressing into disk-shaped specimen. The leakage tests by macroscopic photographs of the SSPCMs and pure PW at 25^{o}C and elevated temperature up to 100^{o}C were performed, resulting in pure PW was in a molten state and the primary shape was completely changed while sph-BN/PW composites perfectly kept their primary form even at temperatures much beyond the melting point of PW. The phase change enthalpies and heat storage capacities of sph-BN/paraffin SSPCMs were determined by differential scanning calorimetry. In addition, the latent heats of the SSPCMs increased with increasing contents of paraffin in the composites. The thermal conductivity shows a slight decrease as the ratio of paraffin increases; yet it is still higher than that of pure paraffin, due to the existence of thermally conductive sph-BN in the organic matrix. As mentioned above, SSPCMs we developed represent an important step to develop leakage-protective PCMs with high performance and enhanced thermal conductivity. Therefore, we believe our work can be widely applied to latent heat thermal energy storage.

High-Performance Electrodeposited Copper Wicks for Heat-Spreading Vapor Chambers Jui-Cheng Yu[1], Heng-Chieh Chien[2] and Chien-Neng Liao[1]; [1]National Tsing Hua University, Taiwan; [2]Industrial Technology Research Institute, Taiwan

With the increasing heat flux in electronic packages or power electronic devices in the last decade, vapor chambers have been considered a promising solution to this problem due to their excellent thermal performance. A capillary wick structure plays an important role in producing the capillary pressure that drives two-phase circulation in phase-change heat transfer devices such as heat pipes and vapor chambers. In this study, the porous Cu wick structures were fabricated using a new electrodeposition process and examined for their capillary performance. This Cu wick exhibits large channels generated by hydrogen bubbles and small pores in the dendritic Cu deposits produced by high-current electrodeposition. Adjusting the morphology of dendritic copper deposits by using different electrodeposition current densities and copper sulfate concentrations in the electrolyte can effectively enhance the capillary wick performance. The Cu wick is then thermally treated at 700 °C in ambient N_2 for 90 min to improve its structural integrity. The Cu wick shows a superior capillary performance K/R_{eff} of 1.5 ± 0.06 mm and excellent structural stability. Such a high capillary performance can enhance the mass transport rate and effective transport distance of the working liquid in vapor chambers for high-density and long-range heat dissipation applications. Test results demonstrated that a vapor chamber integrated with an electrodeposited Cu wick has excellent heat-spreading characteristics, with an effective thermal conductivity of up to 13500 W/m×K.

5:00 PM EN11.09.07

Shape Stabilized Phase Change Materials Based on Polyethylene Glycol/Carbon Black/Multi-Walled Carbon Nanotubes for Latent Heat Thermal Energy Storage Systems Hyunji Kang, Hyung Jin Mun and Yong-Ho Choa; Hanyang University, Korea (the Republic of)

An impending shortage of fossil fuels, combined with the deterioration of the ecological environment, has sparked widespread interest in environmentally friendly renewable energy sources. Utilization of renewable energy and the development of high-performance energy storage solutions are now essential for scientific and technical progress. Thankfully, thermal energy storage (TES) technologies provide a unified answer to the supply continuity issues of sustainable energy storage systems. TES technologies are often classified as latent heat storage, sensible heat storage, or thermochemical energy storage. In general, latent heat storage is larger than sensible heat storage; as a result, less mass and volume of the material is necessary to achieve a high level of energy efficiency. Furthermore, the phase change occurs at a constant temperature, therefore avoiding corrosion by temperature and other handling issues. The PCM's latent heat property is employed to store energy during phase change. The phase shift includes liquid-vapour transition (latent heat of vaporization) and solid-liquid transition (latent heat of fusion), with the latter being used more often. PCMs are being researched in a wide range of industries, including the construction industry, automotive industry, asphalt industry, food industry, textile industry, and battery thermal management systems[1].

Organic PCMs, such as paraffins, fatty acids, esters, alcohols, polyethylene glycol (PEG), etc., are widely used as TES materials since for their chemical stability, low cost, high phase transition enthalpy, adequate phase change temperature range, and little supercooling. Despite the improvement of latent heat storage technology, liquid phase leaks, poor thermal and electrical conductivity, low photoabsorption capacity, and intrinsic rigidity of pristine PCMs have often hindered the efficient collection and release of energy as needed. Liquid phase leakage and low thermal conductivity of pristine PCMs may cause possibly dangerous conditions and slow thermal charging/discharging rates, respectively. Concerning liquid phase leaks, the most common option is to put nanoporous supporting materials into PCMs to produce shape-stabilized composite PCMs through capillary force and hydrogen bonding interactions. Adding carbonaceous materials, two-dimensional boron nitride nanosheets and MXenes owing to their high electrical conduction, outstanding solar absorption, and high thermal conductivity is a thoughtful approach to achieving highly effective electric to thermal conversion and solar to thermal conversion in materials with poor thermal/electrical conductivity and low photoabsorption capacity[2].

Here, PEG is used as a PCM, and carbon black and CNT are used to construct a supporting material and conductive pathway simultaneously. As a representative linear polymer, PEG is a typical and excellent solid to liquid PCM with the superior properties of nontoxicity, relatively high latent heat storage capacity, broad selectivity of molecular weight, low vapor pressure when melted, and excellent thermal and chemical stability. As a result of the shape-stabilized PCM process, PEG is well attached to the porous structure of carbon, and PEG leakage is prevented above PEG's melting points. Based on the interaction of the synergistic conductive network of CB/MWCNT, the thermal conductivity of composite is improved.

SESSION EN11.10: Thermal Energy Storage and Utilization I
Session Chairs: Sumanjeet Kaur and Zhengmao Lu
Thursday Morning, April 13, 2023
Moscone West, Level 2, Room 2005

9:15 AM EN11.10.01
High Density Thermal Energy Storage by Highly Stable Glauber's Salt Composites with Low Supercooling for Building-Scale Application Sung Bum Kang, Youngmun Lee, Daniel Hsieh, Wuchen Fu, Ho Chan Chang, Jay M. Taylor, Mayur S. Prabhudesai, Nenad Miljkovic, Sanjiv Sinha and Paul V. Braun; University of Illinois at Urbana-Champaign, United States

Phase change materials (PCM) are a promising candidate for thermal energy storage in building infrastructure, enabling grid-integrated peak load shaving by utilizing energy production in off-peak hours. Glauber's salt ($Na_2SO_{4.}10H_2O$, Sodium sulfate hydrate) are highly attractive due to their high energy storage capacity and low cost but Glauber's salt suffers from long-standing challenges including high supercooling (> 15^{o}C) and low thermal cyclic stability, which is a major setback for practical building-scale energy storage applications. Here, we developed a unique ionic molecular nucleating agent for Glauber's salt which reduced the supercooling temperature to less than 5^{o}C. By combining this nucleated SSD with a polymer, phase segregation of salt hydrate for over 100 thermal cycles without degradation was achieved. Key was that the polymer confined the SSD crystals, preventing phase separation. In addition, we applied our stable Glauber's salt composite in a miniatured building model and demonstrate that our PCM composite can be utilized for real-world building infrastructure.

9:30 AM EN11.10.02
Interpreting T-History Data on Supercooling and Phase Change Enthalpy of a Salt-Hydrogel Complex for Building Thermal Management Youngmun Lee, Daniel Hsieh, Wuchen Fu, Ho Chan Chang, Sung Bum Kang, Mayur S. Prabhudesai, Jay M. Taylor, Paul V. Braun, Nenad Miljkovic and Sanjiv Sinha; University of Illinois at Urbana Champaign, United States

Phase change materials (PCMs) are promising materials for storing and discharging latent heat in buildings to regulate the thermal environment. Measurement of salt hydrate PCM thermal performance is often challenging because of supercooling and phase segregation. Though differential scanning calorimetry (DSC) has been widely used to measure thermal properties of various phase change materials, DSC uses milligrams of sample and is unrealistic for predicting large-scale materials performance. The T-history method [1], in contrast, handles higher volumes but the analysis typically requires a lumped capacitance assumption. Here, we report and analyze T-History data on a novel salt-hydrogel complex with high viscosity, that renders low Biot number sample preparation extremely challenging. We re-examine the standard T-history method and compared against DSC data in this complex material. We report details of an experimental setup, built with necessary additions to a controlled environmental chamber. We carefully examine the validity of the lumped capacitance assumption and suggest a modified analysis using a computational approach for reliable data. Experimental parameters such as ramp rate and temperature range of the environmental chamber are considered via computational modeling to understand the effect of ramp rate on supercooling [2]. Finally, we report thermal cycling experiments on the salt-hydrogel complex. Our modified approach to measuring supercooling and enthalpy of fusion at large scales is important in better understanding the performance of phase-change materials at scale for building thermal storage.

Thermochemical Heat Pipes for District Heating and Long Distance Thermal Transport Yanan Zhang and Robert Y. Wang; Arizona State University, United States

District heating plays an important sustainability role by delivering waste heat to user-occupied buildings through the use of hot water as an energy carrier. However, one limitation of district heating is the thermal energy losses that occur when heat is transported over long distances. These losses occur because the thermal energy is stored as sensible and latent heat in the water, which is inevitably dissipated to the outdoor ambient environment during long distance transport. In this talk, we explore the combination of thermochemical heat and chemical separation to facilitate a new type of district heating system. This system is capable of transporting waste heat over arbitrarily long distances, and we refer to it as a "thermochemical heat pipe."

In brief, the proposed district heating system transports thermal energy from power plants to user-occupied buildings through reversible liquid-phase endothermic/exothermic reactions. Waste heat from the power plant is used to both (i) drive the endothermic cleavage of an adduct molecule into two small reactant molecules and (ii) chemically separate the reactant molecule via distillation. The separated molecules are then pumped to their destination where they are combined in an exothermic reaction that provides heat to buildings (and chemically reform the adduct molecule). The adduct molecule is then pumped back to the power plant for re-use. Thermodynamic analysis of the system shows that heat transport efficiencies of ~30% are possible when only the thermochemical energy storage component is used. This efficiency can be boosted up to ~70% by incorporating heat exchangers that recover the sensible and latent energy components prior to long distant thermal transport. Pump work analysis shows that thermal transport over thousands of kilometers is feasible when transport is done in the liquid phase.

Impact on Energy Use and Load Shifting of Material Properties of Enclosure-Based Phase Change Materials Energy Storage Systems Charles Booten, Ravi Kishore, Marcus Bianchi, Judith Vidal, Ph.D and Roderick Jackson; NREL, United States

Deploying phase change material (PCM) in building envelopes can be effective in reducing space heating/cooling loads and providing load shedding and shifting capacity. However, the full potential of PCM-integrated envelopes can only be harnessed if the PCM undergoes a complete phase change, and the stored energy is effectively transferred to the interior of the building. Thus, there have been proposed dynamic insulation materials and systems (DIMS) to vary the thermal resistance of building envelopes based on the indoor and outdoor conditions to maximize PCM phase change. We also perform a sensitivity analysis of the impact of system and material properties such as latent heat, PCM thickness, transition temperature and range, density, thermal conductivity, and DIMS switch ratio on load shifting. We examine a novel wall design, comprising of a layer of PCM between two layers of DIMS. The PCM-DIMS-integrated wall provides significantly higher energy saving potential than the DIMS-only integrated wall or the PCM-only integrated wall in all climates and wall orientations analyzed in this study. Depending on the climate, the PCM-DIMS-integrated wall could provide 15% to 72% reduction in annual heat gain and 7% to 38% reduction in annual heat loss. We also show that optimized properties can result in a 70% reduction the wall related heat gain during peak hours with only a minor increase in total-daily heat gain. The analysis presented in this study serves to encourage the development of scalable dynamic insulations combined with thermal energy storage systems for buildings.

Salt Hydrate Eutectics: Tailored Design of Equilibria, Reversibility, and Stability in Complex Phase Change Material Systems Sophia Ahmed, Anirban Chakraborty, Denali Ibbotson, Sarah Lak, Kartik Rajagopalan, Achutha Tamraparni, Charles Culp, Jonathan Felts, Emily Pentzer, Svetlana A. Sukhishvili, Choongho Yu and Patrick Shamberger; Texas A&M University, United States

A critical aspect of thermal energy storage systems for the built environment is the development of thermal energy storage media that will reversibly store and discharge thermal energy repeatedly within a defined temperature range. For example, to optimize efficiency, some environmental climate control and air conditioning systems require thermal energy storage between 5 to 25 °C. To address this need, eutectic salt hydrates have been identified as promising candidate systems that will allow for the tailoring of bespoke low cost thermal energy storage systems, due to the large number of potential eutectics distributed across a broad temperature range. However, these phase change materials are associated with a number of known limitations (undercooling, phase segregation, low heat transfer rate) which limit their practical use in energy storage systems. Individual strategies have been identified to overcome many of these challenges. For example, nucleation agents are utilized to decrease undercooling, while thickeners or polymers which form salogels are utilized to limit phase segregation. However, the interaction between these different strategies has not been systematically investigated.

Here, we present recent efforts to expand the palette of low cost high energy storage density salt hydrate eutectics developed for building thermal energy storage applications. We compare theoretical predictions against validated eutectic compositions and properties, and highlight some of the advantages and challenges associated with these materials. We specifically address efforts to overcome the known technical limitations of salt hydrates, and their relevance to salt hydrate eutectic systems, including 1) the introduction of specific nucleation agents to promote reversibility in salt hydrate systems, 2) the introduction of polymer salogels to stabilize systems from phase segregating, 3) the introduction of expanded graphite networks to improve heat transfer through these systems, 4) the use of encapsulants to encase PCM particles, and 5) the use of scaled testbeds to evaluate stability of systems under use conditions. Addressing all of these challenges results in a complex multi-phase material system which introduces additional interactions. Here, we will focus on both individual strategies and the resulting interactions, using development of zinc nitrate hexahydrate-based eutectic systems as an example model system. We will demonstrate successful implementation of tailored low-cost PCM systems, and will emphasize ongoing challenges in this area.

11:15 AM EN11.10.06
Thermal Conductivity of a Novel Salt-Hydrogel Complex as a Phase Change Material for Building Thermal Management Daniel Hsieh[1], Youngmun Lee[1], Mayur S. Prabhudesai[1], Sung Bum Kang[1], Ho Chan Chang[1], Wuchen Fu[1], Jay M. Taylor[1], Paul V. Braun[1,2], Nenad Miljkovic[1,1,2] and Sanjiv Sinha[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Materials Research Laboratory, United States

Use of electricity for space heating, ventilation and air conditioning in buildings may be better managed through temporary energy storage. Compared with electrochemical storage, the levelized cost of thermal energy storage systems can be lower depending on geographical location and thermophysical properties [1]. In any phase change material (PCM), the rate of absorption and release of thermal energy increases with higher thermal conductivity [2]. However, leading PCMs like paraffin waxes have thermal conductivities on the order of 0.1 W/mK. Glauber's salt, a salt hydrate, possesses a relatively high thermal conductivity but suffers from supercooling and phase segregation. Research has shown that polymer-based composites with salt hydrates can prevent phase segregation and limit supercooling over hundreds of cycles [3] though the thermal conductivity of the composite may be reduced leading to low energy storage rates. Here, we report thermal conductivity measurements on polymer hydrogels which are stable in solutions of Glauber's salt. To measure thermal conductivity of soft gels, we use a 3-omega method [4] where heat flows bidirectionally through a substrate below and through a gel placed on top. This suits measurements of both gels and liquids unlike transient plane heat source or transient hot wire methods. We report measurements of thermal conductivity of salt-hydrogel complexes as a function of temperature, cross-linking and salt concentration. In addition, we present modeling of thermal conductivity of sodium sulfate solutions with available theories. We finally employ polarized optical microscopy to observe inside the transparent hydrogel networks, showing that precipitating crystals may influence thermal conductivity measurements for high salt concentrations. Our thermal conductivity results combined with enthalpy of phase change, mass density and specific heat are essential to accurately design thermal storage systems for energy-efficient buildings.

11:30 AM EN11.10.07
Role of Ba-containing Compounds in the Nucleation of Solid Calcium Chloride Hexahydrate Denali Ibbotson, Sophia Ahmed and Patrick Shamberger; Texas A&M University, United States

Currently, heating and cooling of commercial and residential buildings is one of the leading consumers of energy in the country, accounting for 40% of building energy demand and about 75% of all electricity use. One method used to increase HVAC system efficiency and to allow for more efficient load displacement, is to incorporate phase change materials (PCMs) into thermal energy storage systems, as PCMs are able to passively store and release heat, allowing for a pathway to displace peak energy load for buildings to better align with available excess energy generation. However, robust and economical phase change materials that are tailorable to a specific desired energy storage temperature are needed to accomplish this task. Salt hydrates represent one class of PCMs of interest due to their high volumetric energy densities, low cost, and the ability to tailor the energy storage temperature through the design of custom salt hydrate eutectics. However, they can also experience undercooling, a nucleation-limited phenomena which results in the existence of a metastable liquid below the melting point. This phenomena can lead to undesired issues, including incongruent melting and phase segregation. To induce nucleation, and thereby improve the reversibility of the thermal energy storage process, nucleation agents can be added to a PCM system to induce nucleation, and thereby suppress the formation of metastable phases. In many cases, the underlying mechanisms governing which nucleation agents introduce potent nucleation sites and which do not, are not well understood.
In this study, we investigated the dependence of undercooling in calcium chloride hexahydrate ($CaCl_2.6H_2O$), a low-cost salt hydrate that melts at 29°C, on the crystal structure, chemistry, and the solubility of a family of Ba-based compounds. We utilized calorimetric techniques to measure undercooling in small quantities of calcium chloride hexahydrate with different nucleation agents, and differing weight percentages of the nucleation agents. We observed in several cases that the addition of barium-based nucleation agents resulted in at least a 10°C reduction in the undercooling, enabling practical utilization of $CaCl_2.6H_2O$. However, some variability existed between different compounds, as nucleation agents such as barium carbonate and barium hydroxide were observed to be effective nucleators and resulted in a larger reduction of the undercooling, while nucleation agents such as barium iodide or barium chloride dihydrate had minimal effects on the reduction of the undercooling. Additionally, we observed that the presence of insoluble particles of the nucleation agents aided in reducing the undercooling of the system and also resulted in more consistent melting behavior. The structure of the nucleation

agents was also noted to have little effect on the undercooling, however it was observed that a cation substitution reaction can occur while the Ba-based nucleation agent is in solution. Therefore, a resulting phase from the reaction of the Ba-based nucleation agent with calcium chloride hexahydrate could be responsible for the reduction in undercooling, which is an area that will be further investigated. If we can pinpoint the attributes and mechanisms that make Ba-based compounds effective nucleation agents, then it will allow us to design more efficient phase change materials that are better suited for thermal energy storage applications.

Thermodynamic Analysis of a Smart ThermOREsponsive (STORE) Polymer Desiccant Dehumidification and Cooling Cycle Jordan D. Kocher[1,2], Shannon K. Yee[1] and Robert Y. Wang[2]; [1]Georgia Institute of Technology, United States; [2]Arizona State University, United States

Smart ThermOREsponsive (STORE) polymers represent a new class of desiccant materials that could significantly advance performance in dehumidifiers and air conditioners. STORE polymer desiccants regenerate by undergoing a hygroscopic-to-hydrophobic phase transition at a lower critical solution temperature (LCST). This regeneration mechanism leads to fundamental advantages relative to traditional desiccants. The performance of traditional desiccants is intrinsically tied to psychrometrics because they regenerate by desorbing *gaseous* water into a stream of hot dry air. In contrast, the performance of STORE polymers is intrinsically tied to materials chemistry. STORE polymers instead regenerate by releasing *liquid* water through their LCST phase transition, and this relaxes constraints on entropy generation and minimum regeneration temperature.

In this talk, we present a thermodynamic description of a theoretical air conditioning cycle that uses STORE polymers, which we refer to as the "LCST cycle." We combine the First and Second Law to demonstrate that this cycle has three major advantages relative to the traditional desiccant cycle: (i) regeneration at lower temperatures, (ii) the ability to directly harvest liquid water, and (iii) significantly higher coefficients of performance (COPs). For example, this new cycle can achieve a COP of ~4 when regenerated at 80 °C, whereas traditional desiccant cycles asymptote to a COP of ~ 1. Due to its liquid water harvesting capability, the new cycle potentially eliminates water consumption when used with evaporative cooling, or it can be directly used for atmospheric water harvesting.

This research was performed under an appointment to the Building Technologies Office (BTO) IBUILD- Graduate Research Fellowship administered by the Oak Ridge Institute for Science and Education (ORISE) and managed by Oak Ridge National Laboratory (ORNL) for the U.S. Department of Energy (DOE). ORISE is managed by Oak Ridge Associated Universities (ORAU). Direct Ink Writing of Three-Dimensional Thermoelectric Microarchitectures Seong Eun Yang, Fredrick Kim, Hyejin Ju, Han Gi Chae and Jae Sung Son; Ulsan National Institute of Science & Technology, Korea (the Republic of)

Micro thermoelectric modules can be used to develop unique components such as energy harvesters, active coolers, and thermal sensors in various integrated systems. However, the fabrication of these modules still relies on expensive traditional microfabrication processes that produce only two-dimensional (2D) thermoelectric films. This limitation severely limits the formation of a temperature gradient across the thermoelectric film, so that sufficient power is not generated to run the integrated system. Here, we present direct ink writing of a micro-scale three-dimensional (3D) thermoelectric architecture for fabricating high-performance micro-thermoelectric generators. We synthesized a Bi_2Te_3-based TE particle ink with extremely viscoelastic properties and applied it to a direct-write process to print microscale 3D TE filaments with high aspect ratios and controlled diameters ranging from 180 µm to 810 µm. Thereby, we could build highly performant 3D TE architectures such as arches and lattices standing on a substrate by computer-aided model design. Our group demonstrated that the addition of a $Sb_2Te_4^{2-}$-based chalcogenidometallate (ChaM) ionic additive ensured the viscoelasticity of the TE particle colloidal ink, enabling 3D layer-by-layer deposition of the TE ink. However, the moderate viscoelasticity observed in these inks was not sufficient for the direct writing process. To overcome this problem, we introduced a new design principle for TE particles in terms of size, size distribution and surface state. First, we demonstrated that the smaller size and narrower size distribution of TE particles results in higher viscoelasticity due to an increase in the effective volume occupied by the particles. Second, the controlled oxidation of the TE particle surface minimizes the screen effect due to the ChaM additive, resulting in a higher viscoelasticity of the ink than that observed with the non-oxidized particle ink. Based on these results, TE inks were optimized to achieve the extremely high viscoelasticity required for 3D direct writing. In addition, the sample dispalyed ZT values of 1.1 for p-type and 0.5 for n-type, similar to the ZT values of typical Bi_2Te_3-based bulk ingots. The direct writability of TE inks allows for microscale TE leg design for optimized thermal management, maximizing temperature gradients and output power in µ-TEGs. We demonstrated the fabrication of µ-TEGs via direct 3D writing of a TE leg with an aspect ratio of 4.1 on a patterned electrode array. Upon heating, the high anisotropy of the TE leg created a large temperature difference of 82.9 °C, resulting in a power output in the order of µW for the unicouple of the TE leg.These results validate the practicability of our 3D direct writing process for fabricating high-performance µ-TE modules that can be integrated into the electronic systems

Doped-PbTe Thermoelectric Inks with Viscoelasticity for 3D Printing of Systemically Optimized Power-Generating Tube Jungsoo Lee, SungYoub Kim, Han Gi Chae and Jae Sung Son; Ulsan national institute of science and technology, Korea (the Republic of)

Thermoelectric (TE) technology offers a promising means of improving fossil energy efficiency by generating electricity from waste heat from industrial or automobile exhaust gases. In these applications, thermoelectric modules must be designed in terms of system integration for efficient heat transfer, system simplification and low processing costs. Despite recent advances in material efficiency, the structural designs of TE legs and modules are subject to limited design flexibility within conventional planar structures. For real-world TE power generation applications, the modular structure sometimes needs to be customized for integration with thermal systems or may require geometric or heat-source-structure adjustments. For example, tubular thermoelectric generators (TEGs) have been extensively studied in academia and industry to improve fuel energy efficiency by recovering automotive or industrial waste heat. One significant problem in these applications is the unavoidable temperature drop at the interface between the conventional planar TEG and the exhaust gas pipe due to non-adaptable thermal contact, which significantly reduces the output power. Therefore, post-processing is required by pressing the TEG into the pipe with high force; however, this renders a heavy system. These limitations of modular structures stem from the fundamental challenges of

processing the bulk-scale materials used to fabricate TEGs, such as top-down dicing, metallization, and soldering. This is because precise engineering of the structure for customization of TE legs and modules is not possible.
Three-dimensional (3D) printing technology offers an innovative way to address these challenges through cost-effective direct molding and computer-aided design of 3D bulk-scale TE legs and modules with optimized structures. In this presentation, we report a 3D printing method of PbTe thermoelectric materials for fabrication of systemically optimized high-performance power generation TE tubes. The electronic doping-induced surface charges in PbTe particles were shown to significantly improve the viscoelasticities of inks without additives, thereby enabling 3D printing of PbTe for precise shape and dimension engineering with figures of merit of 1.4 for p-type and 1.2 for n-type materials. The performance of power-generating TE tube fabricated from 3D printed p-type and n-type PbTe tubes has been demonstrated experimentally and computationally as an effective strategy for designing system-adaptive, high-performance thermoelectric generators.

SESSION EN11.12: Virtual Session I

Dynamic Building Envelope Materials for Enhanced Thermal Management and Energy Efficiency Gang Tan[1] and Tengyao Jiang[2]; [1]Zhejiang University, China; [2]Nanjing Tech University, China

Building envelopes, including opaque structures such as roofs and walls as well as transparent structures like windows, account for significant heat losses or heat gains that introduce huge heating and cooling loads, respectively, to the HVAC system. Considering the weather variation with seasons, adaptive building envelopes, through either passive or active approaches, are preferred to achieve high performance in the terms of both thermal management and energy efficiency.
Aimed at enhancing heat gains in winter and heat sheds in summer, roofs and walls can be equipped with solar heating materials and radiatvie cooling materials that could be mechanically switched. Two recent examples are given with one controlled by the electrostatic force and the other fabricated from interwoven surfaces, which produced higher energy savings compared to the solely radiative cooling technology. However, perspectives on weather self-adaptive materials in building applications, especially for opaque structures, are offered to further discuss about the advanced materials with highly responsive feature and broader modulating band from solar to long wavelength infrared spectra.
The thermo-responsive materials, W-doped VO_2 particles and hydrogels, have been utilized to develop dynamic windows in order to optimize the solar light transmission and long wavelength radiation triggered by the change of the ambient temperature. A scalable thermochromic smart window showed independent management over the visual, near-infrared (NIR), and long wavelength infrared (LWIR) radiation (De_{LWIR}=0.4) and presented dynamic heat dissipations while maintaining day lighting capability. When hydrogel material is applied to windows in a commercial building, the interactive effect of the low-e coating has been investigated and the design method has been provided. Numerical energy saving calculations to an as-synthesized hydrogel film combined with an IR-reflective coating have been conducted to evaluate the ultimate solar regulation performance and yielded annual space cooling energy savings of up to 30.6 kWh/yr.m^2 for Tucson, AZ, USA based on the area of window glass.
To incorporate the numerical calculation for the spectra-selective radiative cooling material into the whole-building simulation tool, a systematic strategy of developing a new long-wavelength radiation spectrum integral module (LRSIM) suitable for the state-space model has demonstrated good accuracy (< 3% deviation from measured data) with acceptable computational cost. However, although methods for evaluating the energy savings of the passively-driven dynamically-adaptive materials for building envelopes such as chromic materials have been studied and developed, there lacked of numerical algorithms and engineering-level control profiles to maximize the advantages of harvesting heat or cooling from natural resources (e.g., solar or outer space). Additional research work is needed to bridge this gap and therefore motivate the wide utilization of actively-enforced dynamic materials in buildings. As an example, a new electro-chromic window is used to present the different energy performances under the three pre-defined operation schedules, based on occupancy schedule, cooling/heating demand schedule, and the day lighting dominated schedule, for a single-room building in various climates.

8:30 AM EN11.12.02
Large-scale Fabrication and In-operando Crystallization Study of Expanded Graphite/Zinc Nitrate Hexahydrate-Potassium Nitrate Eutectic Composites with Robust Thermal Properties. Anirban Chakraborty, Choongho Yu, Patrick Shamberger and Sophia Ahmed; Texas A&M University, United States

High enthalpy of fusion (ΔH_{Fusion}) and suitable melting point (M.P.) makes zinc nitrate hexahydrate (ZNH) and its eutectics popular as phase change materials (PCM) for low temperature thermal energy storage (TES). Primary challenges in salt hydrates are their low thermal conductivity (k) and stability after thermal cycling. Past studies have attempted to enhance k by adding loose carbonaceous fillers like expanded graphite (EG). However, infiltrating salt hydrates within binder incorporated, hydrophilic-treated, robust EG matrices that are reliable up to ~1000 thermal cycles is yet unexplored. For practical application of PCM composites like electronics, solar plants, green buildings, etc. reliable thermal performance throughout its operational lifetime is essential. Nevertheless, the reliability of thermal conductivity in EG/salt hydrate composites over relevant numbers (~10^3) of melt/freeze cycles has barely been studied. Here we propose, a methodology for large-scale fabrication of PDMS-bonded, ZNH/KNO_3 composites, tailoring enhanced k and ΔH_{Fusion}, with reduced supercooling (ΔT_{Sup}), M.P. and endothermic range. The binder imparts strong connections between the EG to improve thermal conductivity and stability of TES properties up to 1,000 melt/freeze cycles. The thermal conductivity increased with EG content, although its initial magnitude and long-term retention were observed to be tradeoffs. In-operando crystallization studies to further understand the variation of thermal conductivity, revealed the influence of carboxymethyl cellulose (CMC) thickener in attenuating k fading over prolonged melt/freeze cycling. The thickener prevented the formation of large PCM crystals that could potentially impair thermal connections between EG. We believe the outcome of this study introduces a new dataset to the scientific community regarding robust ZNH eutectic composites for low temperature TES applications.

8:45 AM EN11.12.03
Sticky Thermoelectric Materials with Ultra-thin High Performance Foam for Hierarchically Designed Flexible Peltier Sheets Norifusa Satoh[1], Masaji Otsuka[1], Jin Kawakita[1], Junnosuke Murakami[2], Junichi Nakadate[2] and Takayuki Nakanishi[2]; [1]National Institute for Materials Science, Japan; [2]Sekisui Chemical Company, Limited, Japan

To improve energy efficiency of temperature conditioning for human body and to also prepare for extreme heat with climate change, Peltier human coolers have been developed and commercialized [Ref. 1]. However, its usage has been limited, such as a neck cooler, because the commercial Peltier devices are heavy and solid, constraining the size of contacting area for heat transfer. To slim their thickness and weight and to also meet the multiple complex requirements for mass production of flexible Peltier sheets, we have designed and developed sticky thermoelectric (TE) materials with a strategy adopting from other organic devices like organic light-emitting diodes and dye-sensitized solar cells: hierarchically hybridizing the multiple components to meet each requirement [Ref. 2-4]. At the microscale hybridizing inorganic TE particles with low-thermal-conductive organic solvents, the sticky TE materials suppresses the thermal conduction, which enable to keep the temperature difference based on the Peltier effect even on the thin sheet structure for flexibility. At the nanoscale, the surface/interface modification reduces the electrical resistance between TE particles. At the atomic scale, the Seebeck coefficient of TE particles is optimized. Instead of the organic sheet sealant surrounding the sticky TE materials, in this study, we employ an ultra-thin foam sheet because of its high sealing ability, low thermal conductivity, and shock absorption capacity. We observed that the low thermal conductivity contributes to keeping larger temperature difference between the upper and lower sides, and also confirmed that the shock absorption capacity relaxes the tension on the upper and bottom electrode sheets during the bending. We discuss details in this presentation.

Smart Materials for Sustainable Energy Storage in Refrigerated Spaces Nastaran Barhemmati; Viking Cold Solutions Inc, United States

The sustainability and high performance of refrigerated space used for the preservation of perishable products capitalize on conservation techniques that reduce environmental impact. The concept encompasses a variety of strategies including the exchange or improvement of mechanical refrigeration systems by Thermal Energy Storage (TES) that incorporate Phase Change Materials (PCM), and advanced refrigeration controls powered by cloud-based optimized algorithms. TES as a part of an integrated system improves overall efficiency resulting in lower energy costs while improving the shelf life and quality of perishable foods and other products. The system employs Thermal Energy Storage cells installed in refrigerated rooms in combination with intelligent controls. The smart PCM in TES is highly efficient at capturing thermal energy while the PCM is undergoing a phase change from solid to liquid, and collectively the PCM has a large latent heat compared to sensible heat. The Phase Change Material in the TES system provides latent heat capacity to the refrigerated environment, allowing the TES to absorb a large amount of thermal energy from the surrounding environment while remaining at the same temperature. This function allows the refrigerated environment to maintain an optimal targeted operating temperature for an extended period of time without running the mechanical refrigeration equipment, thus saving a substantial amount of electricity.

Nanostructured Passive Cooling Based on Evaporation and Radiation Jia Zhu; Nanjing University, China

Nanostructures with carefully tailored properties can be used to manipulate the flow of light, heat and water, to enable high performing passive cooling through evaporation and radiation. I will present our recent progress.

The first example is cooling photovoltaic device through evaporative cooling. We demonstrate a monolithic tandem solar electricity-water generator that synergistically produces electricity and clean water by utilizing the full spectrum of solar irradiance. This design posseses two components: a top infrared-transparent photovoltaic device using above-band-gap photons, and a bottom solar water purifier using the below-band-gap photons. A well-designed water-proof thermal interconnecting layer (WTIL) makes these two components work synergistically: the bottom purifier serves as an evaporative cooler of the top solar cell to increase its efficiency, whereas the thermalization energy of the top cell is reutilized by the bottom purifier for producing more clean water. We experimentally demonstrate that this prototype hybrid tandem design can be applied to various solar cells such as silicon and perovskite.

The second example is about passive cooling. Radiative cooling which sends heat to space through atmospheric transparency window without any energy consumption, is attracting significant attention. For radiative cooling to achieve high cooling performance, it is ideal to have a selective emitter, with an emissivity dominant in the atmospheric transparency window. Here we will present a hierarchical design for a selective thermal emitter to achieve high performing all-day radiative cooling. Moreover, it is revealed that nano-processed silk possesses excellent performance of radiative cooling. Eco-friendly radiative cooling materials demonstrate excellent potential for protecting ice from melting under sunlight.

9:30 PM EN11.13.02
Germanium-Sensitized Cell Using Glycerol Electrolyte Haruki Kohata, Mone Hemmi and Sachiko Matsushita; Tokyo Institute of Technology, Japan

1. Introduction
There's an increasing demand for novel energy production technology to achieve environmental sustainability. As "heat" is ubiquitous, thus a probable candidate for energy source, our group has been investigating semiconductor-sensitized thermal cells (STCs)[1],[2]. Unlike conventional systems, STC can convert heat into electricity without the emission of CO_2 or temperature difference, enabling the production of clean energy in various conditions.
STCs' mechanism originates in that of the dye-sensitized solar cell (DSSC). However, instead of photoexcited charges, STC uses thermally excited charges of the semiconductors to facilitate redox reaction in the electrolyte until it reaches an equilibrium at the electrodes' surface. By disconnecting the circuit, ions in the electrolyte diffuse and go back to their original equilibrium[3]. This charging and recovering phenomenon has been reported with STC comprised of Ge as a semiconductor and Cu ion-dissolved polyethylene glycol (PEG) as an electrolyte at 80°C[4]. However, its long-term stability remains a challenge, due to volatility and poor heat resistance. In this work, we propose STC using glycerol (Gly) as a solvent to enhance the long-term stability of STCs.

2. Experimental

The STC was manufactured in a glove box under Ar atmosphere. The electrolyte was prepared by mixing CuCl, CuCl2, LiCl, Gly or PEG on the hotplate for 2 h. The concentrations were: LiCl (0.30 mmol /PEG or Gly(g)) and Cu ion (1.0 mmol / PEG or Gly(g), Cu^+:Cu^{2+} = 1:1). An *n*-Si substrate (1.5 cm × 2.5 cm) on which Ge was deposited was used as the working electrode. An FTO glass substrate was used as the counter electrode, on which the double-sided insulating tape (114 µm thickness) with a hole of 6 mm diameter was attached. The electrolyte was dropped into the hole and *n*-Si/Ge substrate was used to cover the hole to form a cell (with the Ge side touching the electrolyte). For fabricated cells, cycliv voltammetry (CV) and long-term operations were performed.

3. Discussions
Open circuit voltage (V_{OC}) and short-circuit current (J_{SC}) of fabricated cells were obtained using CV at the scan rate of 10 mV/s. The V_{OC} and J_{SC} were 250 mV, 7.9 µA /cm^2 using Gly, compared to those of 350 mV, 4.8 µA /cm^2 using PEG. The larger J_{SC} by the replacement of PEG by Gly is probably attributed to the larger dielectric constant of Gly, causing larger diffusion of Cu ions. The use of Gly increased the power by more than 3 times, from 1.29 µW/cm^2 with conventional PEG solvent, to 5.50 µW/cm^2.
The long-term operation was performed at 80^{o}C. After 200 nA discharging, the V_{OC} measurement was immediately initiated for 5 h at 80^{o}C. As a result, stable V_{OC} and J_{SC} were obtained even after the second cycle. Moreover, the charge transfer resistance at Ge/electrolyte surface did not show a significant difference before and after charging.

4. Conclusion
In this study, we investigated the battery performance of STCs using glycerol as a solvent. It was discovered that glycerol's high dielectric constant enabled remarkably stable discharge cycles of STCs for the first time. This discovery brought us one step further toward the utilization of heat, a potential energy source.

Thermo-/Electrochromic and Passive Radiative Materials for Thermal Management of Buildings and Human Body Yanfeng Gao; Shanghai University, China

Thermochromic energy efficient windows represent an important protocol technology for advanced architectural windows with energy-saving capabilities through the intelligent regulation of indoor solar irradiation and the modulation of window optical properties in response to real-time temperature stimuli. In this presentation, recent progress in some promising thermochromic systems is summarized from the aspects of structures, the miro/mesoscale regulation of thermochromic properties, and integration with other emerging energy techniques. Furthermore, the challenges and opportunities in thermochromic energy-efficient windows are outlined to promote future scientific investigations and practical applications in building energy conservation. The presentation also talks about our recent progress in electrochromic materials. Besides the scope of buildings, the development of a textile that cools skin both in sunshine and in room can not only protect the human body from a severely hot working environment but also save energy by lowering air conditioner load. We have developed several concepts that combine solar energy reflection and "passive radiative cooling" for strengthening both solar energy blocking and heat dissipation through long-wave infrared (LWIR) radiation at wavelengths of 8–13 µm. For example, a technique is achieved by coating a textile with an Al_2O_3 dispersed-cellulose acetate. Cellulose acetate possesses high emissivity in the LWIR region, which can promote effective LWIR radiation (2.5–25 µm). Al_2O_3 has a high thermal conductivity (30–40 W m^{-1} K^{-1}) and can enhance solar energy reflectivity. By coating Al_2O_3-cellulose acetate, solar energy reflectivity of the textile significantly increases from 62.6% to 80.1% (0.3–2.6 µm). A cooling performance experiment reveals that this modified textile can reduce the temperature of simulated skin by 2.3–8 °C compared to that of an unmodified reference. Furthermore, in a real-life cooling performance experiment, a modified T-shirt can avoid the overheating of actual human skin by 0.6–1.0 °C, corresponding to a temperature decrease by 1.9–3.3 °C for the internal surface of the textile.

9:00 AM *MD01.01.01
Machine Learning in the Quantum Regime Through Physical-Principle-Informed Representations Qimin Yan; Northeastern University, United States

Materials design in the quantum regime call for the integration of multi-tier materials information that goes beyond atomic structures. Especially, many quantum behaviors are greatly controlled by local bonding environments and physical constraints related to symmetry. In this talk, I will give several examples of how domain knowledge and physical principles for quantum material systems can be incorporated into machine learning frameworks through representation learning to greatly improve the performance of machine learning models for property predictions. Motivated by Pauling's rules, I will show that local bonding environments (structure motifs) can be incorporated into a graph-based machine-learning architecture to make reliable property predictions for solid-state quantum materials including complex metal oxides. The proposed atom-motif dual network model demonstrates the feasibility to incorporate beyond-atom materials information in a graph network framework and achieves state-of-the-art performance in predicting the electronic structure properties of complex metal oxides. Through unsupervised learning, abstracted material information such as chemical formulas and motif connections can be combined with national language processing technologies to effectively represent fundamental elements in materials and use them in downstream learning tasks. I will demonstrate how contrastive representation learning can be used to incorporate physical constraints that control the collective behavior of electron densities into neural-network-based density functional design. At the end of the talk, I will discuss the continued development of machine learning models for quantum materials that embrace local/global symmetries and symmetry-based interactions.

High-throughput Virtual Screening of Existing Organic Chromophores for Materials Discovery Omer Omar[1], Daniele Padula[2], Tahereh Nematiaram[1] and Alessandro Troisi[1]; [1]University of Liverpool, United Kingdom; [2]Universitá di Siena, Italy

High-throughput virtual screening (HTVS) has, in recent years, become an extremely powerful tool in the discovery of novel organic optoelectronics due to advances in hardware and architecture, facile access to both experimental and high-level theoretical datasets and vast improvements to quantum chemical methods. We have already taken advantage of HTVS[1] by considering the Cambridge Structural Database,[2] where we have successfully predicted candidates for singlet fission,[3,4] thermally activated delayed fluorescence,[5] non-fullerene electron acceptors[6] and luminescent crystals which show superradiance or near-infrared emission.[7] The main advantage of searching a database with known experimental structures, along with low bias, is the potential to source candidates and test them experimentally with no worry regarding synthetic feasibility; a serious downfall of any *de novo* study.

Our latest HTVS study considers the much larger ZINC database;[8] a set of many millions of small-to-moderate organic compounds. With a quote of approximately 13 million structures that are 'commercially available' this unfeasibly large set forms the library of our study. With innovation in the form of conjugated core clustering, conformational analysis, accurate experimental calibration and rigorous protocol benchmarking, we are able to accurately assess, with TD-DFT, the electronic structures for the entire set of 13 million with the computation of approximately 150 thousand unique structures. This forms one of the largest quantum chemical datasets to date.

The ZINC database of commercially available compounds was chosen specifically for easy access to real compounds which can be ordered and tested in our own in-house laboratories. From of our wealthy database, we have verified our protocol experimentally and identified promising materials for both near-infrared and anti-Kasha dual emission by testing over thirty unique compounds using absorption and fluorescence-lifetime spectroscopy. These properties are extremely rare and coveted and have applications in a wide range of photonic devices.

An additional, extremely rare phenomenon that has been sought recently within our optoelectronic database is the violation of Hund's rule in some molecules, or in other words, compounds that exhibit an inverted singlet-triplet gap[9] due to atom-localised intramolecular charge transfer (*i.e.* lowering the exchange energy to degeneracy between S_1 and T_1 state) coupled with spin polarisation in the S_1 state due to large contributions from double excitations. This becomes invaluable for devices (e.g. OLEDs) which seek to harvest triplet excitons by making the reverse intersystem crossing energetically favourable. Promising theoretical results using high-level multireference wavefunction methods suggest totally new design rules beyond the known heptazine case due to the low bias in our datasets.

Machine-Learning Potentials for Molecular Dynamics Simulations of CO_2 Chemisorption and Diffusion in Mg-MOF-74 Bowen Zheng[1,2], Felipe Lopes Oliveira[3], Rodrigo F. Neumann[3], Mathias Steiner[3], Hendrik Hamann[1], Grace Gu[2] and Binquan Luan[1]; [1]IBM T. J. Watson Research, United States;

[2]Univerisity of California at Berkeley, United States; [3]IBM Research-Brazil, Brazil

For curbing the global temperature increase, effective approaches for carbon capture are needed. By utilizing amine-based liquid sorbents, current methods suffer from a high-energy cost for the thermal desorption step that is responsible for 60-80% of the total operating costs. The use of solid sorbent materials for carbon capture has been proposed as an alternative to amine-based liquid sorbents due to their lower desorption energy requirement, which can potentially boost the commercial viability of point-source carbon capture.

Among various porous solids for gas separation and purification, metal organic frameworks (MOFs) are promising materials that potentially combine high CO_2 uptake and CO_2/N_2 selectivity. So far, within the hundreds of thousands of MOF structures known today, it remains a challenge to computationally identify the best suited species. First principle-based simulations of CO_2 adsorption in MOFs (particularly, the ones with open metal sites) would provide the necessary accuracy, however, they are impractical due to the high computational cost. Classical force field-based simulations would be computationally feasible but they do not provide sufficient accuracy. Thus, the entropy contribution that requires both accurate force fields and sufficiently long computing time for sampling is difficult to obtain in simulation. The effect of chemisorption on an open metal site manifests itself more prominently at lower pressures, precisely where the desorption step happens and, therefore, is of utmost importance for the regeneration cost.

Here, we report the quantum-informed machine-learning force fields (QMLFF) for atomistic simulations of CO_2 in MOFs. We demonstrate that the method has a much higher computational efficiency (~1000x) than the first-principle one while maintaining quantum-level accuracy. As a proof of concept, we show that the QMLFF-based molecular dynamics simulations of CO_2 in Mg-MOF-74 can predict the binding free energy landscape and the diffusion coefficient similar to experimental values. The combination of machine learning and atomistic simulation paves the way for more accurat

A Generalized Model for Charge Transfer Integral Predictions Using Graphs and Transfer Learning Michael Rinderle, Neel Misciasci, Ioannis Kouroudis and Alessio Gagliardi; Technical University Munich, Germany

In recent years, many machine learning models were developed to predict charge transfer integrals in organic semiconductor materials [1, 2]. While reporting good prediction accuracy for one specific molecule or a small number of closely related molecules, the transferability of the trained models to other molecules is limited. Typically, tens of thousands of configurations are needed to train a model with sufficient accuracy. The large amount of required training data is a limiting factor for the development of generalized machine learning models to predict charge transfer integrals.
To address this issue, we applied transfer learning techniques to obtain a more generalized model. This led to improved predictions of unseen molecules. Furthermore, adding a few configurations of a new molecule significantly increased the accuracy. In order to predict molecules of various sizes, we use graph structures to encode molecule information and implement message-passing and pooling layers to extract a fixed-size feature vector for further prediction in a deep neural network.
We present an extendable framework to predict charge transfer integrals in organic semiconductor materials and reduce the number of training configurations needed to generate a model that can be applied to new molecules.

Rationalizing Space Charge Layer Formation in Li^+ Solid State Electrolytes—Data Driven Surrogate and Bayesian Optimized Inverse Problem
Ioannis Kouroudis, Manuel Gößwein and Alessio Gagliardi; Technical University Munich, Germany

Ion conducting solids find uses in energy storage and conversion, with a prominent application being all-solid-state batteries. However, despite significant research into interface reactions, passivation layer formation and electrochemical stability still remain fundamentally not understood. To this end, a range of simulation tools have been developed to model experimental observations and shed light to the underlying physical mechanism. Most ab-initio simulations however require significant computational resources and an irreducibly large amount of time. Therein lie two fundamental bottlenecks of any simulation based investigation. Firstly, solving the inverse problem of determining the necessary for the simulation but unmeasurable physical parameters of the system, often requires multiple trial and error runs, a process which is typically arduous. Secondly, a full investigation of the parameter space is simply infeasible both time and resource -wise.

In this study we propose a solution to both these bottlenecks and apply it to the formation of the space charge layer (SCL) in Li^+ ion conducting solid state electrolytes (SSE). A kinetic Monte Carlo (kMC) model is constructed and compared with an experimental setup, where the SCL thickness is measured [1]. However, the kMC model inputs, namely permittivity concentration of Li^+ in the SSE bulk and maximum concentration of Li^+ , cant be directly measured.

To this end, we have constructed a Gaussian Processes surrogate model and used it in conjunction with Bayesian Optimization [2] to solve the inverse problem and generate parameter suggestions that fit the kMC simulations to the experimental observations. To test the effectiveness of this method beyond the fitting of one experimental setup, we additionally created synthetic experiments and tasked our pipeline with reclaiming their physical parameters. Our results showed that the inverse problem is solved in a data efficient and highly accurate way. To test the limits of this claim, we constructed a synthetic experiment with more particles which caused simulation time to increase tenfold, in comparison to the simulations used for training the surrogate. However, our algorithm has managed to extrapolate, fitting the parameters with accuracy higher than 90% from the very first parameter suggestion. This is vitally important as it shows that training the model on relatively inexpensive configurations we can extract information for exponentially more expensive areas of the parameter space at a fraction of the time.

To exploit the predictive capabilities of the surrogate model, a full parameter space investigation was performed. This allowed for a deeper insight in the dependence of the SCL to the parameter combinations, shedding light to the potential underlying mechanisms.
Additionally, the model allows to identify regions of high uncertainty, which may be refined by targeted kMC simulations for improved accuracy.
Hereby, highly accurate parameter screening is achieved at low computational cost, up to five orders of magnitude lower than a direct kMC simulation.

***Ab Initio* Thermodynamics and Atomistic Modeling of NiTi SMA with Machine Learning Interatomic Potentials** Prashanth Srinivasan and Blazej Grabowski; Universität Stuttgart, Germany

Equi-atomic Nickel-Titanium (NiTi) shape memory alloy (SMA) possesses interesting properties such as pseudo/super-elasticity and shape memory effect. They arise from the ability of the alloy to exist in two different phases and undergo a stress- or a temperature-induced reversible phase transformation. Austenite is the high-temperature parent phase which has a B2 cubic crystal structure, and it transforms into the low- temperature martensite, which has a B19' monoclinic structure. Modeling the behavior of NiTi is challenging, since there are other competing phases (orthorhombic B19 or the base-centered orthorhombic B33). The thermodynamic phase stability still remains ambiguous and one needs to resort to *ab initio*-based methods such as density functional theory (DFT). DFT predicts the B33 phase as the lowest energy structure at 0 K (Huang et. al., 2003), although it has never been experimentally observed. Ab initio molecular dynamics (AIMD) calculations have shown that the B19' and B2 phases are entropically stabilized at temperatures above ≈100 K (Haskins et. al., 2016), but the calculations were restricted to a single exchange correlational functional (XC). Additionally, studying kinetic effects during the phase transformation using only DFT is also severely expensive.

In this work, we try to address both the above issues. Using a recently developed thermodynamic integration (TI) technique (direct upsampling, Jung et. al., 2022) aided with machine-learning based moment tensor potentials (MTPs, Shapeev 2016), it is possible to efficiently calculate high-temperature thermodynamic properties and phase stability to DFT accuracy. We perform such calculations to analyze the prediction of three different XCs (GGA, LDA and SCAN) in the phase stability of NiTi in order to find the most accurate representation. We also perform large-scale molecular dynamics (MD) simulations using the MTPs fitted to high-temperature AIMD data from the different XCs, in order to study the kinetically-driven phase transformation behavior in each of these cases. Preliminary results show that the B2 and B19' phases do get en- tropically stabilized with temperature for all XCs. The MTPs are extremely accurate in predicting the energies and forces of various phases in comparison to previously existing conventional interatomic models such as the EAM and the MEAM. Only the MTP fitted to the SCAN XC data predicts a reversible B2-B19' transformation. In the case of GGA and LDA, the B2 phase transforms into a B19 phase on cooling, suggesting that there might be an energy barrier in the B2-B19' transformation path.

Direct Inverse Design of Molecules in Graph Space Felix Therrien, Alexander Davis, Edward H. Sargent and Oleksandr Voznyy; University of Toronto, Canada

True inverse design of materials--providing properties and obtaining candidate materials with these properties--is the holy grail of computational materials discovery. To achieve this goal, typical materials discovery pipelines generate material structures, predict their properties and repeat these two steps in an iterative fashion. In recent years a number of graph neural networks (GNNs) have been developed in order to accelerate this process that had previously relied first principles methods such as density functional theory. Here, we exploit the intrinsically invertible nature of these neural networks to directly generate molecular structures with desired input properties. Starting from a random graph, we perform a gradient ascent through the fixed weights of the GNN in order to optimize its output towards the desired property. Basic chemistry rules are enforced through an additional objective function and simple constraints on the graphs construction. We demonstrate how this method can generate realistic molecules with specific properties (e.g., a HUMO-LUMO gap of 3 eV) using widely adopted GNNs trained on the QM9 database.

11:30 AM MD01.01.09

Structure-Property Relationship of Dynamically Crosslinked Polymer Networks via 3D Convolutional and Graph Convolutional Neural Networks Alexandra Filiatraut and Mehdi Zanjani; Miami University, United States

In recent years, Machine Learning techniques have evolved to address many complex issues across different disciplines, including unique materials science applications. Two such Machine Learning techniques, Convolutional Neural Networks (CNNs) and Graph Convolutional Neural Networks (GCNNs) provide algorithms that process data networks for learning and prediction of various system features and properties. The ability of such Machine Learning techniques to process architecturally-structured data makes them ideal for processing 3D representations of polymer networks to predict material properties. Our study considers polymer composites synthesized from dynamically crosslinked networks. Such polymer networks consist of multiple components that can interact with each other in complex ways. The polymer backbone and the crosslinking agents may be designed in a variety of architectures with the potential to deliver a wide range of physical properties. Understanding the effect of polymer network architecture on the resulting properties of the material is an important and challenging task. CNN and GCNN techniques can provide a useful platform to investigate structure-property relations of crosslinked polymer networks.

In this study, we compare the two aforementioned Machine Learning techniques to determine their efficacy in predicting mechanical properties of dynamically-crosslinked polymer materials. We investigate the relationship between polymer network configuration and the resulting mechanical properties of crosslinked polymer composites. Molecular Dynamics (MD) simulations are employed to generate stress-strain curves for a variety of crosslinker and backbone polymer configurations. The results of the MD simulations are gathered as the reference dataset to be utilized within both Machine Learning (ML) frameworks. We establish "3D images" of the polymer network configurations obtained from MD simulations to build a CNN model, and develop "particle connectivity maps" to set up a GCNN framework, in order to investigate the relationship between the architecture of the network and the mechanical behavior of the material. We discuss the efficiency and accuracy of both methods in evaluating the mechanical properties of each system and study the impact of the configurational details of each network on its properties. The results of this work provide an insight into the use of CNN and GCNN techniques to predict mechanical properties using 3D representations of polymer systems. Additionally, this work helps identify crosslinked polymer network architectures that can deliver desired mechanical properties for future experimental implementation.

Physics-integrated Neural Differentiable (PiNDiff) Model for Isothermal Chemical Vapor Infiltration Process Deepak Akhare, Tengfei Luo and Jian-Xun Wang; University of Notre Dame, United States

Composites are a class of materials actively considered for various applications in today's aerospace, automotive, and civil industries owing to their high strength and lightweight. The performance, quality, and repeatability of the composite materials are greatly influenced by the manufacturing process. The mechanical properties of the composites depend on various variables and parameters of the manufacturing process, which are challenging, if not impossible, to determine and optimize experimentally. Traditional first-principle modeling approaches are not accessible due to the complex physics involved. Moreover, the functional form of the consultative relations used in the numerical model needs to be approximated with the help of experimental studies, thereby limiting its applicability. On the other hand, purely data-based DNN models, although showing great promise, heavily rely on "big data" and often suffer from the generalizability issue in out-of-training regimes, impeding their effective applications in modeling complex composite manufacturing processes. A hybrid model that combines incomplete physics knowledge with available measurement data within a differentiable programming framework opens new avenues to tackle the challenges. In this work, a physics-integrated neural differentiable (PiNDiff) model is developed, where the partially known physics is integrated into the recurrent network architecture to enable effective learning and generalization. The merit and potential of the proposed method have been demonstrated in modeling the densification behavior of composite during the isothermal chemical vapor infiltration (ICVI) process. The ICVI process, one of the chemical vapor infiltration (CVI) processes, is widely used to manufacture carbon-carbon (C/C) and C/SiC composites. Modeling the ICVI process using the traditional first-principle approach will be a near-to-impossible task owing to the number of species produced due to pyrolysis and the complex reaction occurring in the ICVI process. The proposed PiNDiff model handles these complexities using a homogenization approach and learns the unknown physics brought out by the homogenization assumption. The PiNDiff model learns unknown physics from limited, indirect data and, meanwhile, can be used to infer unobserved variables and parameters. The demonstrated PiNDiff strategy may provide a general strategy to model phenomena where physics is only partially known and sparse, indirect data are available.

SESSION MD01.02: Machine Learning II
Session Chairs: N M Anoop Krishnan and Qimin Yan
Monday Afternoon, April 10, 2023

1:30 PM *MD01.02.01
Combining High-Throughput Calculations with Machine Learning to Predict Phase Preferences of Transition Metal Dichalcogenides Pratibha Dev[1], Pankaj Kumar[1,2], Vinit Sharma[3] and Sharmila N. Shirodkar[1]; [1]Howard University, United States; [2]Present address: University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Layered transition metal dichalcogenides (TMDs) are a chemically distinct and technologically important family of materials, which can adopt one of the several known crystal structures. A question that naturally arises is: *What dictates the observed phase preference of TMDs?* An answer to this important question can help to understand and hence, manipulate composition-structure-property relationships, paving the way for engineering properties of TMDs. In fact, this is an old problem, which was actively debated in the 1960s to1980s. It has once again become an important and relevant question with the emergence of 2D quantum materials. By combining high-throughput density functional theory-based calculations with machine learning techniques, we address this six-decade old question about TMDs for a much larger chemical phase-space than what was considered in the earlier works. Our analysis not only rediscovered known physicochemical attributes considered by earlier researchers, but also discovered other factors that were not previously known to influence the structural preferences displayed by TMDs. This work [Phys. Rev. Materials **6**, 094007 (2022)] demonstrates how machine learning can be used to tackle old problems in Condensed Matter Physics.

2:00 PM MD01.02.02
Predicting the Mechanical Response Profile of Porous Materials via their Microstructures Winston Lindqwister and Jacob Peloquin; Duke University, United States

Porous media represent a wide range of materials that have yet to be fully understood and present a challenge in being harnessed to their full ability. From rocks to bone to cement, the ubiquity of porous materials across engineering disciplines cannot be overstated. However, due to the non-uniformity of their structures, it has been challenging to accurately assess performance of these materials across a wide variety of stimuli, such as mechanical response or diffusivity. Recent work has shown that this complexity may boil down to the great heterogeneity and stochasticity of a porous material's microstructure. Unfortunately, due to the multiscale effects and Multiphysics inherent to these systems, an exact relationship between a porous material's microstructure and its structural performance remains elusive. Although destructive testing and finite element analysis are proven methods for calculating a porous material's properties, the former is costly, wasteful, and impractical at larger scales, and the latter is computationally intensive and time-consuming. Machine learning has proven itself over the past few decades as a method of expediting the discovery of correlations within data and creating powerful predictive models. However, common obstacles for creating an effective machine learning model include having a lack of data for training the model and having an overcomplicated set or unnecessary number of input features. In order to overcome the challenges and drawbacks of using these various methods, we have developed a methodology for analyzing porous material structure-property relationships that includes generating realistic synthetic structures, extracting relevant and useful geometric descriptors for defining the structures, and using these descriptors of reduced complexity to train a machine learning model that predicts the mechanical response of the structure from its descriptors. Through this work we aim to accelerate the analysis of porous material structure-property relationships via a machine learning model trained on microstructural features.

2:15 PM MD01.02.03
Harnessing Neural Network for Predicting X-Ray Spectroscopy of Amorphous Carbon Materials Hyuna Kwon[1,2], Wenyu Sun[2], Yu-Ting Hsu[2], Wonseok Jeong[2], Shubham Sharma[2], Matthew Carbone[3], Fikret Aydin[2], Xiao Chen[2], Deyu Lu[3], Liwen Wan[2], Michael Nielsen[2] and Tuan Anh Pham[2]; [1]University of California, Riverside, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Brookhaven National Laboratory, United States

X-ray absorption spectroscopy (XAS) provides a wealth of information about the local structure of materials. Recently, significant advancement has been made in the development of machine learning models for predicting local environments of absorbing atoms from XAS. However, existing studies have primarily focused on crystalline systems, while less has been paid to more complex and disordered systems. In this work, we develop a neural network model for predicting XAS spectra of amorphous carbon (a-C) using the local structural descriptor as a sole input. In addition, we compared the performance of different structural descriptors, including the Local Many-Body Tensor Representation (LMBTR), Atom-Center Symmetry Function

(ACSF), and Smooth Overlap of Atomic Positions (SOAP). We find that the use of LMBTR yields the highest accuracy, and the inclusion of both bond length and bond angle information is necessary for accurate XAS prediction. Furthermore, among the three representations, LMBTR offers a unique advantage in interpretability as the input components can be easily associated with specific structural features. We also extend our model to predict not only local structure features of a-C, such as bond lengths and angles but also its global chemical composition from XAS spectra.

2:30 PM MD01.02.04
Asking Graph Neural Networks the Right Questions for Material Discovery. Jason B. Gibson, Ajinkya Hire and Richard Hennig; University of Florida, United States

The ability of machine learning to extract structure-property relationships from density functional theory calculation has enabled the acceleration of material discovery and characterization. Recent publications continue to bolster ever-increasingly accurate models. However, when these models are used in practice, the model's performance is often quite different than the test scenario suggests. This performance discrepancy can often be attributed to the subtleties of how we pose the question that we train the model to answer. In this talk, I will first describe a data augmentation technique we developed to screen for thermodynamic stability [1]. This data augmentation technique yielded a 3-fold reduction in formation energy prediction error compared to previously published models. The model was designed to change the question we ask during training from "what is the formation energy of this structure?" to "what is the formation energy of this structure once relaxed?". I will then describe a new graph neural network architecture and the subtle changes we made during training that profoundly affected the model's performance. The network uses a novel graph embedding and two disconnected graph neural networks to predict the probability of experimental synthesizability of a structure generated by substitution from a prototype structure. Preliminary results show that this method boasts a significant performance boost compared to compositional-based models.

2:45 PM MD01.02.05
Developing Single Deep Neural Network for Predicting Complete Phonon Properties of Inorganic Crystals Spanning 63 Elements Ming Hu; University of South Carolina, United States

Existing machine learning potentials for predicting phonon properties of crystals are limited to either small amount of training data or a material-to-material basis, primarily due to the exponential scaling of model parameters with the number of atomic species or elements. This renders high-throughput infeasible when facing large-scale new materials. Unlike previous machine learning models with inherently limited training on small data and global properties, we develop Elemental Spatial Density Neural Network Force Field (Elemental-SDNNFF) with abundant atomic level environments as training data. Benefited from this innovation, we integrate >30 million atomic data to train a single deep neural network without increased expensive ab initio simulations. The effectiveness and precision of the Elemental-SDNNFF approach is demonstrated on a set of >100,000 inorganic crystalline structures spanning 63 elements in the periodic table by prediction of complete phonon properties. Our algorithm achieved a competitive force root mean square error of less than 10 meV/Å and a speed-up of 3 orders of magnitude in comparison to first principles. Self-improvement schemes such as active learning and data augmentation techniques are also incorporated allowing human-free refinement of the force accuracy on arbitrary combinations of chemistries. As case studies of our predicted phonon properties, deep insight into the ultralow lattice thermal conductivity (<1 W/mK) of 774 predicted Heusler structures are gained by p-d orbital hybridization analysis and charting the data in the bonding-antibonding map, which offers a quick approach for future screening of crystals with strong intrinsic phonon anharmonicity. We also searched Weyl points with predicted phonon band structures of 1,662 half and 1,550 quaternary Heuslers. Topological Weyl points were found in more than 68% and 87% of half and quaternary Heuslers, respectively, with identification of a new class of two-band charge-2 WPs referred to as "double Weyl points". Our algorithm is promising for accelerating discovery of novel phononic crystals for emerging applications, such as heat dissipation in electronics, thermoelectrics, and coherent phonons for quantum information technology.

TEM Image based MXene 3D Structure Construction using a Minimum Energy Based Deep Learning Algorithm Congjie Wei[1], Jiaxin Zhang[2] and Chenglin Wu[1]; [1]Missouri University of Science and Technology, United States; [2]Oak Ridge National Lab, United States

With the significant improvements and developments in transmission electron microscopes (TEM) techniques, accurate observation and identification is now more commonly adopted in angstrom-level precision, which reveals as sequential images about the real-space information. However, it still has difficulties to analyze the spatial defect distribution, phase transformation and dynamic phenomena since the TEM images can only record the appearances of the surface atoms while the out-of-plane information is severely missing. In this work, a first principle based deep learning algorithm is proposed and adopted to reconstruct the 3D transition states of a MXene healing process experimentally observed. Starting from the TEM image, all related Ti and C atoms around or within the laser-made hole could be categized into 3 groups based on the confidence of the information obtained from the TEM images. Around hole atoms are assumed to have crystalline structure and set as the input along with the in-plane information of atoms that can be observed directly within the hole. Out-of-plane information of the latter group of atoms are then treated as the output of the algorithm along with the spatial distribution of all underlying atoms. The input and output information are reformed into graphical representations and treated as a graph reference problem. The trunk of this algorithm is set as a deep convolutional neural network incorporated with attention-based and non-attention-based components. To conform to the distance prediction, smooth potentials are constructed for Ti-Ti, Ti-C and C-C interactions based on first principle calculation. The minimum potential energy accumulation of all atoms within the hole is set as one of the convergence conditions of the algorithm along with the fitting of the training data sets. Our models are trained on defected MXene structures optimized with DFT, where different sizes and number of atoms are considered. The predictions of this algorithm fit well with the TEM images and help with the understanding of the healing processes observed in MXene materials.

SESSION MD01.03: Machine Learning III

Microscopy is All You Need Sergei Kalinin and Kevin Roccapriore; University of Tennessee, United States

Machine learning and artificial intelligence (ML/AI) are rapidly becoming an indispensable part of physics research, with domain applications ranging from theory and materials prediction to high-throughput data analysis. Over the last several years, increasing attention is attracted to the use of AI interacting with physical system as a part of active learning – including materials discovery and optimization, chemical synthesis, and physical measurements. For these active learning problems, microscopy arguably represents an ideal model application combining aspects of materials discovery via observation and spectroscopy, physical learning with relatively shallow priors and small number of exogenous variables, and synthesis via controlled interventions. In this presentation, I will discuss recent progress in automated experiment in electron and scanning probe microscopy, ranging from feature to physics discovery via active learning. The applications of classical deep learning methods in streaming image analysis are strongly affected by the out of distribution drift effects, and the approaches to minimize though are discussed. I will further illustrate transition from post-experiment data analysis to active learning process, including learning structure-property relationships and materials discovery in composition spread libraries. Here, the strategies based on simple Gaussian Processes often tend to produce sub-optimal results due to the lack of prior knowledge and very simplified (via learned kernel function) representation of spatial complexity of the system. Comparatively, deep kernel learning (DKL) and structured Gaussian Processes methods allow to realize both the exploration of complex systems towards the discovery of structure-property relationship, and enable automated experiment targeting physics (rather than simple spatial feature) discovery. The latter is illustrated via experimental discovery of ferroelectric domain dynamics in piezoresponse force microscopy. For probing physical mechanisms of tip-induced modifications, I will demonstrate the combination of the structured Gaussian process and reinforcement learning, the approach we refer to as hypothesis learning. Here, this approach is used to learn the domain growth laws on a fully autonomous microscope. The future potential of Bayesian active learning for autonomous microscopes is discussed. These concepts and methods can be extended from microscopy to other areas of automated experiment.

Explainable Machine Learning for Hydrogen Diffusion in Metals and Random Binary Alloys Grace M. Lu[1], Matthew Witman[2], Sapan Agarwal[2], Vitalie Stavila[2] and Dallas Trinkle[1]; [1]University of Illinois Urbana Champaign, United States; [2]Sandia National Laboratories, United States

Hydrogen diffusion in metals and alloys plays an important role in the discovery of new materials for fuel cell and energy storage technology. While analytic models use hand-selected features that have clear physical ties to hydrogen diffusion, they often lack accuracy when making quantitative predictions. Machine learning models are capable of making accurate predictions, but their inner workings are obscured, rendering it unclear which physical features are truly important. To develop interpretable machine learning models to predict the activation energies of hydrogen diffusion in metals and random binary alloys, we create a database for physical and chemical properties of the species and use it to fit six machine learning models that achieve root-mean-squared-errors between 105-124 meV on the testing data. By analyzing the feature importances of these fitted models, we identify relevant physical properties for predicting hydrogen diffusivity. While metrics for measuring the individual feature importances for machine learning models exist, correlations between the features lead to disagreement between models and limit the conclusions that can be drawn. Instead grouped feature importances, formed by combining the features via their correlations, agree across the six models and reveal that the two groups containing the packing factor and electronic specific heat are particularly significant for predicting hydrogen diffusion in metals and random binary alloys. This framework allows us to interpret machine learning models and enables rapid screening of new materials with the desired rates of hydrogen diffusion.

11:15 AM MD01.03.03
Overcoming Time Step Limitations in Molecular Dynamics Simulation with Machine Learning Fei Zhou; Lawrence Livermore National Lab, United States

Molecular dynamics simulations are usually limited to small time steps of about 1 fs, a major limitation on the capability of atomistic simulations to reach large time scales. We present a machine-learning method to accelerate molecular dynamics simulations by taking very large time steps. The data-driven approach, built with equivariant graph neural networks, is trained from MD trajectories to faithfully reproduce the same dynamics. The method was demonstrated on a few representative case studies, including single-particle in a 1D double-well potential, and solvated butane dihedral angle dynamics. We show that quantitative agreement on these barrier-crossing events can be achieved with our approach.

11:30 AM MD01.03.04
Modeling Ring-Opening Polymerization with Machine-Learned Committors Jacob Gissinger and Kristopher E. Wise; NASA Langley Research Center, United States

Many important industrial and biological processes depend on ring-opening polymerization (ROP), including large-scale production polymers, such as nylon 6, and a variety of biodegradable polymers and high-performance resins. Large-scale simulations (>200K atoms) of ROP were performed using a deep neural network-based method that captured the effect of the local chemical environment of the reactive sites using training data from quantum chemical methods. The utility of this method was demonstrated by modeling the cationic ROP of bis-benzoxazine, a promising resin for use in advanced high-temperature application composites (>200°C). Density functional theory calculations were used to map out the various ring opening and polymerization reaction paths that occur during the thermal processing of bis-benzoxazine. The probabilities of these reactions, as a function of local atomic configurations, were used to construct committor functions using a neural network approach. The learned committor functions were then used to determine when a particular reaction occurred within the REACTER framework for reactive molecular dynamics simulations. The experimentally observed exotherm that occurs during bis-benzoxazine ROP was captured in an effective manner in the simulations by imposing a local heating of the system that corresponds to the enthalpy of reaction for each reaction. The dependence of the final polymer morphology on the ROP reaction temperature was analyzed at the molecular scale. The results presented in this work indicate that machine-learned committor functions are a promising approach for incorporating high-fidelity reactivity criteria that capture the effect of local chemical environments into large-scale polymerization simulations.

11:45 AM MD01.03.05
Deepfaking Low-Energy Interface Structures Using a Generative Adversarial Network Adrian Xiao Bin Yong and Elif Ertekin; University of Illinois Urbana-Champaign, United States

Understanding the properties of solid-solid interfaces is important to a wide range of applications, from energy-storage devices to electronic devices to surface coatings. However, interfaces are challenging to model explicitly because the interface structure is not limited to a single possible configuration, unlike the unit cell of a single phase which often has only one ground-state configuration. Certain interfaces can exhibit significant disorder due to atomic rearrangement, chemical mixing, variable composition, etc., where there is likely an entire distribution of structures that reflect the real interface. In such cases, an interface structure search, that extends beyond simply pressing two slabs of materials together, would be necessary to identify energetically favorable interface structures. A random search of low-energy structures by generating atoms randomly at the interface is computationally expensive and inefficient, leading to the need for a more intelligent search scheme. We will demonstrate that the interface structure search problem can harness the power of machine learning not only through machine learning interatomic potentials to accelerate relaxations, but also through generative modeling. By training a generative model on a dataset of low-energy interface structures, the generative model can learn the underlying distribution and generate new low-energy structures. The generative model we have developed is a generative adversarial network (GAN), applied to lithium halide solid electrolyte/cathode interfaces for all-solid-state battery application. We will show that the GAN is capable of learning from the low-energy structures to generate a large number of atoms (> 250 atoms), and outperforms random search.

Semi-Supervised Prediction of Double Transition Metal MXene Stability Kat Nykiel and Alejandro Strachan; Purdue University, United States

MXenes are a recently discovered class of 2D materials with important electronic, optical, and magnetic applications. Double transition metal (DTM) MXenes are particularly of interest due to the tunability of their properties and the top-down synthesis approach of MXenes. Experimentalists have synthesized more than 46 DTM MXenes that have been published in open literature. Each DTM MXene is etched from a bulk M'M"AX phase, where each M', M", A, and X indicate a different element resulting in a large domain of possible combinations and relative lack of synthesized examples. We apply semi-supervised learning methods that leverage the unlabeled data to better predict synthesizable materials and guide experiments. In this work, we compare several pseudo-label semi-supervised learning approaches to predict stable DTM MXenes. The previously published experimental DTM MXenes are used as labels and unlabeled data is collected using a high-throughput density-functional theory workflow for 8712 MAX phases and their 726 MXenes. From these results, several DTM MXenes were predicted to be stable in ambient conditions, potentially expanding the family of DTM MXenes and providing a framework for predicting synthesizability of new material candidates.

2:00 PM MD01.04.02
Machine Learning to Describe Structure-Property Relationships Within a Large Cluster Expansion Approach Cindy Wong and Andre Schleife; University of Illinois at Urbana-Champaign, United States

The cluster expansion (CE) approach is used to describe and model the configurational site disorder of alloy materials systems and how changes in the local arrangement can affect materials' properties. When increasing the cell size used in the expansion, the number of non-degenerate configurations exponentially increases thus manually sampling the resulting configurational space becomes expensive when using first-principles density functional theory (DFT). In this work, we demonstrate the use of machine learning to model the structure-property relationship of 36-atom $Be_{(1-x)}Zn_xO$ clusters by uniformly selecting 5% of all configurations and their dielectric functions from DFT as the training set. The model is used to predict the remaining 95% of total configurations and its accuracy is demonstrated by using thermodynamic averages compared to results from smaller supercells. We then discuss the best practices and considerations when applying this approach to other multicomponent systems like dataset size and curation followed by descriptor quality when making predictions.

Deep Learning Prediction and Optimization of Photon Upconversion in Lanthanide-Doped Nanoparticles Eric Sivonxay, Xiaojing Xia, Emory Chan and Samuel M. Blau; Lawrence Berkeley National Laboratory, United States

Deep learning prediction and optimization of photon upconversion in Lanthanide-doped nanoparticles
Eric Sivonxay, Samuel M. Blau

Lanthanide-doped upconverting nanoparticles (UCNPs) have unique optical properties, capable of near-infrared excitation to yield visible and ultraviolet emissions. UCNPs have broad applications ranging from biosensing and drug delivery to super-resolution microscopy. Factors affecting the nonlinear photophysical properties of UCNPs include size, shape, doping, shell thickness, and surface ligands, defining a vast chemical design space. Due to the complexity of the energy transfer networks formed by the 4f electron shells of the lanthanide dopants, rationally designing UCNPs with high upconverting efficiency for tailored applications remains unfeasible. While Monte Carlo simulations allow for reasonably accurate in silico prediction of optical properties, calculations scale poorly with particle size and dopant loading, constraining the search for UCNPs with desirable properties to be fundamentally Edisonian. Here, we report efforts to overcome these challenges by combining high-throughput data generation with nanoparticle representation learning. We combine a high-performance implementation of lanthanide energy transfer Monte Carlo with automated workflows and HPC resources to generate the first large dataset of over 5,000 simulated spectra for UCNPs. We then develop a novel representation of nanoparticle features, enabling deep learning of spectra. Finally, we apply these models to optimize UCNP heterostructure, targeting high UV emission for 3D printing, and present preliminary results.

Atomistic-Scale Simulations of Realistic, Complex, Reactive Materials—The ReaxFF Method, its Applications and Recent Developments Adri Van Duin, Yun Kyung Shin and Benjamin Evangelisti; Pennsylvania State Univ, United States

The ReaxFF method provides a highly transferable simulation method for atomistic scale simulations on chemical reactions at the nanosecond and nanometer scale. It combines concepts of bond-order based potentials with a polarizable charge distribution.
Since its initial development for hydrocarbons in 2001[1], we have found that this concept is transferable to applications to elements all across the periodic table, including all first row elements, metals, ceramics and ionic materials[2]. For all these elements and associated materials we have demonstrated that ReaxFF can accurately reproduce quantum mechanics-based structures, reaction energies and reaction barriers, enabling the method to predict reaction kinetics in complicated, multi-material environments at a relatively modest computational expense. At this moment, over 1000 publications including ReaxFF development of applications have appeared in open literature and the ReaxFF code has been distributed around the world and has been implemented in major open-source and commercial computational chemical software packages.
This presentation will describe the current concepts of the ReaxFF method, the current status of the various ReaxFF codes, including parallel implementations, new force field development algorithms that speed up the ReaxFF parameterization from months to weeks and acceleration methods that allow for microsecond-range predictions. Also, we will present and overview of recent and developing applications to complex materials, with a focus on 2D-material defect chemistry[3-4], metal deposition[5-6] and an expansion of ReaxFF for events in graphitic, metallic and polymer materials that require explicit electrons (e-ReaxFF)[7].

3:30 PM MD01.04.06
Recursive Training for Deep Material Network and the Prediction of the Elastic-Plastic Behavior of Heterogeneous Microstructures Dongil Shin[1], Ryan Alberdi[1], Ricardo A. Lebensohn[2] and Remi Dingreville[1]; [1]Sandia National Laboratories, United States; [2]Los Alamos National Laboratory, United States

Recent developments to integrate micromechanics and neural networks are providing a promising path forward on rapid prediction of multiscale heterogeneous materials with similar accuracy as direct numerical simulations, such as finite-element analysis, for instance. Our approach here, called `Deep Material Network' (DMN), consists of a multi-layer network structure and micromechanics building blocks. DMN is trained on elastic properties data and provides a reduced-order model of the microstructures' representative volume elements (RVE), which can be extrapolated to non-linear constitutive behavior in an online mode. However, up-to-date training methods consisting of random initialization of the network parameters occur with inevitable uncertainty. Here, we present a recursive training strategy based on the visualization of the network as a DMN-RVE. In this methodology, the network is represented as a RVE derived from its architecture (number of layers) and parameters. The network is then trained recursively by using the converged DMN-RVE for a given number of layers, as a starting template for the initial parameters for the next DMN architecture with a higher number of layers. The result is an improvement in the training and performance of the network compared to random initialization, and the intuitive representation of the network during the training process. This approach opens new strategies for machine-learned, microstructure-based, and multi-scale modeling of complex materials.
Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

3:45 PM MD01.04.07
Ensemble Models for the Growth of Colloidal Sol-Gel Materials Tim Erdmann[1], Jason Chen[2], Sarathkrishna Swaminathan[1] and Dmitry Zubarev[1]; [1]IBM Research, United States; [2]The University of Chicago, United States

Sol-gel processes have been applied for the preparation of various high-performance and biocompatible solids ranging from ultra-light aerogels to sustained drug-release materials, metal oxide semiconductors, and tough ceramics. Using the sol-gel method to establish versatile functional modifications on various surfaces is furthermore a straight-forward and cost-efficient approach. To allow for operational flexibility, control and reproducibility of the process, knowledge about the reaction progress is crucial. This is however a non-trivial problem due to the competing underlying mechanisms of hydrolysis and polycondensation and the consequently resulting orthogonality of the reaction parameters. In our talk we will focus on spin-on-glass as an example for sol-gel materials and will discuss the selection of key reaction parameters, their translation into arguments experimentally executable by a synthesis robot, the analysis of the reaction progress by GPC, and how the workflow was established by hardware/software components. We will continue presenting how the sparse dataset – covering only 0.38 % of the experimental space resulting from the number of (semi-)continuous key reaction parameters and variability thereof (92,610 combinations) – was used for the development of ensemble models based on polynomial regression. In validation experiments the ensemble regressors correctly predicted the ranges for dispersity and molecular weight in about 70 % of the cases.

4:00 PM MD01.04.08
Inferring Interatomic Forcefields from Trajectories Using Graph Neural Network and Symbolic Regression Ruoxia Chen and Mathieu Bauchy; University of California, Los Angeles, United States

Classical molecular dynamics (MD)—the workhorse of computational material science—relies the accurate knowledge of the interatomic forcefields. In that regard, analytical forcefields are fast, physics-informed, and interpretable, but are hard to parameterize and often biased due to the choice of the underlying analytical form. On the other hand, machine-learned forcefields are non-biased, but are more computationally expensive and tend to offer poor generalizability to new phases or conditions. Here, we present a new approach that is able to infer analytical interatomic forcefields from trajectories produced by Density Functional Theory (DFT). Our approach is based on fitting DFT results by a message-passing graph neural network (GNN), which is then simplified into an analytical forcefield using symbolic regression—without any assumption regarding the nature of the analytical form. We show that the forcefields that are discovered offer an accuracy that matches that of machine-learned forcefields, at a fraction of the computing cost, and feature improved generalizability.

4:15 PM MD01.04.09
Forcefield Parameterization via Differentiable Molecular Dynamics Abhijeet S. Gangan and Mathieu Bauchy; University of California, Los Angeles, United States

In classical molecular dynamics, the quality of the forcefield is determined by how well it reproduces the desired physical properties in comparison to those achieved in experiment/*ab initio* settings. To achieve this the forcefield parameters are chosen either by physical intuition or are optimized with respect to some target (ground truth) properties like energies or forces. This makes it important to parametrize the forcefield in an accurate and efficient manner. Optimization of a forcefield is typically done using either gradient-free or gradient-based algorithms. In the case of gradient-based algorithms, the gradients of the loss function have to be computed. Since the analytic gradients are not known, approximations like the finite difference are made to compute the gradients. Such approximations introduce errors and their computation is inefficient in higher dimensions. Automated (algorithmic) differentiation (AD) solves this problem by enabling the computation of gradients in an efficient way. AD libraries like JAX have enabled end-to-end differentiable simulation packages like JAX-MD. JAX-MD provides a framework for physics simulation primarily focused on molecular dynamics. Differentiable simulation enabled by JAX and JAX-MD allows for the computation of gradients that are utilized for computing the relevant properties (forces etc) as well as in optimizers that use gradients of the loss function. This enables parametrization based on static (energy, forces, elastic constants, etc.) and dynamic properties (radial distribution function, etc.). We demonstrate this by parameterizing forcefields in an efficient manner by using gradient information provided by JAX and JAX-MD. We also compare it with gradient-free optimization methods and highlight the advantages offered by differentiable simulation.

8:30 AM *MD01.05.01
Virtual Inspection of Advanced Manufacturing via Digital Twins Brian Giera, Brian Au, Brian Weston, Kyle DeVlugt, Haicho Miao and Seth Watts; Lawrence Livermore National Laboratory, United States

A digital twin is an amalgam of physics-based (high fidelity or reduced order) and/or data driven models that describe a physical system, as shown below. Digital twins exist in a variety of settings ranging from manufacturing and inspection equipment, supply chains, city planning, and so on. In the context of advanced manufacturing (AM), the inputs/outputs of the digital twin and its real-world counterpart are indistinguishable, i.e., both operate on identical machine instructions and produce identical data structures. Like many, LLNL's approach requires continually refining the digital twin with real data to better capture behavior of its real counterpart via advanced analytical techniques. As such, a digital twin's evolving parameter set can inform of machine health and aging behavior, providing actionable insights on lifetime performance. Digital twins offer an inexpensive and risk-free environment for machine operator training and troubleshooting complex toolpaths. A suite of digital twins that capture all fabrication and inspection platforms of a given AM process can accelerate production for "born-qualified" parts at scale with minimized and quantified defects. This talk will walk through examples of how we are leveraging data from integrated pairs of real and digital twins of inspection and fabrication platforms to become more flexible and agile.

9:00 AM MD01.05.02
Continual Learning for Accelerating Flow Battery Redox-Active Material Development Yucheng Fu, Amanda A. Howard and Panos Stinis; PNNL, United States

Redox flow batteries hold great promise for large-scale energy storage applications due to their scalable capacity and low fire risks. The machine learning-based regression models have demonstrated their capability to provide high throughput performance predictions as a function of the battery cell design, operating conditions, and relevant material properties. However, due to the large design space of the molecular especially for the emerging organic redox-active materials, new datasets to be used for algorithm training can be available only incrementally. Moreover, it is computationally inefficient to simply add them to the existing material datasets and retrain the machine learning algorithms. To remedy these difficulties and help to accelerate the redox-active material design, we have developed continual learning methods for flow battery predictions that can train on incremental datasets, without a replay of previous datasets. Our multifidelity continual learning method takes advantage of correlations between the datasets to improve predictions without catastrophic forgetting that can occur for the earliest datasets. This approach can be combined with existing continual learning techniques, such as elastic weight consolidation, and other neural network training methods, such as physics-informed neural networks, to improve the flow battery performance predictions.

9:15 AM MD01.05.03
Unifying the Duality of Crystalline Order-Disorder Characterization with Denoising Score Function Model Yu-Ting Hsu[1], Babak Sadigh[1], Nicolas Bertin[1], Cheol Woo Park[1], James Chapman[2], Vasily Bulatov[1] and Fei Zhou[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Boston University, United States

In atomistic modeling of solids, methods to elucidate structural phases and defects obscured by the noise of thermal fluctuations are essential for analyzing and understanding the simulated atomic order-disorder. With the perspective that the challenge of delineating order-disorder features from thermal perturbation is akin to determining signal from noise, we consider classifying the ordered phases and locating the disordered defects—two important tasks that are typically tackled separately—to be fundamentally the same problem and address it with a unifying approach complementary to current characterization techniques: a denoising score function that minimizes thermal noise. Our approach is based on a geometric and probabilistic standpoint of denoising structures to maximize their likelihood towards that of ideal reference structures, as opposed to traditional methods relying on structure/material-specific physical knowledge, or emerging data-driven approaches that rely on large datasets derived from interatomic potentials and MD simulation. The denoising score function is approximated with a rotationally equivariant graph neural network (NequIP) trained without physical knowledge about the reference structures. Focusing on single-element systems in this work, our denoising model effectively reduces molecular dynamics (MD) noise of perturbed BCC, FCC, and HCP structures up to the melting point and trivializes phase identification of an MD trajectory of Cu nucleation from melt. The denoising model is also shown to minimize thermal noise without impacting meaningful disordered features such as point defects, dislocations, and grain boundaries in MD simulations at elevated temperatures, thereby facilitating the identification of disordered defects. The denoising model, trained without any simulation data, is potentially a powerful, flexible denoising filter that can be integrated in the analysis workflows of massive atomic simulations. Lastly, future work for generalizing the denoising model to multi-element systems and other complex structure and defect types is discussed.

9:30 AM MD01.05.04
Weak-Formulated Physics-Informed Machine Learning for Nondifferentiable Heterogeneous Material Domains Zhizhou Zhang and Grace Gu; University of California, Berkeley, United States

Physics-informed machine learning has attracted great research interest for its ability to perform data-free training by direct supervision of partial differential equations (PDE). Recent advancement in operator learning further allows deep neural networks to not only learn functional solutions, but also projections between input and output fields, which can potentially be used as surrogate physics models. Despite the abovementioned achievements, there has been limited attention on solving balance of linear momentum for solid heterogeneous material mediums, where physics-informed learning is difficult to implement due to nondifferentiable constituent material domains and irregular boundaries subject to deformation. In this work, we propose a weak formulated physics-informed loss based on the deep operator network architecture to tackle the challenges in solid mechanics. Without loss of generality in network architecture, sensor points are sampled based on the nodes of a lagrangian mesh. Numerical integration will be performed over the sensor points to estimate the system energy which serves as part of the loss to be minimized. Such weak formulation converts spatial divergence into integral and provides precise tracking of material points and boundary deformation. Additional sensor points are sampled within each Lagrangian element where the material is assumed homogeneous to allow regularization of training via the strong form PDE. Our method is expected to achieve over 97% R^2 accuracy under a purely data-free training scheme for arbitrary material domain shape, with a fully generalized model that performs single solution learning as well as operator learning under a universal architecture.

9:45 AM MD01.05.05
Automated Chemical Structure Prediction Using Multi-Modal Spectral Data and Machine Learning Peggy P. Li, Evan Antoniuk, Bhavya Kailkhura and Anna Hiszpanski; Lawrence Livermore National Laboratory, United States

Spectroscopic data of various types – infrared (IR), mass (MS), or nuclear magnetic resonance (NMR) – are critical tools chemists use to deduce the chemical structure of molecules present in samples. However, this exercise becomes increasingly challenging when the sample is unknown or contains a mixture of molecules. In such cases, a primary method of structure elucidation is by pattern-matching the spectra against large libraries of reference spectra or standards using rule-based software. While useful, these softwares fail when they encounter samples whose spectra are not available, and for this reason, standardless and machine-learning-driven approaches of chemical structure elucidation from spectra data are highly desired. We build upon prior machine learning work for structure elucidation, focusing on multi-modal spectral data.

We have developed models that predict chemical structure directly from four types of spectral data - IR, MS, H-NMR, and C-NMR, without requiring a library of reference spectra, as well as evaluated different combinations of those four spectra. The ability to incorporate these different data modalities and evaluate their relative importance to structural elucidation is a unique benefit of these machine learning approaches. Our model is a multilayer perceptron, the simplicity of which was more suitable for our relatively small dataset. This dataset contains around 7k molecules, from the NIST WebBook. Based on the input spectra, the models output for several hundred substructures the probabilities that they are present in the sample. These probabilities then serve as input to a beam search algorithm previously developed by the Markland and Kanan group (Huang Z. et al. Chem. Sci., 2021, 12 (46), 15329), which generates a ranked list of the potential chemical structures. From these molecule prediction results, we see that using all four modalities of spectra indeed gives us the best top-1 and top-10 scores, with a top-1 score 8% better and a top-10 score 7% better than the best single modality model (IR). This increase in performance could be useful to improve the performance of a machine learning model that lacks a large training dataset. Interestingly, the MS modality does not increase performance by as much as we expected, and we are investigating that further. This is surprising as NMR and MS is commonly used for structure elucidation by chemists. Our hypothesis is that our substructures need to be curated to better work with our MS spectra.

Data-Driven Approaches to Accelerate Experimental Discoveries Xiaolin Zheng; Stanford University, United States

Experimental researches are typically labor-intensive, especially when multiple parameters affect the experimental output. The amount of control experiments needed is enormous to understand and optimize those parameters. The rapid advancement and easy access to machine learning offer great opportunities to accelerate experimental discoveries. In this talk, I will present two examples of using machine learning to guide experimental research. The first example demonstrates a data-driven approach to designing soft materials that predict experimental synthetic recipes based on specified mechanical properties. We use polyurethane (PU) elastomer as a model soft material and experimentally varied the mechanical properties of the PU elastomer by modulating the mixing ratio between components of the elastomer. We used the experimental data to train a regression model. The resulting model takes desired mechanical properties as input and returns synthetic recipes of a soft material, which is subsequently validated by experiments. The second example studies the electrochemical production of valuable chemical hydrogen peroxide (H_2O_2). We apply a machine learning-assisted prediction to map out the performance of electrochemical H_2O_2 production over the continuous parameter space of electrolyte composition and applied potential. The continuous model enables us to evaluate the thermal efficiency, H_2O_2 electricity cost, and time needed to produce H_2O_2 over a broad range of electrolytes and applied potential conditions.

11:00 AM MD01.05.07
CHGNet: Pretrained Neural Network Potential for Fast and Accurate Charge-constrained Molecular Dynamics Bowen Deng[1,2], Peichen Zhong[1,2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Molecular dynamics (MD) simulation coupled on systems with complex electron interactions remains one of the biggest challenges for atomistic modeling. While classical force fields often fail to describe the electronic coupling with ionic rearrangements, the more accurate spin-polarized *ab initio* molecular dynamics (AIMD) suffer from the computational complexity that prevents long-time and large-scale simulation, which are essential to study ion migrations and phase transformations.
In this work, we present the Crystal Hamiltonian Graph Neural Network (CHGNet) as a novel approach that uses a graph neural network (GNN) based force field to model a universal potential energy surface that can describe both atoms and electrons. CHGNet is pretrained on a large Materials Project Trajectory (MPtrj) Dataset, which consists of over 1 million inorganic structures from over 10 years of density functional theory (DFT) static and relaxation trajectories at the Materials Project. We demonstrate the performance of CHGNet molecular dynamics in Li-ion solid-state electrolyte and phase transformation in Li-ion cathode materials.

Accelerated Modelling of Interfaces for Electronic Devices using Graph Neural Networks Pratik Brahma[1], Sinead Griffin[2] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The modern Si transistor gate stack is comprised of multiple material interfaces whose electronic interactions greatly affect the electron transport and ultimate transistor performance. In particular, the heterogeneous semiconductor-dielectric gate stack introduces many atomic-scale modelling challenges, which if addressed, can help design higher performance gate sacks for next generation transistors. Towards this goal, grand challenges for the electronic device modelling community include: (i) incorporating the physics of defect formation across a large number of interfaces, (ii) adjusting for ultrathin layers, which leads to surface energy and interface interactions dominating the electronic transport properties rather than bulk interactions, and (iii) accounting for different crystalline states across the gate stack (e.g., single crystalline channel, amorphous and polycrystalline gate dielectrics). There are currently two primary methods to model these complex systems: (i) Empirical methods which fit material parameters to experimental results that are scalable but suffer from accuracy limitations due to neglection of ab-initio physical equations, and (ii) Ab-initio methods which accurately solve the quantum Hamiltonian of the heterostructure system but are time consuming and impractical for large systems containing thousands of atoms and varied crystalline states.

In this work, we aim to overcome the scalability-accuracy trade-off in modelling electronic heterostructures by using graph neural networks [1] with the scalability and flexibility of empirical methods and with the accuracy of ab-initio methods like density functional theory (DFT). Machine learning techniques help to characterize the relationships between local atomic chemical environments and global electronic transport properties e.g. injection carrier velocity, gate capacitance, band gap, etc. We focus on the model system HfO2-SiO2-Si, the gate stack for state-of-the-art transistors, in which hafnium dioxide and silicon dioxide are amorphous and silicon is crystalline. The neural network is trained on data generated using DFT for a small number of atoms (~ 50 -100) to capture the local chemical correlations and learn the energy-conserving force fields. Thus, the network can efficiently generate samples to produce histograms needed to calculate the properties of an amorphous/polycrystalline heterostructure and predict electronic properties accurately for up to system sizes of five hundred atoms. This work paves the way for a fast and scalable method to model modern advance electronic transistors with ab-initio accuracy.

Predicting Secondary Phase Formation at the Solid-Electrolyte/Cathode Interface Using Machine-Learning Interatomic Potential Wonseok Jeong, Aniruddha M. Dive, Kwangnam Kim, Brandon Wood and Liwen Wan; Lawrence Livermore National Laboratory, United States

All-solid-state Li-ion batteries are attractive next-generation energy-storage devices that offer potential improved safety, energy density, and durability in comparison with conventional Li-ion batteries. One of the key phenomena that deteriorate the performance of all-solid-state Li-ion batteries is the side reaction occurring at the solid-electrolyte/cathode interface, which exacerbates at elevated temperatures during co-sintering and can lead to formation of unwanted phases that impede Li-ion transport. It is unclear how these secondary phases are dynamically formed at the atomic scale and under what conditions. In this work, we explore the nucleation and evolution of secondary phases, such as La-Co-O, at the $Li_7La_3Zr_2O_{12}$ (LLZO) solid-electrolyte and $LiCoO_2$ (LCO) cathode interface, from atomistic simulations. To start, we set up a series of ab initio molecular dynamics (AIMD) simulations of small LLZO|LCO interfacial model, to probe early-stage interfacial degradation and to identify chemical motifs that can lead to the formation of La-Co-O secondary phase. We then directly simulate the phase evolution of La-Co-O using metadynamics and machine-learning interatomic potential. Adopting machine-learning interatomic potential allows us to perform large-scale simulations in close-to-real time and length scale with quantum-level of accuracy. In addition to the dynamics simulations, we also carry out crystal structure prediction (CSP) simulations for La-Co-O and Li-La-Co-O systems. For multi-component systems such as (Li)-La-Co-O system, CSP involves extensive search of the energy landscape, thus we adopt the machine-learning potential for CSP within the SPINNER framework to predict meta-stable structures that may be formed at the LLZO|LCO interface during operation.[1]

This work was sponsored by the Office of Energy Efficiency and Renewable Energy, Vehicle Technologies Office and was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. A portion of this research was performed using computational resources sponsored by the Department of Energy's Office of Energy Efficiency and Renewable Energy and located at the National Renewable Energy Laboratory.

Towards Predictive Constitutive Models of Biomaterials Using Machine Learning and Molecular Simulations Sinan Keten; Northwestern University, United States

Transitioning from plastic to synthetic biomaterials is important for producing biodegradable packaging, manipulating food texture, developing biocompatible medical grafts, and enhancing durability of textiles. Structural biomaterials such as titin, silk, collagen, resilin and mussel foot proteins exhibit fascinating mechanical behavior. These model materials are critical starting points for identifying relationships between sequence and mechanical properties and are often used as templates to design synthetic biomaterials with tunable properties. Current experimental and computational methods for characterizing structural proteins are time and resource intensive, which hinders the rate at which favorable sequence mutations can be tested. Complex strategies for developing constitutive relations of these materials are most successful when computational and experimental techniques are combined to account for variable pre and post yield behavior. For resilin, silk, and other protein families, sequences vary across species producing an envelope of material properties related to sequence variability. In this work, we aim to establish a connection between molecular mobility and mechanical properties of protein-based materials using existing data sets, and molecular dynamics simulations, and machine learning methods trained on molecular-scale data. We then explore how predictions from these models can be utilized develop predictive constitutive models that can sequence-dependent mechanical properties of these protein-based materials.

2:00 PM MD01.06.02
Mixed-Variable Adaptive Design Framework with Bayesian Optimization for Multi-Property Optimization of Anisotropic Nanodielectric Materials using "on-demand" Simulations Yigitcan Comlek[1], Prajakta V. Prabhune[2], Ravishankar Sundararaman[3], Linda S. Schadler[4], Catherine Brinson[2] and Wei Chen[1]; [1]Northwestern University, United States; [2]Duke University, United States; [3]Rensselaer Polytechnic Institute, United States; [4]The University of Vermont, United States

Design and development of novel polymer nanodielectrics still remains a challenge due to high number of parameters and properties from different domains involved with the process. Specifically, the mixed-variable multi-scale design space formed by interface choices, and microstructural variations creates a bottleneck in the design optimization. We propose a physics-based adaptive nanodielectrics design framework for multi-property optimization. The framework adopts a descriptor based anisotropic microstructure design technique that controls the non-spherical filler design variables, namely volume fraction, orientation, dispersion, and aspect ratio to generate microstructures, and incorporates attractive extrinsic and intrinsic interfaces as supportive mechanisms into the design. A novel and interpretable machine learning model, Latent Variable Gaussian Process (LVGP), is trained to capture and understand the underlying relationship between mixed-variable design space, interface (qualitative) and microstructural (quantitative) variables, and the properties. Finally, a multi-property Bayesian optimization is performed with the help of "on demand" finite element simulations to find the Pareto Front between mechanical and dielectric properties of anisotropic nanodielectric materials, while providing interpretability about the design process through global sensitivity analysis.

2:15 PM MD01.06.03
Random Forest Prediction of Crystal Structure from Diffraction Patterns Samuel P. Gleason[1,2], Alexander Rakowski[2], Jim Ciston[2] and Colin Ophus[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Electron microscopy, and specifically diffraction patterns, contain a wealth of information regarding the structure of a crystalline material. Specifically, electron diffraction can be used to determine crystal phases of nanoscale sample volumes produced by synthesis methods, track how chemical processes alter crystals, and provide quantitative information on a crystal's lattice structure. However, it is a consistent challenge to determine this information for a new material or even a new phase of an existing material. This challenge is exacerbated by the high electron scattering cross section, frequently leading to multiple scattering in a specimen and breaking the direct relationship between structure factors and diffraction intensities often present in x-ray and neutron diffraction experiments. In these situations, manual exploration of fully dynamical simulated diffraction patterns of individual crystals, and then mapping these patterns to the experimental pattern, is required. This is often a time consuming process with no obvious start point when many very similar structures are possible. Therefore, this project developed a predictive model to make inferences about the crystal structure of a material from its diffraction pattern.

In this work, py4DSTEM was used to simulate diffraction patterns for thousands of unique materials extracted from the materials project [1],[2]. Our database contains 100 unique zone axes for each material and a range of material thicknesses, providing a database containing millions of patterns. These patterns were then used to build a random forest model capable of predicting the space group, point group, crystal system, lattice parameters and thickness of an unlabeled pattern [3]. This model achieves a reasonably high top line accuracy for crystal structure prediction, correctly identifying the crystal system from an indivudual diffraction pattern of arbitrary zone axis and thickness greater than 60% of the time. However, top line accuracy is not the only, or even the primary, value of this model, as a significant utility of this approach is the ability to return a complete set of predictions for each tree in the random forest model. By examining the spread of predictions for an individual pattern across all the decision trees that make up the random forest model, the correct crystal system can often be deduced, even if the top line prediction is incorrect. In cases such as these, the spread of predictions may indicate a great deal of uncertainty between two similar crystal systems, providing a significant boost for a user searching for a theoretical crystal which matches the experimental pattern. Additionally, the spread of the lattice parameters, the lengths of the three lattice vectors and their angles, further narrow down the possible structures, even in situations where the top line prediction is inaccurate for these quantities. This model can be used to significantly accelerate the analysis diffraction patterns, especially for situations where the crystal hasn't been seen in experiments before. Additionally, integration of this model with a 4DSTEM experiment would allow on the fly labeling of an entire sample with phase and thickness information.

Data-Driven Discovery of Dynamics from Time-Resolved Coherent X-Ray Scattering Nina Andrejevic, Qingteng Zhang, Tao Zhou, Mathew Cherukara and Maria K. Chan; Argonne National Laboratory, United States

Coherent X-ray scattering techniques are often used to interrogate materials' structural and dynamical properties at mesoscopic time and length scales. In particular, X-ray photon correlation spectroscopy (XPCS) exploits correlations between scattered intensity fluctuations over time to derive insights about microscopic sample dynamics, from particle diffusion in colloidal suspensions to fluctuations of magnetic domains. However, the interpretation of complex XPCS signatures is often challenging or only in terms of approximate phenomenological models. In this work, we develop a machine learning framework to uncover mechanistic models from time-resolved coherent scattering measurements directly from data. Combining the method of neural differential equations with a computational forward model of the scattering method, we recover the time evolution of several model dynamical systems without access to real-space dynamics. We evaluate our approach against experimental considerations such as sampling and noise and discuss the interpretability of the learned models. Finally, we demonstrate a simple proof of concept for applying our framework to experimental data.

2:45 PM MD01.06.05
Multi-Objective Bayesian Optimization of Complex, Concentrated Alloys Jacob Startt[1], Sean Donegan[2], Megan Mccarthy[1], Mitchell A. Wood[1] and Remi Dingreville[1]; [1]Sandia National Laboratories, United States; [2]Air Force Research Laboratory, United States

High-entropy alloys (HEA) and the broader class of multi-principal element alloys (MPEA) and baseless alloys, collectively called complex, concentrated alloys (CCA), sit at the forefront of the state-of-the-art in high-strength metals research. The near equiatomic concentrations of components in these alloys promote a multitude of desirable effects, ranging from entropic phase stabilization to atomic size mismatch and local magnetic strengthening mechanisms. Often, the combined effects of these properties lead to CCAs with high temperature mechanical strengths that far surpass that of our best high-strength steels and Ni superalloys. While the origins of these properties are typically rooted in the compositional disorder of CCAs, their complex compositional domain is also what ultimately makes the task of engineering or tailoring specific properties a nearly insurmountable hurdle when approached with traditional experiment-based optimization techniques. In this work, we demonstrate how Bayesian inference led multiscale modeling of relevant atomic and microscopic properties can instead be used to efficiently navigate the vast compositional space of these CCAs to optimize multiple properties at the same time. We utilize a diversity guided multi-objective Bayesian optimization (MOBO) scheme, involving objective modeling via Gaussian processes (GP), to optimize sets of mechanical and thermodynamic properties in several refractory body-centered cubic (BCC) CCA systems, including MoNbTaTi, MoNbTaWVCrMn, and MoNbTaWTiV. In doing so, we also attempt to base descriptions of important macroscopic properties on easy-to-obtain atomic level properties from multiscale ab-initio and molecular dynamics calculations to best expedite the process of data generation and objective optimization. By identifying the compositional neighborhoods that yield the best combinations of desired alloy properties, a large portion of the legwork can be eliminated before any physical experiment is performed, greatly reducing the associated cost and time to develop new state-of-the-art CCAs.

Uncovering Fast Solid-Acid Proton Conductors Based on Dynamics of Oxyanion Groups and Proton Bonding Strength Konstantin Klyukin[1,2], Pjotrs Zguns[1], Ju Li[1,1] and Bilge Yildiz[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Auburn University, United States

Achieving high proton conductivity in inorganic solids is very attractive for many electrochemical devices such as in required for low-power nanoelectronics and energy-efficient fuel cells and electrolyzers. A deeper understanding of physical traits of the material to regulate the Grotthuss mechanism of proton diffusion is crucial to accelerate the discovery of new electrolytes with high proton conductivity. In this work, we investigated proton conductivity in electrolyte materials from the solid-acids family. We have performed ab initio molecular dynamics, phonon spectra and atomic structure calculations to map structural, chemical, and dynamic properties of the material to rate-limiting steps of proton diffusion. We have identified a set of physical descriptors, specifically the acidity of donor/acceptor groups, bond lengths, and vibrational frequencies of cation framework, that control the kinetics of local proton hopping and structural reorganization to facilitate long-range proton diffusion. Finally, we use these descriptors for high-throughput screening of materials databases and discuss how our results can be useful in the design of novel electrolytes with high proton conductivity.

4:00 PM MD01.06.07
A Crystal Generative Model Conditioned on Space Group Rees Chang[1], Nick Richardson[2], Alex Guerra[2], Angela Pak[1], Ni Zhan[2], Alex M. Ganose[3], Adji B. Dieng[2], Ryan Adams[2] and Elif Ertekin[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Princeton University, United States; [3]Imperial College London, United Kingdom

This presentation will highlight our explorations of approaches to deep generative models for atomic crystals. Generative modeling of crystals is challenging due to the hard constraints with respect to symmetry and stability, variable lattice sizes and numbers of atoms, and mix of both discrete and continuous attributes. Existing methods aim to learn the distribution of stable atomic configurations without consideration of space group symmetries. To overcome this limitation, we are using highly interpretable GFlowNets to generate crystals approximately from the Boltzmann distribution and conditioned on space group and/or chemistry. The model is also explicitly trained to avoid creating invalid structures. We will present the performance and implications of our framework, highlighting the advantages of symmetry-aware generation towards inverse design of materials.

4:15 PM MD01.06.08
Interpretable Physics-Inspired Graph Neural Network Force Fields for Atomistic Modeling Hong Sun[1], Zhitao Chen[2,1] and Amit Samanta[1]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Santa Barbara, United States

Graph neural networks have attracted enormous attention in atomistic simulations due to its natural ability to capture geometric information about the distribution of atoms in a structure. Many graph neural network (GNN) models proposed in the literature for atomistic modeling involve massive high-dimensional atomistic features, typically ~100-300 basis functions, and complex message passing mechanisms between different GNN layers and stacks that are coupled with complicated node and edge update operations. However, training such a complex GNN model requires a huge training set, a lot of memory, and often the high flexibility comes at the cost of low scalability and poor interpretability. To address this limitation, we propose a physics-informed GNN interatomic potential which generalizes the concept of embedded atom method (EAM) by combining pair and many-body interactions with nonlocal embedding energy interactions that incorporates long-range and high order interactions. The proposed GNN framework adopts a gated workflow with two message passing layers, which allows us to seamlessly model the pair and many-body energy contributions from the traditional EAM model while learning the complex, high-order interactions in the nonlocal embedding energy through message aggregation. In contrast to many, evenly spaced radial basis functions used in other GNN models, only 10-20 atom-centered, even-tempered Gaussian functions are sufficient to featurize our GNN model. This hybridization of physics informed EAM with a nonlocal embedding energy using GNN makes the proposed machine learned interatomic potential more computationally efficient and interpretable. The ability of the proposed GNN framework to model complex energy landscapes is demonstrated by developing potentials for elemental systems, like Nb, Pt, C and benchmarking with existing state-of-the-art GNN potentials. Our EAM inspired GNN model provides a new way of integrating established physics principles with modern deep learning models, which makes the predicting of materials properties more efficient and interpretable.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory (LLNL) under Contract DE-AC52-07NA27344. This work was funded by the Laboratory Directed Research and Development (LDRD) Program at LLNL (project tracking code 21-ERD-005). 4:30 PM MD01.06.09
An Unsupervised Data Mining Methodology for Analysis of Molecular Dynamics Sampling of Local Coordination Fabrice Roncoroni, Ana Sanz-Matias, Siddharth Sundararaman and David Prendergast; Lawrence Berkeley National Laboratory, United States

Molecular dynamics (MD) simulations present a data-mining challenge, given that they can generate a considerable amount of data but often rely on limited or biased human interpretation to examine their information content. By not asking the right questions of MD data we may miss critical information hidden within it. We combine dimensionality reduction (UMAP) and unsupervised hierarchical clustering (HDBSCAN) to quantitatively characterize the coordination environment of chemical species within MD data. By focusing on local coordination, we significantly reduce the amount of data to be analyzed by extracting all distinct molecular formulas within a given coordination sphere. We then efficiently combine UMAP and HDBSCAN with alignment or shape-matching algorithms to classify these formulas into distinct structural isomer families. The outcome is a quantitative mapping of the multiple coordination environments present in the MD data. The method was employed to reveal details of cation coordination in electrolytes based on molecular liquids and polymers.
The tool is written in python, leverages available open-source data science modules and integrates with the Atomic Simulation Environment (ASE).

4:45 PM MD01.06.10
Transferability of Machine-Learned Force Fields to Capture Material Properties Shaswat Mohanty[1], SangHyuk Yoo[2], Keonwook Kang[2] and Wei Cai[1]; [1]Stanford University, United States; [2]Yonsei University, Korea (the Republic of)

Molecular dynamics (MD) based techniques have been widely applied to materials science, polymer chemistry, biochemistry, and medical science. One of its underlying shortcomings is the insufficient accuracy of the force fields used. Machine-learned approaches to aid MD simulations are of growing interest with efforts focused on developing accurate and efficient force fields. Graph neural networks (GNN) provide a scalable force field with limited computational expense to predict the atomic forces. This paves way for a promising approach to obtaining a O(N) scaling for force fields trained on ab-initio data as opposed to the $O(N^3)$ scaling of ab-initio simulations.

However, before we deploy GNN-based force fields, we need to test their reliability and accuracy. Most existing studies focus on the radial distribution function and self-diffusivity to assess reliability, which is not a sufficient test. To this end, we present a series of benchmarking tests, including the equivalence of the radial distribution function and self-diffusivity from MD and GNN-MD simulations on a set of GNN-based force fields (Li et al. (2022)). The force field is trained on liquid and solid configurations with the Lennard-Jones interatomic potential. We also compare the computational X-ray photon correlation spectroscopy (XPCS) analysis to test the density fluctuations induced by the dynamics. A model trained exclusively on liquid configurations can capture the equilibrium lattice spacing in solid phase but it cannot accurately capture the vibrational frequency distribution. As a consequence, we show that a model also needs to be trained on solid configurations to successfully capture the spectrum of vibrational frequencies and the phonon density of states. We finally demonstrate the extensibility of the force field to capture rare events of defects in solids such as vacancy diffusion and the training procedure that needs to be employed to accurately capture the rate of such events. In summary, (i) these benchmarking tests provide a more expansive test on the reliability of the GNN-based force fields that are being trained and (ii) the model preparation techniques provide a guide on how dataset engineering (as opposed to feature engineering) can capture rare events such as vacancy diffusion in GNN-MD simulations.

5:00 PM MD01.07.01
Designing Beam Shape of Lattice Structure for Enhancing Mechanical Characteristics Based on Multi-objective Bayesian Optimization Jinwook Yeo and Seunghwa Ryu; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Lattice structures, a kind of metamaterial, with high strength and low density have gained significant attention due to the ever-increasing need for designing lightweight strong parts. Most existing studies examined a variety of lattice structures made of uniform cross-section beams, which does not encompass a vast design space related to the beam shape. Moreover, very sharp corners formed at the cross-sections of the beams serve as the source of stress concentration that significantly hampers the strength of the lattice structures. In this research, we explore the beam shape thoroughly as a new design space in a variety of lattice structures based on smooth Bezier curve generations and search for the ultimate performance of the lattice structures. The elastic modulus of the lattice structures with the free-form beam shape is evaluated via finite element method, and the optimal beam shape for the ultra-stiffness and low density is designed through multi-objective Bayesian optimization (MBO). The efficient search of the optimal shape via MBO enables us to search for the optimal beam shapes for many different lattice structures. The lattice structures with optimal shapes are manufactured using 3D printing, and significant improvement in specific stiffness is confirmed in comparison with existing designs.

5:00 PM MD01.07.02
Deep Learning Algorithm to Improve Predictive Performance of Strain Fields in Grid Composites Donggeun Park and Seunghwa Ryu; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

For design problems concerning astronomically large number of configurations in multimaterial 3D printers, multiple optimization frameworks have been suggested that efficiently leverage the predictive power of deep neural network (DNN). Especially, the design of grid composites with superior mechanical properties has gained significant attention as a testbed for the DNN-based optimization methods. However, publicly available DNN architectures have been utilized so far that were not specifically developed for the grid composites and thus show weak generalizability in exploring unseen configurations away from training datasets. Here, we propose a multiscale kernel neural network (MNet) that can efficiently predict the strain field within a grid composite subject to an external loading. MNet enables accurate prediction of the strain distribution for completely new configurations in unseen domain, and reduced mean absolute percentage error (MAPE) by 50% compared to a benchmark, U-Net. MNet maintained superb performances with less than one-third of dataset, and can be applied to grid composites larger than the composite configurations used for the initial training. By investigating the inference mechanisms from the kernels of multiple sizes, we revealed that the MNet efficiently extracted various spatial correlations from the material distribution. It is envisioned that MNet can be applied to design problems concerning random checkerboard configurations in various engineering disciplines.

5:00 PM MD01.07.04
Virtual Node Augmented Machine Learning for Material Property Prediction Ryotaro Okabe, Abhijatmedhi Chotrattanapituk, Zhantao Chen and Mingda Li; Massachusetts Institute of Technology, United States

Graph Neural Network (GNN) has been broadly used in material science to understand the material properties related to the interactions among atoms[1]. We deal with the atom and the interactions among neighborhoods as nodes and edges of the graph, respectively. By aggregating the node features of the output layer, we can get unique prediction results of material properties. However, there is a risk that the aggregation process, such as summation and averaging, in the final layer could cause the loss of essential information. Therefore, it is demanding to develop a GNN model that allows us to decide the dimension of output features flexibly.

In this presentation, we present a GNN model that directly predicts the physical properties of materials only with simple inputs like atomic coordinates. We have augmented virtual nodes[2] to the existing Euclidean neural network of E(3)NN[3] as output nodes. Depending on the model and property, we can decide the number and the positions of virtual nodes. This approach has made it possible to deal with the outputs whose dimension varies among different materials.

We have applied the GNN model augmented with virtual output nodes for predicting properties like phonon bands[4] and magnetic structures[5]. This work could lead to deeper insights into the material's microscopic dynamics and interactions of magnetic moments inside the materials.

Machine Vision for Optoelectronic Perovskite Film Characterization Milan Harth[1], Ioannis Kouroudis[1], Luigi Vesce[2], Maurizio Stefanelli[2], Aldo Di Carlo[2] and Alessio Gagliardi[1]; [1]TUM - SNE, Germany; [2]University of Rome "Tor Vergata", Italy

We present our research for fast and reliable bandgap and absorption quality value extraction for triple-cation perovskite thin films from sample scans. To this end, thin film samples were synthesized via blade-coating and their photoluminescence, ultraviolet-visible spectra and the film thickness were collected. For qualitative evaluation of the absorption of perovskite films for use in photovoltaic modules we propose a method of computing a dimensionless figure of merit we called the Area Under Absorption Coefficient (AUAC). Our approach consists of perform regression tasks aimed at predicting the properties of interest using machine learning methods, namely convolutional neural networks. Similar methods have been reported in literature before [1,2,3], while the novelty lies in using very simple imaging techniques, as well as the concept and prediction of the AUAC.
This work demonstrates the usability of simple imaging techniques to characterize repeatedly fabricated experimental samples while requiring only a feasibly acquirable initial amount of data. Our reported method can help speed up time consuming material optimizations by reducing lab time spent on recurrent characterizations, nicely synergizes with high throughput production lines and could be adapted for quick extraction of other optoelectrical quantities.

Toughness Optimization of Grid Composite Using Hierarchical DNN-based Genetic Algorithm and Active Learning. Jaemin Lee, Donggeun Park and Seunghwa Ryu; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

A grid composite consists of heterogeneous materials arranged in a grid lattice and has been studied extensively with the advancement of 3D printing. Because it offers an astronomically large design space that cannot be explored with conventional composite optimization methods, significant efforts have been paid to devise a systematic design framework that leverages the superior inference of deep learning for optimal configurations with desired properties. In previous studies, the optimum configurations with high stiffness or high strength were sought successfully because one can train a deep neural network (DNN) to predict stiffness or strength from a given composite configuration. However, there have been no studies succeeding in optimizing its toughness that can only be obtained by considering the full crack propagation process, due to the difficulty in training a deep learning model for predicting the toughness. In this study, a novel hierarchical DNN architecture is devised that takes not only the configuration but also the initial stress distribution deduced by a sub-NN trained from a minimal set of simulations for accurately predicting the toughness, and a grid composite configuration with high toughness was successfully designed based on the DNN-based genetic algorithm and active learning. In the optimized configuration, multiple distributed crack nucleation occurs simultaneously and propagates independently without being interconnected to each other, absorbing significant energy until the fracture, which allowed them to have high toughness. The proposed hierarchical DNN architecture that simultaneously takes the 'configuration' and 'easily deducible physical quantity from sub-NN' is expected to be applicable to solve various composite design problems concerning highly complex and nonlinear properties of materials.

Performance Enhancement of the Photovoltaic Cell via Support Vector Machine Based Nanograting Optimization Wonkyeong Jeong, Ki-Hoon Kim and Min Ho Seo; Pusan National University, Korea (the Republic of)

Exploiting a nanostructure is one of the promising strategies for the performance enhancement of a photovoltaic cell, but optimizing the dimension of the nanostructure is still challenging, because of the complexity of the physics of light around nanostructures. Conventionally, to optimize the nanostructure for performance-improved photovoltaic cells, researchers have utilized numerical simulation, such as finite-difference time-domain (FDTD). However, the conventional methods inevitably require massive calculations considering numerous structures for the design optimization, implying extremely time- and resource-consuming. Recently, being more efficient, deep learning-based design optimization has been reported, however, it also requires massive initial expenses of securing more than thousands of big data for accurate theoretical optimization. Thus, there is a huge demand for a more efficient and simpler method to predict the structural optimization of the nanostructure with high accuracy and to demonstrate the performance-enhanced photovoltaic cell.

Here, we introduce a performance-enhanced photovoltaic cell exploiting a nanograting structure, on the surface, that is optimized by a simple support vector machine (SVM) based nanostructure designing method. Using numerically calculated transmittances with respect to various nanostructures in the visible light range as a training set, we first developed the learning model based on the SVM. Importantly, the developed learning model utilizes a Gaussian Radial Basis function (RBF) kernel that is appropriate to the accurate prediction for regression of data having non-linearity. Compared to other models, for example, polynomial (mean squared error, MSE = 0.654) kernel with SVM model or multi-layer regression (MSE = 0.614) model, the developed model with RBF kernel does not show simplicity and efficiency with the far less initial expense (number of learning data = 125) than the conventional method, but it also shows the highest accuracy (MSE = 0.006). Using the developed model, we plotted a contour map of the predicted transmittance of various dimensions of nanograting and through the map, we confirmed that the nanograting of pitch = 200 nm, width = 100nm, and height = 250nm can show the highest transmittance in visible light. To demonstrate the optimized nanograting structure on the photovoltaic cell, we developed a nanofabrication method, combining a conventional semiconductor process and nanoimprinting lithography. Using the developed method, the optimized nanograting transparent polymer film (pitch = 200 nm, width = 100nm, height = 250nm) is fabricated and it is assembled with a commercial photovoltaic cell. Finally, from the measured conversion performance of the fabricated photovoltaic cell, the device with the nanograting showed significant performance enhancement, a 6.6% improvement in efficiency, compared to a control sample without the nanograting.

In summary, we proposed a simple and efficient optimization method of a nanograting dimension for the high-performance photovoltaic cell. Through the theoretical and experimental verification of the developed method, we confirmed that is practically valid to demonstrate the performance-enhanced photovoltaic cell with high efficiency. We expect this method can be widely used for diverse photoelectric energy and sensor applications.

Pneumatic Soft Grasping Robotic Devices Using Reinforcement Learning Zeqing Jin, Zhizhou Zhang and Grace Gu; University of California, Berkeley, United States

Advances in soft grippers have achieved remarkable success in grasping tasks providing superior flexibility compared to rigid grippers. However, challenges still remain in limited loading capacity and understanding the working mechanism of the soft gripper due to its nonlinear behavior and deformation. In this study, by leveraging both soft pneumatic joints and rigid components, a hybrid grasping device is developed to provide superior dexterity compared to conventional electromechanical grippers. A grasping platform is established using a robot arm equipped with the designed hybrid gripper and a depth camera imaging system. Simple and difficult grasping tasks are conducted on multiple objects indicating different difficulty levels using imitation learning methods. Two model-based approaches including CNN and PointNet models are implemented and show good performance on grasping predictions. An average error of 5 mm towards desired grasping spatial locations is reached for the simple grasping task. It is envisioned that such platforms and reinforcement learning approaches can be applied to more complicated grasping problems including irregular shaped objects that requires tailored gestures and grasping trajectories.

SESSION MD01.08: Machine Learning VII

Combining Cluster Expansion and Machine Learning Towards Non-Linear Modeling and Classification Claudia Draxl[1], Santiago Rigamonti[1], Adrian Stroth[1], Manish Kumar[1], Mao Yang[1,2] and Peter Benner[2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Max Planck Institute for Dynamics of Complex Technical Systems, Germany

Despite the success of the cluster expansion (CE) approach demonstrated by numerous applications to alloys, CE may perform poorly in two cases which are common in materials science. These concern properties which depart from linearity as a function of concentration, and properties which split into sub-domains in configuration space, each having distinct physical behavior. Examples include kinks in the energy of formation [1] and metal to insulator transitions in complex alloys [2]. In this work, we combine CE with machine-learning techniques toward non-linear modeling and classification such to overcome these problems. First, the input space is significantly augmented by adding mathematically complex but potentially more descriptive features built upon cluster correlations. Second, state of the art techniques including compressed sensing and support vector machines, are employed to find sparse models that generalize well. Compared to standard CE approaches, the larger input space of the introduced methodology leads to steeper learning curves, which generally means higher requirements with respect to the amount and variety of training data. Since producing DFT data is costly, we make use of an iterative approach that allows for reaching fast convergence, by automatically detecting and adding data from regions in configuration space which are either unexplored or more relevant for the property to be modeled. This approach is especially important for systems with large parent cells [1], where the combinatorial explosion cannot be restrained by limiting the supercell size. All developments are implemented in the CE Python package CELL [3]. We demonstrate our approach by addressing the stability and electronic structure of complex materials, including intermetallic thermoelectric clathrates that are of interest for waste-heat recovery and oxide perovskites that are promising candidates for optoelectronic applications. The modeled properties include the energy of formation, the conducting behavior (metal vs. semiconductor), as well as concentration- and temperature-dependent band gaps.

Billions of Atoms with Machine Learning Interatomic Potentials: Application to Direct Heterogeneous Reactive Dynamics Anders Johansson, Yu Xie, Cameron J. Owen, Jin Soo Lim, Lixin Sun, Jonathan Vandermause and Boris Kozinsky; Harvard University, United States

Machine learning interatomic potentials (MLIPs) have become a prevalent approach to bridging the gap between slow-but-accurate ab initio calculations and fast-but-inaccurate empirical potentials for molecular dynamics. Among MLIPs, there is a pareto front of models with different tradeoffs between accuracy and speed. The FLARE interatomic potential aims to push the boundary of scalability and performance, while maintaining sufficient accuracy to study complex, reactive systems.

FLARE combines the atomic cluster expansion with a sparse Gaussian process. Bayesian uncertainties enable efficient training with active learning and uncertainty-aware, large-scale molecular dynamics simulations. We implement FLARE in LAMMPS with the Kokkos performance portability library, enabling efficient molecular dynamics simulations on GPUs across a wide range of system sizes. Using 27336 GPUs, we demonstrate state-of-the-art scaling and performance in micrometer-scale heterogeneous catalysis simulations with up to half a trillion atoms [1].

8:45 AM MD01.08.04
Adversarial Sampling of Geometries Using Uncertainty Quantification from Single Neural Networks Aik Rui Tan, Samuel Goldman and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

In recent years, neural network (NN) interatomic potentials have been increasingly applied to construct potentials for a wide range of systems since they provide high numerical accuracy like in electronic structure methods and low computational cost comparable to that of analytical interatomic potentials. However, due to architectural limitations, NN interatomic potentials are still constrained by their inability to extrapolate well. In high-dimensional systems such as crystal or molecular structures, NN interatomic potentials often fail to perform robustly in regions outside of well-learned training domains. To expand this learning space, many methods in the realm of active learning and uncertainty quantification (UQ) have been proposed. Here, we apply multiple UQ methods ranging from ensembling, mean-variance estimation, and deep evidential regression, and exploit a differentiable sampling technique based on adversarial attacks to sample atomic configurations with high uncertainty. Evaluation of these methods allow us to benchmark performance of single deterministic networks against ensemble methods for UQ task, especially for large bulk material systems which are restricted by their expensive training costs. Coverage of sampled regions is also evaluated for these UQ methods using statistical analysis after several active learning loops. These models are benchmarked on kinetic barrier sampling in ammonia and bulk interactions in silica glass systems.

9:00 AM MD01.08.05
Physics-Informed Deep Learning for Elasticity—Forward, Inverse and Mixed Problems Chun-Teh Chen and Grace Gu; University of California, Berkeley, United States

Elastography is an emerging imaging modality to estimate the elasticity of biological tissues by comparing ultrasound signals before and after a light compression. Ultrasound examinations are much more accurate in the axial direction than in the lateral direction. However, current elastography methods generally require both axial and lateral displacement components, making them ineffective for clinical applications. Additionally, the assumption of incompressibility adopted in current elastography methods results in inaccurate Young's modulus reconstructions. Here, we introduce a new physics-informed deep learning method for elastography. By integrating a displacement network and an elasticity network, the proposed method can reconstruct the Young's modulus field of a heterogeneous object based on only a measured axial displacement field. Moreover, the proposed method can remove the assumption of incompressibility and reconstruct the Young's modulus and Poisson's ratio fields at the same time. We show that the "egg shell" effect where the stiff material prevents the generation of strain in the soft material could be a source of error, and using multiple measurements can help mitigate this potential problem and increase the prediction accuracy. While the proposed method is an iterative approach, we demonstrate that the initial guess has no significant effect on the final prediction. Lastly, we show that activation functions play an important role when using deep neural networks to approximate physical fields. The proposed method opens new venues for efficiently and accurately solving inverse problems in materials characterization, medical imaging, and beyond.

9:15 AM MD01.08.06
Large Scale Simulations of Soft Materials with Equivariant Deep Learning Potentials Simon L. Batzner, Albert Musaelian, Anders Johansson and Boris Kozinsky; Harvard University, United States

Accurate computationally efficient predictions of the energy and atomic forces of many-atom systems are a long-standing goal in the natural sciences. Interatomic potentials based on Message-Passing Neural Networks have emerged as the leading paradigm toward this goal over the past years. Their propagation mechanics, however, make parallel computation challenging and limit the length scales that can be studied. Strictly local descriptor-based methods on the other hand, have been scaled to massive systems, however, they currently fall short of the accuracy seen in message passing approaches. We have recently introduced the Allegro model, a fully local equivariant deep learning interatomic potential that is massively parallelizable while retaining the high accuracy of equivariant message passing potentials. Molecular dynamics simulations using the Allegro potential recover structural and kinetic properties of an amorphous phosphate electrolyte in great agreement with first principles calculations and can be scaled to 100 million atoms. Here, we demonstrate how Allegro can be used to study complex, soft materials using large-scale Molecular Dynamics simulations.

9:30 AM MD01.08.07
Creating Knowledge Maps from Literature to Accelerate Catalytic CO_2 Conversion Development Anna M. Hiszpanski, Juanita Ordonez, Aditya Prajapati, Huiyun Jeong and David Buttler; Lawrence Livermore National Laboratory, United States

Natural language processing (NLP) is a useful tool for extracting and organizing information from scientific papers, thereby expediting the creation of materials science databases for downstream machine learning. However, less well-explored in the materials science domain is the use of NLP to create knowledge maps – rather than databases – which requires extracting overarching concepts and relationships from documents rather than specific detailed information. Such "knowledge maps" provide better organization, searching, and querying of materials science document sets of interests and can be used as a pedagogical tool, enabling a holistic view of the field and creating non-intuitive connections. We have developed NLP tools for the creation of such a conceptual map for the field of catalytically driven CO_2 conversion. We focus on this field given its global importance and the fact that it has experienced a high volume and diversity of publications in recent years, making it challenging for subject matter experts and newcomers to the field alike to keep up with the literature. Our corpus consists of ~37.7k abstracts and ~9.6k full-text articles broadly pertaining to CO_2 conversion. The key tool to create such conceptual mappings is creating document encoders that accurately capture and represent the concepts contained in papers. For our document encoder, we evaluated several transformer models, including MatBERT, MatSciBERT, and ROBERTa. For each, we analyzed the effect that encoding whole versus partial documents and the order in which text is encoded (randomly or in order as it's written) can have. Our findings show that the MatBERT transformer with the use of more text sampled in a random order tends to best encode documents and capture the concepts contained within them. As an example, this model is able to classify the CO_2 catalytic literature according to the type of catalytic reaction – photocatalytic, electrochemical, or thermohydrogenation – with up to 83% accuracy.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

10:15 AM MD01.08.09
Data-Driven Identification of an Interpretable Model for Diffusivity by Generating the Largest Amorphous Materials Database from *Ab Initio* Molecular Dynamic Calculations Hui Zheng, Eric Sivonxay and Kristin Persson; Lawrence Berkeley National Laboratory, United States

All-solid-state batteries (SSB) are promising to address a portion of the increasing need for energy storage. Amorphous materials demonstrate unique advantages in tunability and processability in electrodes, electrolytes, and their interface coating materials. Investigating the relationship between ion conduction in amorphous materials can provide guidance in selecting materials. However, a comprehensive database is missing to enable such analysis. In this work, we generated the largest diffusivity database of amorphous materials to fill this gap using the AIMD workflow. The database covered a total of 4886 distinct compositions, and 3383 of them include Li. The amorphous structures are generated using the melt-quench procedure. The diffusivities of a subset of amorphous materials at four temperatures from 2500 K to 1000 K with 500 K intervals were calculated. We developed an analytical machine learning model from this diffusivity database using the sure independence screening and sparsifying operator (SISSO) method. The model can predict the temperature-dependent diffusion coefficient from compositional and structural features with high accuracy (R^2=0.95). The model enables a rapid evaluation of diffusion in amorphous solids of different compositions, which can be used to screen suitable candidates for different parts in SSB.

10:30 AM MD01.08.10
Melting and Phase Separation of SiC from Large-scale Machine Learning Molecular Dynamics Yu Xie[1], Senja Ramakers[2,3] and Boris Kozinsky[1,4]; [1]Harvard University, United States; [2]Robert Bosch GmbH, Germany; [3]Ruhr-Universität, Germany; [4]Robert Bosch LLC, United States

Incongruent melting has been reported by many experimental studies with the observation that the SiC decomposes into liquid silicon and solid carbon upon heating. However, contradictory results have also been reported that SiC melts congruently with no decomposition. Ab initio MD provides evidence of carbon clustering during the melting process but did not capture the phase separation limited by the small supercell. Empirical potentials give good approximations of the melting points but all of them have limited ability to describe other phases and thus cannot capture the decomposition in the MD simulation. In this work, we use Bayesian active learning to train a machine learning potential for SiC at a wide range of temperatures and pressures, and observe the phase decomposition process into Si and C-rich phases in both the active learning and the large-scale MD stages. Our results provide a microscopic validation of the incongruent melting hypothesis, resolving the disagreement among experiments of the SiC melting behavior. The occurrence of decomposition also indicates that amorphous SiC can not be produced by melting and quenching but only with irradiation, consistent with existing experimental approaches of the amorphization of SiC.

10:45 AM MD01.08.11
Matbench Discovery - An Automated Benchmark for ML Energy Models Janosh Riebesell[1,2], Rhys Goodall[2] and Anubhav Jain[1]; [1]Lawrence Berkeley Lab, United States; [2]University of Cambridge, United Kingdom

The past 2 years have seen the release of several machine learning models specifically designed to predict the DFT final energy given only the unrelaxed crystal structure. Such models are suited for a materials discovery workflow in which they pre-filter and/or pre-relax structures that are then fed into high-throughput DFT. Examples of such models include
- [BOWSR](https://sciencedirect.com/science/article/pii/S1369702121002984): Bayesian optimizer taking crystal symmetries into account when exploring/exploiting known samples of a crystal's potential energy surface
- [Wren](https://www.science.org/doi/10.1126/sciadv.abn4117) [[arxiv](https://arxiv.org/abs/2106.11132)]: uses composition, spacegroup and Wyckoff symmetries as coarse-grained, relaxation-invariant, enumerable descriptors of a crystal structure to predict the post-relaxation energy
- [M3GNet](https://arxiv.org/abs/2202.02450): trained on VASP relaxation trajectories, M3GNet predicts forces and stresses acting within a structure to perform pseudo-relaxation that yields the energy of a structure more closely resembling the DFT-relaxed crystal

However, even closely following the literature, it remains unclear which methodology and in particular which model performs best.
Matbench Discovery extends the growing Matbench ecosystem by building on the dataset published in Wang 2021 npj Comput Mater. This work generated ~250k structures with chemical similarity-based element substitution. After DFT relaxation, they found 10% (~20k) to lie on the Materials Project convex hull. Our benchmark measures how precisely models identify the 20k stable structures from the 250k search pool, as well as how many false positives each one incurs. The latter lead to wasted compute for relaxing unstable structures.

One unusual but compelling feature of test set is that it was generated by 5 rounds of elemental substitution, each time feeding newly found stable structures back into the pool. This allows for out-of-distribution testing as repeated substitutions on average increase chemical dissimilarity from the training set. Indeed we see a decline in model performance with substitution count which is more pronounced for some models than others. This becomes an important metric that influences model ranking as any prospective discovery campaign for exceptional materials will require models to operate robustly on out of distribution crystals. Models that estimate their own predictive uncertainty in good correlation with their error receive bonus points.

We also look at how model errors compare across crystal structures and identify classes of materials on which all models perform poorly, indicating a lack of attention from the community and/or lower quality training data in certain areas of materials space.

Like the original Matbench, Discovery will grow over time as new models are released. To that end, we publish our train and test data along with code to quickly deploy models on them as a `pip`-installable Python package. This allows model authors to add their models to our automated leaderboard by making pull requests to the [Matbench Discovery repo](https://github.com/janosh/matbench-discovery) with their benchmark results and code used to generate them. The Discovery website is kept up to date through continuous deployment.

The utility of this work is twofold:
1. Make it easy for future researchers to identify SOTA ML models that predict stability given only the unrelaxed crystal. This enables informed decisions when choosing ML filters for high-throughput discovery projects.
2. On a more philosophical note, by keeping the leaderboard up to date with new model releases, we ultimately hope to answer the question which methodology works best; DFT emulators like M3GNet, one-shot predictors like Wren or a new method yet to be released?

11:00 AM MD01.08.12
A Lightweight and Flexible Schema for Materials Data to Interface with Self-Driving Laboratories Rishi Kumar and Anubhav Jain; Lawrence Berkeley National Laboratory, United States

The advent of machine learning and laboratory automation in materials science has reinforced the need for a performant and flexible solution for materials data storage. Self-driving laboratories in particular require that data be available and malleable for any analysis required during online learning by an AI agent. We propose a graph-based database schema and associated python library for the entry and retrieval of experimental and computed materials data. In contrast to rigid table-based schemes, our graph approach accommodates the evolving workflows of a research setting. Furthermore, we keep the data structure similar to that generated by recent text-mining efforts to facilitate fusion of local data with the literature. This database was developed to support self-driving labs at Lawrence Berkeley National Lab executing diverse experiments ranging from spincoating to solid-state synthesis.

Our schema is designed to be lightweight and flexible while adhering to FAIR principles. Data is entered (either by operators or the self-driving lab codebase) from the perspective of the experimentalist as a directed acyclic graph (i.e. sequence) of nodes (i.e. steps) which process, measure, and analyze materials. Analysis is distinguished from measurement to establish extracted features as first-class components, as well as to enable multiple interpretations of the raw data. The directed graph structure naturally captures material flows within and across experiments; an experiment that uses a material generated by another experiment will generate an edge which connects the two graphs. Finally, the data can be filtered by any step of the experimental life cycle (e.g. by input material, by process variables, or by analysis results) to generate tabular datasets amenable to downstream analysis.

We conclude by demonstrating this schema for the storage and manipulation of data generated by self-driving laboratories at Lawrence Berkeley National Lab. In particular we show how text-mined recipes for solid-state synthesis are joined with experimental data in our database to inform experimental campaigns. While we show this in an automated laboratory setting, we stress that our schema has been kept lightweight to ease its adoption in traditional laboratory environments. The code to deploy this schema is publicly available on our GitHub repository.

SESSION MD01.09: Machine Learning VIII

1:30 PM *MD01.09.01
Structure Generation in the Representation Space Victor Fung; Georgia Institute of Technology, United States

Data-driven methods have the capability to greatly accelerate the rate of materials discovery and design over conventional human-guided approaches. Generative models are one such recent example which could potentially be used to generate completely novel materials with specified functional properties. When applying generative models for determining atomic structures, a key prerequisite lies in using suitable structural fingerprints or representations for the machine learning model, analogous to the graph-based or SMILES representations used in molecular generation. These representations would need to be invariant to translations, rotations, and permutations, while remaining invertible back to their Cartesian coordinates. The challenges associated with simultaneously meeting both invariance and invertibility requirements have prompted us to propose an alternative approach to this problem by developing methods for accurately reconstructing the structure using optimization-based techniques which can be applied towards non-invertible representations. Our recent findings show this approach can reliably reconstruct atomic structures with high accuracy, and when paired with a generative model, can produce diverse structures with very high data efficiencies.

2:00 PM MD01.09.02
Accurate Simulation of Precipitation Events Using Diffusion Probabilistic Models Cheol Woo Park, Babak Sadigh, Yu-Ting Hsu and Fei Zhou; Lawrence Livermore National Lab, United States

Simulation of microstructure evolution have largely relied on coarse-grained models that obey evolution principles described by partial differential equations. However, quantitatively capturing the precipitation kinetics in these models remains a challenge. In this talk, we show that stochastic dynamics that occur on the coarse-grained level in microstructure evolution can be learned in a data-driven manner using a diffusion probabilistic model (DPM) which enables the model to accurately reenact nucleation and growth. We demonstrate the capability of DPM by replicating the precipitation dynamics of a symmetric Lennard-Jones binary mixture. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

2:15 PM MD01.09.03
Multitask Learning of Collective Variables and Reactive Force Fields for Enhanced Sampling of Rare Catalytic Events Boris Kozinsky[1,2], Lixin Sun[1], Simon L. Batzner[1], Albert Musaelian[1], Jonathan Vandermause[1], Yu Xie[1] and Steven B. Torrisi[1]; [1]Harvard University, United States; [2]Bosch Research, United States

Accurate reaction rate prediction is crucial for designing highly efficient heterogeneous catalysis. Ab initio molecular dynamics can be used because it precisely models chemical reactions. But they often scale poorly and thus are prohibitive for long simulation time to accumulate sufficient statistics. On the other hand, enhanced sampling techniques can accelerate the simulation but require good collective variables, which can be hard to design for complex reactions.
In this work, a data-driven method is used to address these two problems using a multitask learning framework [1] based on Neural Equivariant Interatomic Potentials (NequIP) [2]. The framework trains force fields with quantum chemical accuracy and discovers critical collective variables for highly efficient free energy landscape exploration. This learning framework is demonstrated on estimating the reaction free energy of formate dehydrogenation on a Cu(110) surface.

[2] S. Batzner, A. Musaelian, L. Sun, M. Geiger, J. Mailoa, M. Kornbluth, N. Molinari, T. Smidt, B. Kozinsky, "E (3)-Equivariant Graph Neural Networks for Data-Efficient and Accurate Interatomic Potentials", Nature Comm. 13, 1 (2022)

2:30 PM BREAK

3:30 PM *MD01.09.04
Pretraining for Property Prediction of Crystalline Materials Kishalay Das[1], Bidisha Samanta[2], Pawan Goyal[1], Seung-Cheol Lee[3], Satadeep Bhattacharjee[3] and Niloy Ganguly[1]; [1]IIT Kharagpur, India; [2]Google, India; [3]Indo Korea Science and Technology Center, India

In this talk, we will describe our attempts towards large-scale pretraining to be able to predict properties of crystalline properties to lower the need for large property tagged datasets. We will present a deep-learning framework, CrysXPP that uses an autoencoder, CrysAE. The important structural and chemical properties captured by CrysAE from a large amount of available crystal graphs data helped in achieving low prediction errors. Moreover, we design a feature selector that helps to interpret the model's prediction. Most notably, when given a small amount of experimental data, CrysXPP is consistently able to outperform conventional DFT. A detailed ablation study establishes the importance of different design steps. We release the large pre-trained model CrysAE. We believe by fine-tuning the model with a small amount of property-tagged data, researchers can achieve superior performance on various applications with a restricted data source.

4:00 PM MD01.09.05
Predicting the Synthesizability of All Crystalline Inorganic Materials with Semi-Supervised Machine Learning and Learned Atomic Embeddings Evan Antoniuk[1,2], Gowoon Cheon[3], George Wang[2], Daniel Bernstein[2], William Cai[2] and Evan Reed[2]; [1]Lawrence Livermore National Laboratory, United States; [2]Stanford University, United States; [3]Google Inc., United States

The autonomous computational design of new materials is being actively pursued as a new paradigm of materials science research. However, the current lack of predictive capabilities for directly identifying synthesizable inorganic crystalline materials is a significant roadblock for achieving autonomous materials discovery. Computationally, inorganic material synthesizability has been assessed by employing high throughput density-functional theory (DFT) to calculate the formation energy of a material or through the enforcement of a charge-balancing criteria. However, using DFT and charge-balancing as proxy methods for assessing synthesizability can only account for 50% and 28% of all previously synthesized inorganic crystalline materials, respectively.

In this work, we develop a deep-learning classification model (*SynthNN*) to directly predict the synthesizability of inorganic chemical formulas without requiring any structural information. We accomplish this goal by training *SynthNN* on a database of chemical formulas consisting of previously synthesized crystalline inorganic materials that has been augmented with artificially generated unsynthesized materials. Chemical formulas are represented by learning an optimal set of descriptors for predicting synthesizability directly from the corpus of synthesized materials, allowing our approach better capture the complex array of factors that influence synthesizability. *SynthNN* offers numerous advantages over previous methods for identifying synthesizable materials. Whereas expert synthetic chemists typically specialize in a specific chemical domain of a few hundred materials, this approach generates predictions that are informed by the entire spectrum of previously synthesized materials. Additionally, since this method trains directly on the corpus of synthesized materials (rather than employing proxy metrics such as energy above the hull or charge-balancing), this approach also eliminates questions of how well these metrics can describe synthesizability. Finally, this method is computationally efficient enough to enable screening through billions of candidate materials.

We benchmark the performance of *SynthNN* in a head-to-head material discovery comparison against 20 expert chemists and material scientists. *SynthNN* outperformed all experts, achieved 3.6X higher precision and completed the task five orders of magnitude faster than the average human expert. Remarkably, without any prior chemical knowledge, our experiments indicate that *SynthNN* learns the chemical principles of charge-balancing, chemical families and ionicity, and utilizes these principles to inform synthesizability predictions. Since *SynthNN* can be seamlessly integrated with Materials Screening or Inverse Design workflows, the development of *SynthNN* serves to greatly improve the success rate of computational material discovery efforts by ensuring that the candidate materials discovered through these efforts are synthetically accessible.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

End to End Force Field Parametrization for Polymer Electrolytes Using Machine Learning Pablo A. Leon and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Solid polymer electrolytes (SPEs) are seen as promising alternatives to conventional liquid electrolytes in lithium battery systems due to their low density, mechanical compliance, and low flammability but are challenged by lower ionic conductivity. Molecular dynamics (MD) simulations can be used to guide the design of novel SPEs by allowing quantitative determination of separable anion and cation diffusions as well as local solvation environments. Classical potential MD simulations update molecular conformations by the net force on each atom due to covalent and nonbonded interactions. However, these classical potentials are often not well defined for novel systems as they require materials- and local environment-specific parameters such as unique bond stiffnesses which are either meticulously hand-tuned across decades or unchangeable due to proprietary licenses.

In this work, we explore the effects of anharmonic bonded interactions on ionic solvation and conductivity in polymer and liquid electrolyte systems. An in-house, machine learning-based workflow, named AuTopology, was used to autonomously learn the interatomic potential parameters of distinct atomic environments for two different classical models from DFT forces as training data. In particular, the effect of machine learning regularization on dihedral parameters and resulting polymer behavior is highlighted. The learned harmonic OPLS model and anharmonic PCFF+ model parameters were then used to equilibrate condensed-phase simulations at a variety of experimentally-relevant concentrations. These simulations were allowed to run for hundreds of nanoseconds to determine the individual anion and cation diffusivities and resulting conductivities. Using this framework and an in-house database of molecular conformations, we have been able to reproduce wB97XD3-level DFT forces from trained OPLS force fields to within 5.5 kcal/mol-A. Lithium solvation environments and ion diffusivities were found to match legacy parameterizations to the same order of magnitude.

AI as a Peer: Polymer Discovery with Neuro-Symbolic In-telligent Agents Sarathkrishna Swaminathan, Dmitry Zubarev, Tim Erdmann, Subhajit Chaudhury and Asim Munawar; IBM Research, United States

Materials discovery, in the most general form, is a search for materials whose usefulness exceeds available ones. This is a sequential process, such as synthesis and formulation of a polymer, and in executing complex experimental plans at each stage that favor synthesis of polymer with desired molecular weight. The burden of sequential decision-making in experimental material science rests on subject matter experts (SMEs). Artificial intelligence (AI) systems with direct access to the experimental equipment platforms and general capability to plan sequences of experiments show enormous promise in sharing this burden while improving the characteristics of discovery processes. Neuro-symbolic (NS) variant of AI, combining concepts of logic-based reasoning and connectivism, is especially attractive because of highly desirable characteristics in the context of experimental materials discovery. First, explicit symbolic rules that can be reviewed by a SME serve as a safeguard against undesirable experiments. Second, symbolic rules congruent with conceptual structure of SMEs knowledge can be adjusted pro-actively by SME thus reducing learning budget and improving sample efficiency.

Here, we discuss a practical example of SME interactions with logical optimal action reinforcement learning (LOA RL) agent working on synthesis of spin-on-glasses. Our implementation of LOA RL explicitly considers logical structure of the interactions between the agent and the environment. We define the environment as the space of experiments accessible via an automated pipetting reactor and pursue training generalizable RL agents skilled in traversing the space of polymer synthesis. We demonstrate and quantify basic aspects of peer-like interactions between SME and LOA RL agents.

Proton Dynamics Simulations of Solid-Acid Electrolytes Using Active Learning and Equivariant Neural Network Force Fields Menghang Wang, Cameron J. Owen, Yu Xie, Simon Batzner, Albert Musaelian, Anders Johansson and Boris Kozinsky; Harvard University, United States

Understanding the rate-limiting steps of proton conduction across various solid acid electrolytes and the mechanisms behind superprotonic phase transition is crucial for designing next generation energy fuel cells. Due to the high computational cost of ab-initio molecular dynamics, previous studies of proton dynamics were constrained to a hundred atoms within a few hundred picoseconds and thus led to a limited statistics of proton-hopping events. Previous work has used material-specific empirical force fields to study the phase transition of CsHSO4, but it cannot be generalized to understand the mechanism of other solid acid materials.
In this work, we develop machine learning interatomic force fields for CsH2PO4 and CsHSO4 superprotonic conductors combining ab-initio accuracy with scalability to large system sizes and nanosecond time scale. First, we use Bayesian active learning framework FLARE[1] to generate training data containing various atomic configurations. Then, we train an equivariant neural network potential Allegro[2] and deploy it in large-scale molecular dynamics. After demonstrating the fidelity of the machine learning potential by comparing with experimental diffusivities and activation energies, we study the dynamics of oxyanions and protons to identify the rate-limiting step for conduction.

Ab Initio, Classical and Machine-Learning MD Simulations for Modeling Lithium Borosilicate Glasses Shingo Urata; AGC Inc., Japan

Lithium borosilicate (LBS) glass is a typical oxide glass applicable for all solid electrolyte to reduce interfacial resistance between the electrolyte and electrode. Because understanding in the microstructure is essential to improve the ion conductivity, accurate modeling in nanoscale is demanded. However, it is often difficult to reproduce boron coordination change from three-fold (^{3}B) to four-fold (^{4}B) coordinate using a conventional functional type of force-field, which hinders designing high ion-conducting glasses using molecular simulations.

This study, therefore, tried to apply machine-learning potential (MLP) for modeling a series of LBS glasses using DeepMD. The MLP was trained to reproduce a number of data on force and energy calculated by density functional theory (DFT) for crystals and amorphous glass models. The MLP successfully reproduced ^{3}B/^{4}B ratio in the LBS glasses with a few exceptions. Specifically, three-membered rings including boroxol ring, which is composed of three ^{3}B, were generated in high boron-containing LBS glasses in contrast to classical MD simulations with the functional force-field. Ion conductivity and glass transition temperature were also qualitatively reproduced by the MLP, which proved the applicability of MLP to investigate oxide glasses composed of network formers, which flexibly change their coordination.

In this talk, *ab initio* and classical MD simulations will be compared with the MLP-MD. For the classical MD simulations, a Buckingham type of force-field was developed to model LBS glasses by introducing a composition-dependent correction. In comparison with the CMD, the MLP was found to construct energetically more stable glass structures including the three-membered rings more in the microstructures. These results highlighted the advantages of the MLP. In contrast, five-hold coordinated silicon atoms were unreasonably generated, and the glass structures were disrupted at high temperature. This talk will also share these issues when applying MLP for modeling amorphous materials.

8:45 AM MD01.10.02
Investigating Representation Schemes For Surrogate Modeling Of High Entropy Alloys (HEAs) Arindam Debnath and Wesley Reinhart; The Pennsylvania State University, United States

In recent years, High Entropy Alloys (HEAs) have emerged as suitable candidates to replace Ni-based superalloys in gas turbines and jet engines due to their exceptional properties at extreme temperatures. However, the design of HEAs with desired value of properties is a challenging task due to the large and mostly uncharted design space and the difficulty in predicting the non-linear relationships between structure, property, and processing parameters. To further complicate matters, the three traditional paradigms of materials design, namely the trial-and-error method, chemical intuition governed by physical and chemical rules, and computer simulations are also unsuitable for designing HEAs with target properties. The advent of machine learning and data-driven methods has unlocked a new paradigm in the field of materials discovery and is perfectly poised to solve the problem of inverse design of HEAs. However, there are certain challenges that need to be addressed when it comes to utilizing ML tools for materials science problems, most of which arise because of adapting pre-existing methods to solve specific problems.

One such challenge is representing the material system of interest (in this case HEAs) in a format that is machine readable while also incorporating sufficient information. Unlike crystalline materials, where structural information is widely available, such vital information is lacking in HEAs as they mostly exist as random, non-periodic solid solutions. Therefore, most ML studies involving HEAs derive the input features for their model from the chemical composition. Primarily, the atomic fractions of the elements present in the composition are encoded as vectors, which can be either randomly arranged or follow a logical arrangement (like a 1D vector where the elements are arranged according to their atomic numbers or a 2D matrix that follows the periodic table arrangement). Additionally, studies have also utilized some material properties that can be derived from the composition by applying some stoichiometric and thermodynamic rules as features. While all of these feature schemes have yielded great results for predicting specific HEA properties, there has not been a systematic effort to benchmark these schemes.

Therefore, we investigate several commonly used representation schemes for HEAs for predicting thermodynamic and mechanical properties of interest like phase, hardness, and yield strength. The performance of the different models using the different representation schemes on these material properties would indicate the scheme's transferability. To assess the generalizability of the representation schemes, we create multiple scenarios by omitting specific element containing compositions from the training of the respective models and using these omitted compositions as the test set. We anticipate that the insights from these results will help us understand which representation scheme manages to retain the most chemical information and therefore is best suited to solve real-world design tasks.

Exploring the Discrepancies, the Extrapolability, and the Interpolability of Machine Learning Interatomic Potentials Yunsheng Liu and Yifei Mo; University of Maryland, United States

Machine learning interatomic potentials (MLPs) are a promising technique for atomic modeling. Despite its low computation cost, high accuracy, and small errors that are widely reported for MLPs, an open concern is whether MLPs can always accurately reproduce atomistic dynamics and related physical properties in their applications in molecular dynamics (MD) simulations. By testing a number of current state-of-the-art MLPs, we examine the extrapolability and interpolability of MLPs and reveal quite a few discrepancies related to defects and rare events (REs), especially the predicted diffusional properties of the MLP-MD simulations and the phonon dispersion with vacancy defect, comparing with the ab initio computation. Our analyses on atomic dynamics, including defect formation energies, atomic vibrations around the defects, and atom migrations, reveal that the current testing for MLPs based on low average errors is in adequate. To fully capture the true performance of MLPs on extrapolability and interpolability, we further develop and demonstrate quantitative metrics, which are better indicators for the prediction of atom dynamics properties in MD simulations. Leveraging these findings, we develop a RE-enhanced workflow of MLP training consisting of identifying RE data, enhancing training sets, and optimizing MLPs by RE-enhanced force performance scores. The MLPs trained by the RE-enhanced workflow are demonstrated to have improved prediction in diffusional properties. Given the identified errors and improved workflow are general to all MLPs, our study provides guidance for further development, improvements, and wide adoption of accurate, robust, and reliable MLPs for atomistic modeling.

Predicting Small-Molecule Viscosities Using Machine Learning and Physics-Informed Approaches Alex K. Chew, Mohammad Atif Faiz Afzal, Matthew Sender, Anand Chandrasekaran, Lihua Chen, Andrea Browning and Mathew Halls; Schrödinger, United States

Viscosity is a fundamental property that measures how "sticky" - or how resistant to flow - a fluid is, which dictates the performance of a wide range of materials, such as batteries, cosmetic formulations, and pharmaceuticals. Measuring viscosities using experiments or physics-based simulations is slow and tedious, which motivates the use of alternative, fast data-driven approaches to accelerate viscosity estimations. In this work, an extensive collection of over 4,000 experimental viscosity and temperature values for small organic molecules were curated from scientific literature and databases to develop quantitative structure-property relationship (QSPR) models. We compared both traditional-learning and deep-learning QSPR models and identified models that can accurately predict viscosities using molecular descriptors and temperature as inputs. To further improve model accuracy, we added physically relevant descriptors, extracted using classical molecular dynamics simulations, and encoded them into our QSPR models. We employ feature importance analysis tools to evaluate the influence of molecular-based and physics-informed descriptors on QSPR model performance. The data curation of a large viscosity dataset and the development of accurate, physically informed machine learning models enables the screening of viscosities for the design of new materials.

9:30 AM MD01.10.05
Atomistic Dynamics Simulations of Complex Materials and Interfaces with Machine-Learned Force Fields Anders Blom, Julian Schneider, Suresh K. Natarajan, Deb De, Jan-Niclas Luy and Søren Smidstrup; Synopsys, United States

Atomistic modeling is a powerful way to predict the properties of new materials. Progress in computer speed combined with more efficient algorithms have enabled accurate studies even for complicated materials like alloys and interfaces. Static simulations can now be performed for systems containing hundreds or even thousands of atoms using methods such as density-functional theory (DFT), and even millions of atoms with classical interatomic potentials (force fields). Unfortunately, the situation is quite different if one is interested in performing dynamical calculations, which includes studies of thermal conductivity or expansion coefficients, mechanical strength, or structure prediction.

Although DFT can be used for almost any material, the simulation times quickly become unmanageable, as a single molecular dynamics (MD) run over a few nanoseconds could take years for a big system, even if the calculations were heavily parallelized. Conversely, using force fields one could run the simulations in a fraction of the time, but sufficiently accurate force fields are only available for a few selected materials, and usually rather simple ones. For instance, the force field parameters might be fitted for a crystalline material, but the application calls for calculations of an amorphous cell. Parametrizing a new traditional force field for a novel material is a very time-consuming task, and the accuracy is often strongly limited by the functional form of the potentials used; the potentials often fail in high-temperature situations or when trying to predict atom diffusion energy barriers or phase transitions. Moreover, these potentials are rarely able to describe complicated situations such as interfaces or materials with many elements.

Recent efforts in the development of machine-learned (ML) force fields are now however enabling new and exciting quantitative studies of a wide range of problems. ML force fields can in theory be fitted for complex materials and interfaces, work well in sitations far from equilibrium (if properly trained), and are almost as efficient as traditional force fields when running long MD simulations. The one caveat that remains is that while it is possible to obtain near-DFT accuracy in a wide variety for scenarios, the training data used for the fitting must be very carefully chosen, and this is no small or simple task. The challenge is to generate an sufficient quantity of significantly different geometries which still cover the desired application space, as efficiently as possible, in order to minimize the time used to generate the reference DFT data for the fitting.

In this presentation, we will describe how we have created a set of automated protocols that can generate curated training data sets for complex materials such as alloys, interfaces, and surface chemistry applications. In particular, we avoid the use of DFT MD calculations, which can be extremely time-consuming. We will demonstrate how we have successfully and efficiently trained ML force fields to perform detailed structural analysis of phase change materials, molecular adsorption on surfaces for ALD studies, and thermal simulations of 2D materials.

Moreover, we have recently developed an enhancement to the ML potential framework that makes it easier and more robust to fit and use potentials for systems involving many different elements. In the past, applications of ML force fields have been limited to relatively simple materials, but this extension has enabled us to e.g. generate a single potential to generate relaxed and defect-free geometries of high-k metal gate stacks consisting of multiple interfaces and amorphous regions, with a total of 5 elements (Si, O, Hf, Ti, N), and magnetic tunnel junctions (MTJ) with 6 elements (Mg, O, Ta, Fe, Co, W) with a low training error as 5 meV/atom. For these MTJs we show that the resulting magnetic properties are nearly identical compared to DFT-optimized geometries.

Towards Quantum Machine Learning via Tensor Network Architectures Kyriakos Flouris; ETH Zurich, Switzerland

Deep machine learning methods have already established their dominance is most automation tasks and Quantum computing is one of the most promising fundamentally alternative algorithmic structures of the century. Furthermore, tensor networks have been shown to create an equivalent description to quantum algorithms, as it would have been implemented traditionally with gates. Additionally, it is estimated that the fundamentally probabilistic nature of quantum algorithms implies that they can be suitable Bayesian estimators. We implement a simple tensor network as the latent space representation of a manifold learning flow. We explore its theoretical implications and the potential to be used as an efficient lattice model solver.

Combinations of Machine Learning and Thermodynamic Integration Methods to Study Grain Boundary Segregation in Magnesium Alloys at Finite Temperatures Vaidehi Menon and Liang Qi; Univ of Michigan, United States

The segregation of solute elements to grain boundaries (GBs) can change the thermal and mechanical properties of metallic alloys. Atomistic simulations have been widely applied to investigate the thermodynamics and kinetics of GB segregation. However, these simulations are usually limited by the insufficient sampling of various GB sites and inaccuracy descriptions of free energy variations at finite temperatures. To solve these problems, we applied atomistic simulations and machine learning (ML) methods to investigate GB segregation in Mg alloys, which are promising lightweight structural materials. We present our studies of the segregation thermodynamics of solute elements (such as Y and Al) at Mg GBs using molecular dynamics (MD) simulations, thermodynamic integration (TI) methods, and ML.

We construct tens of symmetric tilt grain boundaries (STGBs) with different tilt axes and tilt angles as the GB structure sample set based on evolutionary algorithm [1]. The spectral segregation model [2], which uses a per-site distribution of zero-K segregation energies in the vicinity of each GB from the GB structure sample set, is employed to calculate the average GB segregation concentrations and the effective GB segregation energies at finite temperatures. The average GB segregation concentrations predicted by using the zero-K GB segregation energies show large deviations compared with experimental measurements. To reconcile these inconsistencies, our simulations also extend the current spectral model approach to carry out segregation free energy calculations at finite temperatures by using the TI method. We find that the finite-temperature Helmholtz free energy segregation spectra differ significantly from the segregation energy spectra obtained via 0 K simulations, which can change the GB solute concentration profile and effective segregation energy predictions at finite temperatures. However, a key bottleneck is that the direct TI calculations can only be applied to a small number of GB sites, which are insufficient for the spectral segregation model, due to the expensive computational costs of the TI method. Thus, ML methods are applied to accelerate the predictions of the accurate per-site distribution of GB-segregation free energies at finite temperatures by following steps.

First, we construct an ML surrogate model to predict the zero-K GB segregation energy as the function of local GB structural descriptors. Second, analyses of these descriptors determine the key structural descriptors for GB segregation energies, so the representative GB sites are chosen from the GB structure sample set based on the population distributions of these key structural descriptors. Third, the TI method is applied to calculate the finite-temperature segregation free energies for those representative GB sites. Fourth, ML methods were applied to construct the surrogate model to predict the difference between the zero-K segregation energy and finite-temperature segregation free energy for each GB site. The input descriptors of these surrogate models will be constructed based on both geometric factors and physics mechanisms, such as the estimation of the free energy variations based on the quasi-harmonic approximation. This free energy surrogate model is iteratively improved by including more representative GB sites in the training data sets based on adaptive learning methods. Finally, the free energy of solute segregation energy at each GB site in the GB sample set is predicated based on the surrogate model to get the accurate segregation free energy spectra, which are used for the accurate predictions of the GB segregation thermodynamics consistent with experimental measurements in Mg alloys.

Predicting Thermal Conductivity of Metal-Organic Frameworks using Graph Convolutional Neural Networks Meiirbek Islamov[1], Karl Krauth[2], Hasan Babaei[2], Michael Jordan[2] and Christopher E. Wilmer[1]; [1]University of Pittsburgh, United States; [2]University of California, Berkeley, United States

Metal-Organic Frameworks (MOFs) have gained prominence as revolutionary materials for gas storage and separation applications due to their high porosity, large surface areas, tunable pore geometry and chemistry. However, the practical usefulness of MOFs, especially in gas storage applications, depends on how rapidly they can disperse the tremendous amount of thermal energy generated during the typically exothermic adsorption process. Although adsorption-related properties of MOFs have been extensively investigated, comparatively limited studies have focused so far on understanding their thermal transport properties. To provide a data-driven perspective into this problem, we performed the first high-throughput computational screening of thermal transport properties in MOFs by performing classical molecular dynamics (MD) simulations on a diverse set of hypothetical MOFs. In addition to establishing universal structure-thermal conductivity relationships, we trained a crystal graph convolutional neural network on the thermal conductivities of 5353 hypothetical MOFs that were computationally generated with the ToBaCCo-3.0 code. Our model predicts the thermal conductivity of MOFs in a separate test set with a mean absolute error of 0.072 W m^{-1} K^{-1}. This model only requires MOF atomic and bonding information, which can help accelerate MOF discovery with tailored thermal transport properties by replacing expensive atomistic simulations that require interatomic potentials.

11:00 AM MD01.10.09
Efficient Sampling of Structural Configurations with A Universal Materials Graph Neutral Network Potential Ji Qi and Shyue Ping Ong; University of California, San Diego, United States

Training structure is one key component for fitting robust machine learning interatomic potentials (ML-IAPs). It is usually sampled by short trail runs of *ab initio* molecular dynamics together with manual selection by intervals. This traditional sampling method suffers from high computational cost and low diversity. The as-trained ML-IAPs are not reliable for severe temperatures at or above melting temperatures, thus prohibiting its accurate simulation for amorphous structures and calcination conditions. On the other hand, active learning (AL) strategy has been proposed and verified to effectively sample distinctive configurations in extreme and target scenarios, thus improving the reliability of ML-IAPs. However, AL still requires a good initial training set and intrinsically have to conduct *ab initio* calculations as well as ML-IAP fitting iteratively. In our study, we propose a method to broadly sample training configurations with a universal graph neutral network potential. Our strategy can achieve highly reliable ML-IAPs with one single iteration of optimization, and it is generally applicable to 89 elements in the period table.

11:15 AM MD01.10.10
ET-AL: Entropy-Targeted Active Learning for Bias Mitigation in Materials Data Hengrui Zhang, Wei Chen, James M. Rondinelli and Wei Chen; Northwestern University, United States

Growing materials data and data-centric informatics tools drastically promote the discovery and design of materials. While data-driven models, such as machine learning, have drawn much attention and observed significant progress, the quality of data resources is equally important but less studied. In this work, we focus on bias mitigation, an important aspect of materials data quality. Quantifying the diversity of stability in different crystal systems, we propose a metric for measuring structure–stability bias in materials data. To mitigate the bias, we develop an entropy-target active learning (ET-AL) framework, guiding the acquisition of new data so that diversities of underrepresented crystal systems are improved, thus mitigating the bias. With experiments on materials datasets, we demonstrate the capability of ET-AL and the improvement in machine learning models that mitigating bias offers through bias mitigation. The approach is applicable to data-centric informatics in other scientific domains.

11:30 AM MD01.10.11
Optimizing Thermodynamic Properties of High Entropy Alloys and Hydrides with Lattice Graph Neural Network Models Matthew Witman[1], Norman Bartelt[1], Sanliang Ling[2], Mark D. Allendorf[1] and Vitalie Stavila[1]; [1]Sandia National Laboratories, United States; [2]The University of Nottingham, United Kingdom

Efficient prediction of thermodynamic properties in both closed and open systems is needed to evaluate material performance and permit high-throughput materials discovery for a diverse array of technology applications, from rational design of low-density alloys, to optimizing battery cathodes, to modulating hydrogen absorption equilibria in complex metal alloys. Density functional theory (DFT) is typically needed to relax atomic configurations and predict energetics with sufficient accuracy in these systems. Yet it can be prohibitively expensive to achieve the necessary sampling required by statistical mechanics to converge thermodynamic predictions for even a single complex alloy due to the enormous phase space of possible configurations. Surrogate modeling strategies are therefore required, which critically must be able to predict energetics of these structural relaxations without knowing the relaxed structure, i.e., correctly predict relaxed energetics from an unrelaxed and trivial-to-generate structure representation. Cluster expansion methods can satisfy such requirements but can be very difficult to construct in systems with high compositional complexity. More recently, highly generalizable graph neural network models have been proposed that alleviate the difficulties associated with feature engineering for crystal structures. Therefore, it is now important to investigate their capacity to predict the energy of DFT-relaxed structures from an unrelaxed crystallographic representation, i.e., based on idealized lattice coordinates. Not only do they excel at this for systems investigated herein, but they accurately predict relaxed configurational energies well *outside* their training distribution. Thus, we can rapidly (minutes on a desktop computer) execute the large-scale sampling (hundreds of thousands of configurations) necessary for first-principles statistical mechanics methods to predict various thermodynamic properties, a task that would otherwise be intractable. Two exemplars, optimizing thermodynamic stability of low-density high entropy alloys and the modulating the plateau pressure of hydrogen in metal alloys, demonstrate the power of this approach. Its generalizability, which is limited in principle only by diversity of training data, has significant potential for future development and application to a multitude of materials discovery domains when sampling intensive routines are needed for thermodynamic predictions.

11:45 AM MD01.10.12
Discovering Novel Halide Perovskites using Multi-Fidelity Machine Learning and Graph Neural Networks Arun Kumar Mannodi Kanakkithodi; Purdue University, United States

The ABX_3 perovskite crystal structure is ubiquitous and the subject of extensive study owing to the sheer tunability of electronic and optical properties that can be achieved. Halide perovskites, in particular, are materials of great interest for solar absorption and many related optoelectronic applications such as LEDs, lasers, and UV or IR sensors. The discovery of novel perovskite compositions, including complex alloys with attractive properties, is hindered by the combinatorial nature of the chemical space and a general lack of quantification of systematic inaccuracies in simulations such as from first principles-based density functional theory (DFT). In this work, we generated large datasets of computed stability, electronic band gaps, theoretical photovoltaic efficiency derived from optical absorption spectra, and defect formation energies, of halide perovskite alloys from various DFT semi-local and hybrid functionals. This data is combined with smaller quantities of corresponding experimental measurements collected from the literature, and used for training multi-fidelity machine learning (ML) models to make property predictions at experimental accuracy. Such predictions, using state-of-the-art nonlinear regression techniques including random forests and Gaussian processes, are sequentially improved and coupled with a recommendation engine for new computations and experiments to gradually achieve new stable compositions with targeted band gap and absorption. Initial success if obtained using as inputs compositional information, known elemental properties of A, B, and X species, and one-hot encoding of perovskite phase and data fidelity. We extend these models to a much larger dataset of > 10,000 perovskite structures, wherein entire crystal structures are used as input via a variety of graph neural network-based approaches. This enables inclusion of lattice strain, octahedral distortions and rotations, and different kinds of alloy ordering as implicit inputs to the ML framework, ultimately resulting in general models applicable to any atom-composition-structure combination within the selected halide perovskite chemical space. Best DFT-ML surrogate models are coupled with optimization schemes using methods such as genetic algorithm, used to drive collaborative experiments and further DFT computations, and made available to the community via user-friendly tools on the NSF-funded online repository, nanoHUB.

1:30 PM MD01.11.01
Efficient Implementation of Machine Learned Nonlocal Density Functionals for Molecules and Solids Kyle W. Bystrom and Boris Kozinsky; Harvard University, United States

Machine Learning (ML) has recently gained attention as a means to develop more accurate exchange-correlation (XC) functionals, and in particular could be used to improve XC functionals for solids without using the computationally expensive exact exchange energy. Feature design is one of the main challenges of this approach because the features must include enough nonlocality to capture the complex nonlocal nature of the exact XC functional while also allowing for computationally efficient and scalable implementations. To address this challenge, the CIDER model for designing nonlocal ML functionals is introduced and used to design a nonlocal exchange functional that obeys the uniform scaling rule for exchange. In addition, two efficient methods for evaluating CIDER features are implemented: A quadratic-scaling algorithm for all-electron, molecular density functional theory (DFT) and a quasi-linear-scaling algorithm for plane-wave DFT with the PAW method. Efficiency and accuracy benchmarks for molecular periodic systems are presented, and the importance of the kinetic energy as a feature for learning the exchange functional is discussed.

1:45 PM MD01.11.02
Materials Discovery for High-Temperature, Clean-Energy Applications Using Graph Neural Network Models of Vacancy Defects and Free-Energy Calculations Matthew Witman[1], Anuj Goyal[2], Tadashi Ogitsu[3], Anthony McDaniel[1] and Stephan Lany[2]; [1]Sandia National Laboratories, United States; [2]National Renewable Energy Laboratory, United States; [3]Lawrence Livermore National Laboratory, United States

High-temperature properties of oxides are often governed by O vacancy defect formation. To enable high-throughput screening of thermochemical materials for clean-energy applications, we developed a graph neural network modeling approach for defects. This model accelerates the screening of vacancy defects by many orders of magnitude by replacing the supercell relaxations in density functional theory (DFT) that are otherwise required for each symmetrically unique crystal site. It fully automates the prediction of the DFT-relaxed vacancy formation enthalpy of any crystallographic site based only on the primitive cell of the host crystal structure. It can thus be used off-the-shelf to rapidly screen 10,000s of crystal structures (which can contain millions of unique defects) from existing databases. This modeling approach therefore provides a significant screening and discovery capability for a plethora of applications in which vacancy defects are the primary driver of a material's utility. For example, by high-throughput screening the Materials Project's metal oxides, we rapidly "re-discover" and identify new high potential candidate materials for hydrogen generation via solar thermochemical water splitting and energy storage, for CO2 conversion via reverse water gas shift chemical looping, and for cathodes in solid oxide fuel cells. Thermodynamic modeling on the basis of the high-throughput screening results allows us to connect the predicted defect energies to high temperature process conditions relevant to the different application areas, and we extract the reduction entropies as an additional selection criterion for high-performance materials.

2:00 PM MD01.11.03
Unraveling the Structure-Spectrum Relationship Using Descriptor-Aware Adversarial Autoencoders Xiaohui Qu, Zhu Liang, Deyu Lu, Matthew Carbone, Fanchen Meng, Eli Stavitski and Mark S. Hybertsen; Brookhaven National Laboratory, United States

X-ray absorption near-edge structure (XANES) spectroscopy is a premier tool for materials characterization, which is sensitive to the local chemical environment of the absorber site. However, interpreting XANES is highly nontrivial and first-principles simulations are typically required for descriptor assignment (e.g., oxidation state and coordination number). Although some descriptors have been established with distinct spectral trends, it is much more challenging to systematically discover new descriptors with statistically salient trends in complex materials spaces. A promising approach is to identify spectral trends with dimensionality reduction methods, e.g., principal component analysis or autoencoder. However, the reduced representation, e.g., a latent space in an autoencoder, does not align with descriptors monotonically, and the interpretation of the latent space remains challenging. To achieve a direct mapping between the latent space and descriptor space, the latent space needs to be reorganized to align each dimension with a descriptor.

In this work, we developed a "rank constraint" which operates on top of the adversarial autoencoder (AAE) framework. It forces each latent dimension to "track" a specific structure descriptor monotonically while preserving latent space smoothness. Specifically, we use the Kendal rank correlation coefficient as a soft constraint in our loss functions, which enforces the monotonical dependence of each latent space variable with a chosen distinct physical descriptor. Our new method, the Rank constrained AAE (RankAAE), allows us to effectively reveal the spectral line shape variation for each individual descriptor. Descriptors of the material structure generally have intertwined contributions to the spectral line shape; however, our method is capable of systematically decoupling them. We demonstrated our method using diverse datasets across the eight transition metal oxide families which contain forty thousand simulated spectra of the K-edge XANES. RankAAE not only reproduces well-documented trends from the literature but also reveals three new structure descriptors: oxygen coordination number, the standard deviation in the nearest neighbor bond lengths, and the minimum oxygen-oxygen distance on the edges of the nearest neighbor polyhedron. Our method provides a general framework to enhance the interpretability of a dimension reduction algorithm, which is generally applicable to other spectroscopic data.

Predicting the Strain Field Evolution in 2D Digital Composites with Neural Operators Meer Mehran Rashid, Souvik Chakraborty and N M Anoop Krishnan; Indian Institute of Technology Delhi, India

The search for high-performance materials has led to advanced composite materials with hierarchical designs. However, designing a superior material with targeted properties and performance is challenging due to the vast design combinations and computational limitations imposed by conventional physics-based solvers. To solve this, we use deep learning methods to measure the material response for composite materials subjected to tensile loading. In this study, we attempt to benchmark the state of the art neural operators (SOTA) to predict the strain evolution in 2D composites. We employ (Fourier Neural Operator), DeepONet, Multi-wavelet based transform (MWT), Wavelet Neural Operator (WNO) and Conditional Generative Adversarial Networks (cGAN). By inputting the strain fields corresponding to first few time steps, the Neural Operators (NOs) predict subsequent strain fields until the onset of fracture. Besides, we evaluate the performance of various NO's for material and pixel-wise zero-shot super-resolution. Our results show the superior performance of the FNO with accurate predictions for different use cases.

Physics-Informed Machine Learning Prediction of the Composition and Load Dependence of Glass Hardness Sajid Mannan[1], Daniel Roberto Cassar[2], Mohd Zaki[1], Suresh Bishnoi[1], Johan Frederik Schou Christensen[3], Morten Mattrup Smedskjær[3], Edgar Dutra Zanotto[4], Nitya N. Gosvami[1] and N M Anoop Krishnan[1]; [1]Indian Institute of Technology Delhi, India; [2]Ilum School of Science, Brazil; [3]Aalborg University, Denmark; [4]Universidade Federal de São Paulo, Brazil

Oxide glass materials are crucial for a variety of applications in the automotive, aerospace, electronics, architectural, biomedical, and nuclear industries. However, their brittleness and low fracture toughness make them highly vulnerable to surface damage such as scratches, abrasion, and chipping during processing and application. Such damages can act as crack nucleation sites, leading to catastrophic brittle fracture upon tensile loading [1]. It is thus important to develop glasses with improved damage resistance, e.g., by improving their hardness. To address this problem, we have used a Physics-Informed Neural Network (PINN) to develop a model that can learn from existing data on the composition and load dependence of hardness. The data was extracted from the INTERGLAD database [2], and numerous scientific papers. Both purely data-driven and PINN models were trained. The purely data-driven model successfully predicted the composition dependence but failed to capture the load dependency. On the other hand, the PINN model performed reasonably well in predicting both the target variable and capturing the load dependency of hardness. Furthermore, we employed Shapley Additive Explanations (SHAP) techniques to understand the feature (chemical elements) dependency toward model prediction. The results indicate that nitrogen (N), silicon (Si), and lanthanum (La) contribute significantly to improving the hardness of oxide glasses. In contrast, sodium (Na), phosphorous (P), and tellurium (Te) are found to decrease the hardness of oxide glasses.
Additionally, the PINN model clearly demarcates the load dependency behavior of oxide glasses and indicates that hardness decreases significantly for a slight increase in load values. However, this behavior was observed only at relatively low loads, which we attribute to the Indentation Size Effect (ISE). The derived composition-property relationships can potentially aid in designing glasses with tuned hardness for a variety of applications.

2:45 PM MD01.11.06
Extracting Materials Compositions from Research Papers Using Natural Language Processing Mohd Zaki, Tanishq Gupta, Devanshi Khatsuriya, Kausik Hira, N M Anoop Krishnan and Mausam Mausam; Indian Institute of Technology Delhi, India

Machine learning and natural language processing tools have contributed to the development of materials science specific language models, named entity recognition systems, and classification systems for identifying relevant research papers. To accelerate material discovery, it is important to know about materials already reported in scientific literature. However, the manual curation of such information into both human and machine-understandable forms is quite cumbersome. In this work, we use a graph neural network pipeline powered by MatSciBERT - A materials domain language model, to extract compositions of glasses and alloys reported in research papers. We first discuss the challenges associated with composition extraction, which arise due to different ways of reporting followed by researchers. Further, we analyse the extracted compositions and discuss the potential applications of the generated datasets and the model.

Extrapolative Discovery of Eco-Friendly Dielectric Gases Based on Machine Learning and Quantum Chemical Calculations Hajime Shimakawa, Akiko Kumada and Masahiro Sato; The University of Tokyo, Japan

Material discovery based on Materials Informatics (MI) generally aims to accurately predict material properties and to effectively explore unknown materials that are inaccessible by conventional methods. We have to tackle the fact in that machine learning is strong at interpolative prediction, but weak at extrapolative prediction. Because of the challenges of extrapolative performance of MI, there have been few studies that address this issue. Recently, some studies have reported network optimization methods [1] or flow-based generative model [2] that improve their extrapolative performance compared to conventional methods. However, we don’t have any MI model that has extrapolative performance sufficiently to discover unknown materials yet. We require an MI model that can obtain a correlation between material information and physical property, not as a stochastic distribution, but through physics-based analysis and machine learning. This study realizes the extrapolative prediction by learning linear correlations between quantum-chemical-based descriptors and material properties for each molecular cluster that is divided by quantum chemical information. As one of the successful applications, we design an extrapolative discovery model that can accurately predict boiling point, dielectric strength, and global warming potential (GWP) of gaseus molecules to explore for new eco-friendly dielectric gases beyond existing materials. Our results show that conventional graph-based deep learning and nonlinear machine learning models fail to extrapolative predictions, whereas our proposed model of quantum chemistry-based molecular cluster learning has a promising extrapolative performance. Using LSTM-based SMILES generation and molecular fragment reconstruction, a large number of novel molecular structures are generated and screened for low-boiling point, high-dielectric strength, and low-GWP molecules. As a result, we succeed to obtain new molecules that have powerful properties that overcome the trade-off weaknesses of existing materials and have a potential to contribute to realizing carbon neutrality. Our extrapolative discovery model extends the possibility of materials development with MI.

Artificial Neural Network with Multi-Head Intermolecular Attention Predicts Chemical Reactivity of Organic-Battery Components Jaekyun Yoo and Kisuk Kang; Seoul National University, Korea (the Republic of)

Organic battery system gather lots of attention as post lithium ion battery becuase of its cost effectiveness and eco-friendliness. Organic electrodes, which consists of redox-active organic materials, are key components to implement organic batteries whose energy density and cycle performance is similar with conventional inorganic batteries. Selecting functional materials which are chemically compatible with each other is a prerequisite to discover high-performance organic materials and fabricate these multi-component systems and is especially crucial for their long-term system stability. In that, in the design of new organic-based batteries the exploration of organic compounds for the electrode and electrolyte should consider not only their intrinsic electrochemical activity/stability but also the compatibility among the constituting components. Herein, we report an extensive scheme of predicting the chemical reactivities of any combinations of two organic compounds by employing the so-called Intermolecular Reaction Rate Network (ImRRNet). This new artificial neural network (ANN) platform exploits the novel intermolecular multi-head attention method to predict the precise reaction rate constant between two organic chemicals from their molecular structure and was trained with a large chemical space of 175,987 datapoints on the nucleophilicity and electrophilicity. The intermolecular multi-head attention method successfully identified the local substructure that primarily determines the chemical reactivity of organic molecules by providing a greater attention score in the specific position. This means our new model catch hidden chemical information in the molecular structure even though we never instructed chemical information which belongs to molecular structure excpet reactivity between two molecules. The prediction accuracy of ImRRNet was observed to be remarkably higher (mean absolute error of 0.5760) than other previous ANN models (> 0.94), validating its efficacy for practical employment in the design of multi-component organic-based rechargeable batteries.

4:00 PM MD01.11.09
Novel Graph Imputation Method for Discovering Structure Property Relationships in Materials Vineeth Venugopal and Elsa Olivetti; Massachusetts Institute of Technology, United States

In this work, we present a novel method for materials discovery and property identification through node imputation in Knowledge Graphs (KG). The proposed method extracts a high dimensional embedding for entities in a KG using large language models from which a neural network is trained to generate the graph embedding representation. This allows us to add a node to a knowledge graph that was not present during the training of the graph embedding model and consequently allows for link prediction - thereby connecting the new node to other nodes in the graph. This approach for generating nodes in a knowledge graph is being demonstrated for the first time here.

Knowledge Graphs are an emerging tool for integrating data and relational ontologies through versatile graph databases. They have become the industrial standard for data retrieval and organization as demonstrated by KG use in Google Search, social media sites such as Facebook and LinkedIN, as well as companies with large data inventory such as Ikea and NASA. In the field of materials science as well, several domain specific ontologies and property graphs have been proposed, though the use of knowledge graphs as a relational database tool is not very common at present.

We recently presented MatKG: a knowledge graph in the field of materials science comprising over 80,000 unique entities and over 5 million statements, where each statement is an (entity, relation, entity) triple. The KG covers several topical fields such as inorganic oxides, functional materials, battery materials, metals and alloys, polymers, cements, high entropy alloys, biomaterials, and catalysts. The triples are generated autonomously through data driven natural language processing pipelines and extracted from a corpus of around 4 million published scientific articles. Several informational entities such as materials, properties, application areas, synthesis information, and characterization methods are integrated together with a hierarchical ontological schema, where the base relations are extracted through statistical correlations to which higher level ontologies are appended. Thus the KG is heterogeneous and contains multiple relations between entities. It is shown that a bipartite projection of the base KG leads to comprehensive relational graphs that link materials to their chief attributes and applications and help answer questions such as "what are key attributes of battery materials?" without human intervention. We use a graph neural network based representational learning method to learn embeddings for entities and their relations which translate the graph data structure to a high dimensional mathematical space in which semantic relations between entities can be formulated as algebraic operations.

However, these representation models cannot learn embeddings of entities that were not present during training. Consequently, we are not able to predict links to material or property nodes that are unseen/novel - a key requirement for materials discovery and development. While several node imputation models are currently available today, they require at least a few links to be known of the given node, which is inherently impossible for a newly developed material. The approach we have developed allows for a brand new node to be imputed into a graph by learning the representation from large language models. The neural network architecture used for training, the efficacy of the method, and the entities that are successfully/unsuccessfully imputed using this technique are described. Future directions of development are also discussed.

4:15 PM MD01.11.10
Machine Learning-Based Optimization of Segmented Thermoelectric Generators using Temperature-Dependent Performance Properties Wabi D. Diriba[1], Byungki Ryu[2] and Seunghwa Ryu[1]; [1]Korea Advanced Institute of Science & Technology (KAIST), Korea (the Republic of); [2]Korea Electrotechnology Research Institute (KERI), Korea (the Republic of)

Segmented thermoelectric generators (STEGs) offer an excellent platform for thermal energy harvesting devices because they enhance the performance of power generation for a wide range of operating temperatures. Despite its advantage of direct conversion of thermal energy into electricity, conventional optimization approaches of STEGs are not able to offer a systematic way of selecting the optimal multiple stacks of P-and-N-type thermoelectric materials (TEs) legs from a set of many TE materials. In this study, we propose a systematic machine learning-based optimization to find the optimal STEG for maximizing its performance. A deep neural network (DNN) is trained to learn the inherent nonlinear relationship between the temperature-dependent properties of P- and N-type TE materials, lengths of each segment, and external loads to predict performance outputs. The trained DNN model efficiently explores the design space via a genetic optimization algorithm and suggests new high-performance designs. To expand the DNN prediction accuracy in the new superior STEG designs, the DNN is iteratively updated by augmenting the new designs via active learning. We optimized STEG module with four stacked segments in each leg from 88 P- and 70 N-type TE materials database. The optimized STEG module design exhibits 1.91 and 1.5 times higher power and efficiency compared to the best designs chosen from the initial training dataset composed of 157,916 different STEGs, respectively.

4:30 PM MD01.11.11
Bayesian Optimization and Reinforcement Learning-Based Design of High-Performance Kirigami Piezo-Transmittance Strain Sensors Jimin Gu[1,2], Bowen Zheng[2], Grace Gu[2] and Inkyu Park[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]University of California, Berkeley, United States

Piezo-transmittance based strain sensors, which detect strains by mechanical deformation-induced optical transmittance change, have shown great promise in soft sensing applications due to their fast response, long-term stability, and negligible energy consumption. However, challenges lie in how to further improve their performances of interest such as sensitivity, working range, and deformability to adapt to tasks in extreme conditions like space and wearable device. Kirigami structures, an important subset of mechanical metamaterials, possess highly versatile mechanical properties due to their unique deformation behavior. Additionally, these structures can be highly parameterized, which favorably creates ample opportunities for optimization. In our study, we formulate the problem as a multi-objective optimization with respect to the sensing sensitivity, the linearity of the response, and the failure strain over a large design space of the kirigami structure. First, using finite element simulation results as training data, we develop a surrogate machine learning model that takes in geometric variables and outputs the performances of interest. This surrogate model is used to replace more expensive physical simulations to accelerate the optimization process. Next, we use both Bayesian optimization and reinforcement learning to search for high-performance kirigami designs for piezo-transmittance strain sensing. We show that the optimized kirigami sensors reliably outperform random geometrical configurations. We also conduct feature importance analysis to rank the contributions of individual features as well as feature combinations, which interprets the machine learning-based optimization results and gives insights to better parameterization for next design iterations. As a future step, we aim to conduct experiments to verify the high performance of the designed kirigami piezo-transmittance strain sensors.

Cost-Sensitive Bayesian Active Molecular Design with Auxiliary Properties Elliot Nelson[1] and Dmitry Zubarev[2]; [1]IBM T.J. Watson Research Center, United States; [2]IBM Almaden Research Center, United States

Given the costs of evaluating molecular properties, and the vast size of molecular search space, there is a need for data efficient algorithms which actively and strategically select candidate molecules for evaluation. While target properties are costly to compute or measure, in many cases auxiliary physical/chemical properties can be queried at a lower cost, and are known to be predictive of (and mechanistically related to) target properties. We introduce a Bayesian active learning algorithm which (i) maintains a graphical Gaussian Process based model of the dependencies between molecular structure, auxiliary physical/chemical properties, and target properties such as toxicity and biodegradability, and (ii) adaptively selects properties to evaluate depending on evaluation costs, model uncertainty, and expected task-relevant information gain. We discuss its ability to identify molecules with target property values in a cost-effective manner on a class of anionic photoacid generator (PAG) molecules, and study the dependence of learned molecule evaluation strategies on the relative query costs and mutual information between target and auxiliary properties.

9:05 PM MD01.12.04
An Ensemble Learning Approach for Efficient Crystalline Structure Classification in Atomistic Simulations Yanhao Deng[1], Yangyang Wang[1], Ke Xu[2] and Yanming Wang[1]; [1]Shanghai Jiaotong University, China; [2]Jilin University, China

In atomistic simulations, crystal structure identification could be crucial for many analyses. Traditional classification methods, typically relying on structure-specific formulas and empirical thresholds, may only be available for limited material types, occasionally with an unsatisfactory performance for complex systems. While emerging machine learning (ML) techniques have greatly helped improve the accuracy and applicability of atomic structure prediction, the large training data size requirement and expansive computational costs appear to be issues, especially when it is necessary to retrain the models considering new crystal structures. In order to tackle these problems, here we proposed a flexible ensemble learning framework, where several lightweight ML methods were assembled taking a series of carefully selected bond orientational order parameters as the input features. Our trained model can detect multiple common crystal structures including both pure substances and binary compounds, which exhibited an accuracy of 99.8% on our test dataset, outperforming several deep learning based methods. The model can also predict the relative probabilities of atoms in candidate structures, which may be useful for interpreting more complicated local environments such as the interfaces. In addition, given a completely unknown crystal structure, new knowledge can be more efficiently incorporated into our framework, with the help of generative sampled data from our current model. We believe that the versatility and extendibility of this framework make it a generally applicable tool for classifying crystal structures in atomistic simulations, promoting a deeper understanding in fundamental microscopic phenomena.

9:20 PM MD01.12.05
Predicting PV-PEC Promising Materials Based on Chemical Composition—Data-Driven Accelerated Machine Learning Study Chihun Kim, Seunghwan Jung and Young-Chae Chung; Hanyang University, Korea (the Republic of)

Artificial photosynthesis through solar cells (PV) and photoelectrochemical (PEC) devices utilizing solar energy will play a key role in the production of solar fuels for carbon neutrality. For the efficiency of time and cost in developing new materials for PV-PEC area, we modeled data driven supervised models. Learned classification and regression models can successfully predict electronic properties of materials only based on the chemical composition. Selected 373 features and 6353 experimental data are used for learning. For classification model, oversampling technique are adapted to overcome imbalance of data set. Through learned classification and regression model, materials can be classified by electronic properties only based on information of chemical composition. For regression model, prediction performance is revised by excluding outliers. Through regression model, band gap value can be predicted with low error 0.24 eV, in criteria of MAE. By investigating the features importance and the partial dependence plot, the relationship between target properties and features are unveiled. These models are expected to contribute developing new materials in PV-PEC research area and give guideline for surface engineering on purpose of band gap tuning.

9:35 PM MD01.12.06
Quantitative Evaluation of Fiber Mat in a Two-Dimensional Image with Deep Learning Hiroko Akiyama[1], Yoshihiro Takizawa[2] and Kyoichi Oshida[2]; [1]Ashikaga University, Japan; [2]National Institute of Technology(KOSEN), Nagano College, Japan

Fiber mats are utilized in a wide range of fields since they can be designed with functions such as flexibility, permeability, and adsorption. The functions and properties of fiber mats are related to mechanical properties, porosity, and the size/shape of the fibers and the interspaces among them. The evaluation and analysis of three-dimensional (3D) information is important for material development. While the interspaces can be observed with a microscope, the evaluation with this observation is qualitative. For quantitative evaluation, we analyze digital images taken with scanning electron microscopy.
In this research, we developed an algorithm that calculates the approximate volume of fibers in a two-dimensional scanning electron microscope (2D-SEM) image. Our goal is to generate 3D data from 2D image. Although 3D data can be obtained using 3D-SEM, 3D data construction requires a great amount of time, effort, techniques, and specific software as stereo imaging needs multiple 2D-SEM images taken from different angles. On the other hand, our method to calculate pseudo 3D data needs only a single 2D image. Hence, our method is useful to reduce the costs of evaluation for material development.
We calculated volume fraction of polyacrylonitrile nanofiber mats generated by electrospinning with image processing. First, the region of fibers in 2D-SEM image was extracted. The pixels of fibers were then manually selected, since the existing image processing software did not detect all fibers due to the conditions such as brightness and focus. Secondly, the volume and volume fraction of fibers were calculated by assuming that each fiber is cylindrical with a uniform diameter. For comparison, we experimentally measured the volume fraction of the sample mat as well. As a result, it was found that these values were comparable.
In addition, we have implemented deep learning algorithm in order to automatically extract fiber parts in the images. Selecting pixels of fibers manually is not practical to apply to various images since it takes numerous time and effort. We applied semantic segmentation algorithm, which is a deep learning method for clustering the pixels that represent the same object in an image. Since the pixels of fiber region are extracted with this algorithm, the volume is calculated with the number of the pixels. We used unsupervised learning algorithms among semantic segmentation. Thus it is not necessary to prepare a large amount of training data like supervised learning algorithms. Furthermore, pretrained models of semantic segmentation are available. We implemented several pretrained models specified to microscopic images. Volume fraction was calculated in the same procedure as the above, and we evaluated the results calculated by deep learning with experimental data.

9:40 PM MD01.12.07
Quantum Chemical Data Generation as Fill-In for Reliability Enhancement of Machine-Learning Reaction and Retrosynthesis Planning
Alessandra Toniato[1,2,3], Jan Unsleber[2,3], Alain Vaucher[1,3], Thomas Weymuth[2,3], Daniel Probst[1,3], Teodoro Laino[1,3] and Markus Reiher[2,3]; [1]IBM Research Zurich, Switzerland; [2]ETH Zürich, Switzerland; [3]National Center for Competence in Research-Catalysis, Switzerland

Data-driven synthesis planning has seen remarkable successes in recent years by virtue of modern approaches of artificial intelligence that efficiently exploit vast databases with experimental data on chemical reactions. However, this success story is intimately connected to the availability of existing experimental data. It may well occur in retrosynthetic and synthesis design tasks that predictions in individual steps of a reaction cascade are affected by large uncertainties. In such cases, it will, in general, not be easily possible to provide missing data from autonomously conducted experiments on demand. However, first-principles calculations can, in principle, provide missing data to enhance the confidence of an individual prediction or for model retraining. Here, we demonstrate the feasibility of such an ansatz and analyze resource requirements for conducting autonomous first-principles calculations on demand. We introduce our integrated AI-QC framework and discuss the challenges for the implementation and for the interface of the two technologies at play (IBM RXN platform for AI-based retrosynthesis and SCINE Chemoton for double-ended reaction network exploration). We present proof-of-concept results on two organic reactions (a Williamson ether synthesis and a more complex Friedel-Crafts reaction) and we discuss resource estimates and the scalability of our framework to a production environment.

Machine Learning Predictions for Microscale Strain Accumulation in Polycrystalline Metals Renato B. Vieira[1], William Noh[2], Huck Beng Chew[2] and John Lambros[2]; [1]Pontifícia Univer. Católica, Brazil; [2]Univ of Illinois at Urbana-Champaign, United States

Data-driven approaches based on machine learning (ML) have become increasingly popular for the study of the mechanical response of material behavior as both numerical and experimental novel methodologies have provided a wealth of big-data information for materials. On the experimental side, two dimensional (2D) and three dimensional (3D) full-field techniques such as digital image correlation (DIC) and digital volume correlation (DVC) provide datasets comparable in size and fidelity to numerical techniques such as finite elements (FEA) or molecular dynamics (MD). However, one criticism faced by data-driven approaches used to "fit" such big-data is that they often ignore or oversimplify the underlying physics and as such may not be suitable for predictively analyzing complex phenomena for which physics-based multiscale models are often developed. Failure event prediction in particular is especially challenging because failure is usually driven by local events though it is triggered by global loading, thus by its nature necessitating a multiscale approach. As a result, in this work we try to combine the ML "convenience" of bypassing explicitly modeling with the "physical accuracy" of a multiscale model by using ML within a physics-driven framework by combining experimental data as both training and constraints for the ML framework.

In particular, we wish to use microstructural strain accumulation in metals as a predictor of ultimate failure whether through plasticity, creep, fracture or fatigue loading. Depending on material, grain boundary vs. grain interior (i.e., "mantle vs. core", respectively) strain accumulation can serve as a driver for failure nucleation/initiation at the microscale. Experimental measurements based on high-resolution DIC (HiDIC) techniques which we have developed provide microscale strain fields with sub-grain level resolution that are then used to train artificial and/or convolution neural networks (ANNs and CNNs). Microstructural quantities such as grain misorientation, Schmid factor, and grain morphology, are used to identify strain hot-spot locations. Specifically, using a fitting neural network trained by experimental HiDIC we found that in an austenitic steel alloy the grain boundary inclination angle shows significant correlation with local stain accumulation in the mantle region. Considering the interior (core) strain build-up, we combined HiDIC measurements over large areas of a microstructure with crystal plasticity simulations to identify critical grains (or grain clusters–defined as neighboring grains similarly oriented) which would exhibit critical stain accumulation. Averaging the response, either within a grain or over several grains, allows for the development of an approach that can be more easily implemented at higher length scales to provide predictions of local failure using more global quantities (i.e., a reduced-order model of sorts) based on the knowledge gained through the multiscale ML efforts.

11:00 AM *MD02.01.02
Understanding Strain Hardening of Face-Centered Cubic Metals using Dislocation Dynamics Wei Cai[1], Sh. Akhondzadeh[1], Ryan Sills[2] and Nicolas Bertin[3]; [1]Stanford University, United States; [2]Rutgers, The State University of New Jersey, United States; [3]Lawrence Livermore National Laboratory, United States

Understanding plasticity and strength of crystalline materials in terms of the physics of microscopic defects has been a long-standing goal of materials research. Over the last two decades, much effort has been placed on the prediction of stress-strain curve of single crystals through large-scale dislocation dynamics (DD) simulations. If successful, DD can thus provide a quantitative link, which has been lacking to date, between dislocation physics at the atomistic scale and crystal plasticity at the continuum scale. Unfortunately, the progress in this direction has been limited by the very small strain that can be routinely reached (<1%) by existing DD simulations compared with the typical strain (up to 30%) in experiments. Because of this limitation, a direct comparison between DD predictions and experimental stress-strain curves has been impossible.

A series of advanced time integration algorithms have been developed to expand the strain range of DD simulations. In particular, the pairwise interaction forces between dislocation segments are separated into several groups, and each group is integrated with a different time step size. The resulting subcycling algorithm and implementation to GPU leads to an increase of computational efficiency by more than 1000 times. The new simulation capability enables the prediction of stress-strain curves for shear strains in excess of 1% routinely and repeatedly. As a result, a systematic investigation on the relation between the unit mechanisms and work hardening rate is now possible.

Here we report the latest findings from DD simulations of uniaxial deformation of single crystal Cu along more than 100 loading orientations. These DD simulations generate a large amount data on the dislocation microstructure evolution based on which physics-based constitutive relations can be constructed systematically. The dislocation networks are found to have a much more complex structure than previously expected, in the sense that most nodes (where three dislocation lines meet) are not recognizable from the conventional picture of binary junction formation. The dislocation link length on every slip system is found to obey a distribution describable by the sum of two exponentials. We also report the first direct comparison between DD simulations and Kolsky bar experiments for single crystal Cu under [001] and [011] orientations under identical loading conditions (strain rate ~ 10^4 s^{-1}).

Such a comparison is essential in establishing the fundamental premise of dislocation-based theory of crystal plasticity. We will present the insights gained from these comparisons.

11:30 AM MD02.01.03
Dislocation Evolution in Iron during Nanoindentation Wurong Jian[1], Nicolas Bertin[2], Yifan Wang[1] and Wei Cai[1]; [1]Stanford University, United States; [2]Lawrence Livermore National Laboratory, United States

Nanoindentation has been applied widely to probe the local plastic behaviors of metals. However, the dislocation network under indenter and its evolution have not been fully understood. By comparing molecular dynamics (MD) and discrete dislocation dynamics (DDD) simulations in body-centered cubic (BCC) Fe single crystal in nano-scale volumes under nanoindentation, the DDD parameters can be calibrated and then used in micro-scale volumes. For most DDD simulations, cross slip and jog formation are ignored. Here, their effects on the evolution of dislocation network are studied, which explains why dislocation network evolves differently between the previous DDD and MD simulations.

11:45 AM MD02.01.04
Development of Data-Driven Interatomic Potential for Plasticity Analysis of Zinc Oxide Ceramics Shihao Zhang, Yan Li, Atsutomo Nakamura and Shigenobu Ogata; Osaka University, Japan

The dislocation toughening of ceramics has attracted considerable attention in recent years [1-3] since ceramics are inherently brittle and, thus, do not have a wide range of structural applications. However, understanding at the atomic scale is still lacking. We studied the dislocation-dominated deformation of wurtzite-type zinc oxide (ZnO) ceramic by nanoindentation simulation. ZnO ceramics has recently emerged as a leading semiconducting metal oxide ceramic. We developed data-driven interatomic potentials based on density functional theory (DFT) energy and force databases, yielding DFT accuracy and large-scale atomic simulation (millions of atoms). Large-scale indentation simulations were performed using the developed interatomic potentials to study indentation-induced dislocation nucleation and propagation in ZnO ceramics. An unprecedented phenomenon occurred in which identical rectangular dislocation loops were continuously nucleated from a single dislocation source under the indenter, induced by basal-to-prism dislocation cross-slip. The resulting dislocation loops pile-up, in good agreement with experiments. This study not only demonstrates the effectiveness of data-driven interatomic potentials in the analysis of plastic deformation of ceramic materials, but also provides new insights into the dislocation-dominated deformation behavior of ceramics. Authors acknowledge the JSPS Postdoctoral Fellowships for Research in Japan (Standard) and the Grant-in-Aid for JSPS Research Fellow Grant No. 22F22056.

1:30 PM *MD02.02.01
Using Data-Driven Methods to Learn the Properties of Extended Defects from Atomistic Simulations Nithin Mathew; Los Alamos National Laboratory, United States

Deformation and strength of polycrystalline metallic materials are dominated by motion and interaction of extended defects such as dislocations and grain boundaries. Molecular dynamics simulations have been used successfully for many decades to study the properties of these defects and unit mechanisms pertaining to physical processes involving these defects. In this talk, I will discuss the application of machine learning (ML) techniques on molecular dynamics simulation data to learn the properties of dislocations and grain boundaries in metals. I will demonstrate the utility of both supervised and unsupervised ML to extract physical insights into structure, mobility, and interaction between these defects. In some cases, we observe that the ML models are able to generalize well based on learning from a limited data set, provided that they are trained using a physically meaningful set of descriptors. Techniques to upscale the derived physical insights into mesoscale models for dislocation mechanics will also be discussed.

Predicting Damage Initiation with Computer Vision Bruno Dobrovolski and Brandon Runnels; University of Colorado Colorado Springs, United States

Structural materials are designed to withstand mechanical loading, and are key to ensuring the safety of systems ranging from civil to military. Failure of structural materials can have catestrophic consequences, and so it is necessary to ensure that they perform reliably and predictably in all loading scenarios. In this work, we specifically focus on damage initiation in incipient spall experiments. Work by experimental collaborators at Los Alamos has produced extensive datasets showing void nucleation due to shock loading. Unsurprisingly, it has been observed that grain boundaries (GBs) seem to be preferential sites for void nucleation. Unexpectedly, however, there does not seem to be any definite trend observed in which GBs nucleate voids and which do not; that is, it appears that not all GBs fail equally. Initial analysis has shown that there appears to be no correlation between spall nucleation likelihood and typical GB properties such as energy or CSL ∑ value. Therefore, it is necessary to employ a more sophisticated method of analysis.
Convolutional neural networks (CNN) are a machine learning framework often used in computer vision applications such as image recognition. Multi-channel CNNs (MCCNN) are CNNs that incorporate non-visible channels as well as visible ones. In this work we apply MCCNNs to the problem of void identification in microstructure. Specifically, we train MCCNNs with reconstructed microstructure to resemble the pre-shock state, but categorized by whether the post-shock state contains a void. The channels for the MCCNN include visible channels (micrographs) as well as invisible channels such as

GB energy and CSL ∑. In some cases, these properties (such as the ∑ value) are readily available from EBSD analysis. In other cases, they must be computed using a surrogate model. Of particular interest is the GB energy. GB energy is computed automatically using the lattice-matching method, and then used retroactively to estimate the out-of-plane inclination of the boundary. Finally, the stress-state is etsimated automatically using quasi-static elastic simulations in Alamo. By incorporating all of these effects, the model is therefore able to conglomerate physical properties along with geometric properties in order to determine the subtle trends contributing to void nucleation. In this work, the processing and assembly of the training dataset are presented, along with training results from the MCCNN. This framework will eventually be used to rapidly screen, and perhaps even design, optimal damage-resistant microstructures for structural materials with enhanced safety.

2:30 PM MD02.02.03
Molecular Dynamics Study on the Mechanical Effects of V in FeCo Alloys Mario Hernandez, Joo T. Oh and Zhong Chen; Nanyang Technological University, Singapore

Interatomic potentials for the Fe-Co and Fe-V binary systems have been developed and merged to describe the Fe-Co-V ternary system based on the second nearest-neighbor modified embedded-atom method (2NN MEAM) formalism. Emphasis has been placed on the correct prediction of FeCo elastic properties and antiphase boundary (APB) energies to ensure proper description of the mechanical behaviors. The potentials are then used to analyze the crack nucleation and propagation mechanisms in polycrystalline FeCo and FeCo-2V alloys under different ordering degrees at grain boundaries (GB) and within the grains.
The results show that disordering inside grains has a larger impact on the ductility of the binary FeCo. The mobility of the antiphase domains (APD) inside the grains delays the ultimate tensile strength (UTS) and fracture point. The observed fracture procedure shows that triple junctions of GBs serve as the focal points of stresses concentration. The poor mobility at the triple GBs promotes crack nucleation and crack propagation, leading to an intergranular fracture in ordered and disordered binary alloys.
The effects of adding 2 at. % V to the FeCo alloy have also been investigated via molecular dynamics (MD) and hybrid grand canonical Monte Carlo-MD (GCMC-MD) simulations. It was shown that V prefers to migrate to (a) the GBs in an ordered state, and (b) GBs with some atoms to the APBs in a disordered state. The ordered FeCo-2V displays a decreased UTS and loss of ductility at room temperature. Introducing V exclusively to the APBs greatly increases the mobility of APD and migration of atoms to GBs boosting the ductility of the alloy.

Predictive Fracture Mechanics and Photochemical Reaction Kinetics Modeling of the Reliability of Photovoltaic Modules with Polymeric Encapsulants Undergoing Field Aging Alan Liu and Reinhold H. Dauskardt; Stanford University, United States

Solar photovoltaics (PV) is the fastest growing renewable energy sector, for which silicon-based solar modules comprise a market share of > 90% of the global photovoltaic market. However, reliability remains a pressing challenge. Reliability of solar modules over long lifetimes is crucial for their success as the U.S. and other countries aim to decarbonize power generation. PV modules are subject to environmental stressors (UV exposure, temperature, humidity) that cause degradation within the encapsulant and interfaces, limiting their lifetimes. This is especially problematic in modules with ethylene vinyl acetate (EVA) encapsulants, the dominant encapsulant used today. As the PV industry looks to extend module lifetimes beyond 30 years, more advanced predictive modeling with an emphasis on degradation pathways is critical for the development of next-generation resilient module materials. Previous work has experimentally characterized the adhesion energies of EVA-encapsulated modules over field aging time with well-established fracture testing metrology, and attempted to model the trends with analytical functions [1]. However, the development of an accurate multiscale reliability model that links the microscale chemical processes to macroscale adhesion properties remains elusive. Additionally, previous characterization efforts have shown that the EVA-cell adhesion is initially weaker at early aging times, but at long aging times the EVA-glass adhesion is weaker due to catalyzed hydrolysis reactions [2]. In this work, a novel time-dependent multiscale physics model is presented that connects interfacial bond densities to module adhesion energies, G_C, with detailed chemical kinetics and fracture mechanics calculations. The model addresses the rate and acceleration of degradation pathways at different materials interfaces, the plasticity generated at the interfaces during the delamination process, and changes in encapsulant mechanical properties over aging time. The model's initial conditions, such as the adhesion energy and encapsulant material properties at t=0, are informed by experimental data, while subsequent predictions are data-free and generated from a multi-scale physics model. Additionally, nanoindentation was done on EVA specimens at various stages of field aging to measure their mechanical properties variations over time.
The model predictions of module adhesion energies and mechanical properties, when compared with available experimental data, show a marked improvement from previously developed analytical models. Furthermore, the model can predict switches in fracture interfaces, such as the EVA-cell to EVA-glass fracture transition, while previous models could not. A sensitivity analysis study was conducted by varying the reaction rate constants for deacetylation, beta-scission, and crosslinking reactions to investigate their effects on predicted module adhesion energies. While the model was developed primarily for EVA-encapsulated modules, it is extendible to different encapsulation materials and interfaces by simple tuning of parameters such as the reaction rate constants and initial adhesion energy values. Finally, model extensions to polyolefin elastomer and silicone encapsulated modules are shown in this work to demonstrate its flexibility. This work provides a powerful framework for understanding how the rates of molecular degradation mechanisms can impact module adhesion properties and mechanical properties.

Towards High-Throughput, Small-Scale Fracture Investigations via Machine Learning Christos E. Athanasiou; Georgia Institute of Technology, United States

Investigating mechanical properties at small scales is a challenging endeavor. It requires sophisticated micro-/nano-scale experimental methods combined with laborious/time-intensive finite element computations. In this talk, a new framework for materials characterization at small scales using the latest developments in machine learning will be presented. This framework involves multi-fidelity deep learning and active learning methods limiting the need for finite element simulations. Its application for predicting the fracture toughness of microscale pentagonal cross-sectional ceramic cantilevers as well as micropillars will be showcased, demonstrating that it can significantly accelerate fracture toughness characterizations at small scales.

4:00 PM *MD02.02.06
Machine learning (ML)-Assisted Modeling of Composites Wenbin Yu[1] and Xin Liu[2]; [1]Purdue University, United States; [2]The University of Texas at Arlington, United States

Emerging artificial intelligence (AI) and machine learning (ML) techniques are changing the computational paradigm on the development of lightweight, high performance composite materials and structures. This presentation will introduce our recent works of ML-assisted modeling of composites. The presentation has two parts. The first part is the application of artificial neural network (ANN) models to reduce the computational costs of high-fidelity simulations. In this application, ANN models are trained to be efficient surrogate models for computationally intensive jobs such as multiscale modeling of textile composites, defect evaluation of non-crimp fabric (NCF) composites with fiber misalignment, and structural analysis of cylindrical shell buckling. Different physical constraints are imposed during the training to reduce the physically inconsistent predictions, minimize the required training data size, and customize the solutions with engineering practices. The second application is to learn unknown physics (e.g., constitutive model) with limited experimental data. A novel hybrid finite element-neural network computational framework is developed to enable training an ANN model with indirectly measurable data. This computational framework removes the requirements of training paired data and therefore many previously unlearnable physical laws can be learned within this computational framework. Moreover, the ANN models are fully constrained by known physics and therefore avoid physically inconsistent predictions. This computational framework has been applied to discover failure criteria of composites, nonlinear constitutive laws, and damage accumulation using limited measurable data.

4:30 PM MD02.02.07

Data-Driven Multiscale Modeling to Predict Full-Body Cutaneous Impact Injuries and to Design Protective Appliques Omar Elsafty, Christopher Berkey and Reinhold Dauskardt; Stanford University, United States

Assessing the behavior of skin damage from impacting debris is challenging due to the high input variability found in impacting projectile type and impact parameters, as well as in human skin anatomy and properties. Here we develop a multiscale approach to evaluate the damage mechanisms in human skin caused by high-speed fragmenting debris through the integration of physics-driven finite element modeling and data-driven machine learning algorithms. We use experimental studies to guide and validate our multiscale model and subsequently use our predictions to direct our topology optimization process for developing protective wearable appliques.

The first step of our multiscale approach involves developing a high-fidelity 3D finite element (FE) damage model of full-thickness human skin under highly dynamic impact conditions [1]. We use this model to quantitatively characterize the damage mechanisms that occur for single projectile impacts under different impact conditions, including a range of impact angles, impact energy, and projectile attributes, such as shape, size, and contact friction behavior with the skin. After validating the model using experimental data, it is then used to analyze the effect of epidermal and dermal layer thickness on injury severity. Two prominent damage mechanisms were derived from our model: epidermal tearing and dermal crushing.

Next, multiscale modeling was used to transition to a multi-projectile analysis, which is an integral part of analyzing multi-particle debris impact. As such, a machine learning (ML) pipeline composed of three multi-class classification algorithms was developed to assess injury severity, which is characterized by evaluating wound area, depth, and shape. After the training and optimization of the model using a 1000+ dataset composed of data generated from FE simulations and experimental results, accuracies of 71.8%, 79.4%, and 77.1% were obtained for the wound area, wound depth, and wound shape, respectively. The ML model was integrated with a multi-projectile full-body model that uses Newtonian physics-based equations to derive the projectile path for each fragment that could be in the vicinity of a human body placed a user-defined distance away from a blast source. This set up was used to investigate the frequency of injury severity and type for different body locations. It was found, for example, that 81.8% of severe injuries to the forearm were generated by epidermal tearing due to a high frequency of low-angled impacts.

The information derived from the multiscale analysis was then used to direct the topology optimization process for the design of protective appliques for the forearm. The optimization process was set up to resist in-plane deformation associated with epidermal tearing. Using periodic boundary conditions in the topology optimization simulations, a zero Poisson's ratio mechanical metamaterial structure with superior shock absorption properties was designed to reduce epidermal tearing-based injuries.

In this work, we demonstrate a multi-method approach to analyze cutaneous injuries caused by multi-projectile blast debris and use the results of the analysis to guide our topology optimization process for the design of a metamaterial protective applique structure for the forearm.

Interfacial Deformation Mechanism of {110} Hexagonal Dislocation Networks in BCC Iron Hadi Ghaffarian and Dongchan Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Deformation mechanism of BCC materials has still gained attention due to the unusual behavior of ½<111> screw dislocations at low-temperature regimes. One peculiar plasticity mechanism in BCC materials is the interfacial mobility of hexagonal dislocation networks (HDNs), which occurs under a very low-stress level. The HDN is usually formed as the evolution of the common {1-10} slip plane under martensitic transformation into the low angle twist grain boundary containing interfacial dislocation structure, known as lath boundary structure [1].

Although the mobility mechanism of HDN has already been investigated via atomistic simulations [2-3], they are confined to a few specific directions under strain-controlled shear deformation mode. Therefore, a rigorous and comprehensive understanding of HDNs is still required to recognize the gliding behavior of HDNs. Hence, this study aims to use the molecular dynamics (MD) simulation method to clarify the interfacial shear deformation behavior of HDN under stress-controlled deformation mode. The energy barrier analysis based on the nudged elastic band (NEB) method is used to address the contribution of geometrical and structural features to the in-plane shearing anisotropy of HDN.

For this goal, six bi-crystalline Fe samples containing HDN interface with $\theta=1-6°$ (misorientation angle) were constructed and subjected to in-plane stress-controlled simple shear deformation at 10 K. Our simulation results reveal the dependency of shear resistance on the direction of applied in-plane shear stress as well as the spatial configuration of the HDN structure. As the θ increases, the shear resistance along the [001] direction ($\tau_{c\text{-}0}$) decreases rapidly while the shear resistance along the [110] direction ($\tau_{c\text{-}90}$) increases gradually, implying that the different shearing mechanisms may exist under loading along the [001] and [110] directions. Our simulation results suggest that the mobility of [001] components serves as an important factor in controlling the HDN motion based on its core-structure energy. The core-structure energy per unit length of [001] dislocations ($E_{[001]}$) decreases as the θ increases with a significant jump from −5.917 eV/Å to −8.633 eV/Å between $\theta = 3°$ and 4°. Therefore, the plasticity mechanism of low-angle HDNs and their associated shear resistance anisotropy can be understood based on the core energy of [001] dislocation.

The interfacial mobility of HDN can be explained based on the kink's migration along the ½<111> dislocations with respect to the projection of applied shear stress along the ½<111> dislocation lines. Under shearing along the [001] direction (τ_0), the kinks move in opposite directions on ½[111] and ½[-1-11] dislocation lines. This migration behavior results in the accommodation of kinks on triple-junction nodes, which leads to extending of [001] segments to preserve the continuity of HDN. The new [001] segment possesses excess energy based on its length and core energy at the given θ. As θ decreases, the $E_{[001]}$ and $L_{[001]}$ (length of [001] segment) rise, developing higher required energy to distort the HDN. On the other hand, for the shearing along the [110] direction (τ_{90}), the kink's migration happens in the same direction on ½[111] and ½[-1-11] dislocation lines resulting in simultaneous extension and dissociation of [001] components at each triple junction pair, which preserves the length of [001] segments as well as the HDN shape. Therefore, the $\tau_{c\text{-}90}$ is lower than $\tau_{c\text{-}0}$ due to preserved HDN structure. The $\tau_{c\text{-}90}$ also shows less variation than $\tau_{c\text{-}0}$ as θ changes due to constant $L_{[001]}$ under shearing along the [110] direction.

8:45 AM *MD02.03.01
Bridging Scales in Materials Science with Machine Learning and Data Science Shyue Ping Ong; University of California, San Diego, United States

Machine learning of the potential energy surface has emerged in recent years as an automatable, robust approach to bridging the quantum and atomistic scale in materials science. In this talk, I will focus on practical applications of machine learning interatomic potentials (ML-IAPs) in materials simulation and design. I will demonstrate that the ability to perform accurate simulations at much larger length and longer time scales can provide new insights into the ionic conduction in superionic conductors for all-solid-state batteries. I will also provide examples of how ML-IAPs have been applied in the study of short range chemical order, dislocation motion and mechanical behavior of refractory multiple principal element alloys.

9:15 AM *MD02.03.02
Automated Data-Driven Upscaling of Transport Properties in Materials Thomas Swinburne[1] and Danny Perez[2]; [1]Centre National de la Recherche Scientifique, France; [2]Los Alamos National Laboratory, United States

Transport properties of complex defects are crucial factors that control the performance of many material systems, e.g., the radiation tolerance of materials for nuclear fusion or fission applications. Characterizing the transport of complex defects is however notoriously tedious and time-consuming, especially as the defects grow, leading to a combinatorial explosion in the number of possible conformations and local transition pathways. We will present a large-scale data-driven approach to automatically obtain reduced-order models of defect evolution, transport coefficients, as well as effective continuum transport equations, from large number of short molecular dynamics (MD) simulations. The optimal MD simulations to carry out are identified on-the-fly using a Bayesian uncertainty quantification framework and automatically executed on a massively-parallel task-execution infrastructure. We show how this microscopic information can be systematically and efficiently upscaled into meso and macro-scale representations that can inform microstructure evolution models.

9:45 AM MD02.03.03
Universal Ion-Transport Descriptors and Classes of Inorganic Solid-State Electrolytes Claudio Cazorla and Cibrán López Álvarez; Universitat Politècnica de Catalunya, Spain

Solid-state electrolytes (SSE) with high ionic conductivities are pivotal for the development and large-scale adoption of green-energy conversion and storage technologies like fuel cells and electrochemical batteries. Yet, SSE are extremely complex materials for which general rational design principles remain indeterminate. Here, we unite materials modelling, computational power and modern data analysis techniques to advance towards the solution of such a fundamental and technologically pressing problem. Our data-driven survey reveals that the correlations between ionic diffusion and other materials descriptors in general are non-linear and largest when the latter are of vibrational nature and explicitly account for anharmonicity. Surprisingly, principal component and k-means clustering analysis show that elastic and vibrational descriptors, rather than the usual ones related to chemical composition and ionic mobility, are best suited for disentangling the high diversity of SSE. Our findings highlight the need of considering databases that incorporate temperature effects to improve our understanding of SSE, and point towards a generalized approach to the design of energy materials.

10:00 AM BREAK

10:30 AM *MD02.03.04
Machine Learning Potential to Study Phase Transition in 2D TMD material Wei Gao; Texas A&M University, United States

In Atomistic simulations, the interatomic potential that describes the interactions of atoms determines the fidelity of simulation results. The main disadvantage of the classical interatomic potentials is that they are limited by the fixed functional forms and small number of fitting parameters. As a result, they may not be able to provide reliable predictions. By contrast, machine learning potentials are not relying on a physical functional form, but must learn the physical shape of the energy surface from the training dataset. Therefore, if the training datasets (which usually come from first principle calculations) cover sufficient physics, a well-trained ML potential is able to provide accurate predictions that are comparable to first principle results.

In this talk, I will present a machine learning potential to study the phase transition in two-dimensional (2D) transition-metal dichalcogenides (TMDs) material, using $MoTe_2$ as a model system. 2D TMDs such as MoS_2, WS_2, $MoSe_2$, and WSe_2 present an unprecedented materials family. These materials promise to open up a new age of atomic-scale technology where devices can be scaled down to the truly atomic level and provide novel functionalities that cannot be obtained with conventional materials systems. One of the remarkable features of 2D TMDC is phase transition. Depending on the atom arrangements, 2D TMDC appears in two distinct stable phases: the 2H and 1T′ phases. These two phases exhibit completely different electronic structures, with the 2H phase being semiconducting and the 1T′ phase metallic. The dynamic control of transitions between these two phases can lead to revolutionary device applications.

11:00 AM MD02.03.05
Training Data Generation for Machine-Learning Interatomic Potentials Aparna P. A. Subramanyam and Danny Perez; Los Alamos National Laboratory, United States

Having flexible functional forms, machine-learning (ML) potentials make it feasible to aim for both accuracy and transferability, something that the earlier generations of potentials struggled to achieve. However, given their flexibility, these potentials often fail at extrapolating to properties beyond the training data, which makes the quality of the training set the determining factor in their performance. Training datasets typically consist of DFT energies and forces of relatively small systems, traditionally selected manually or randomly from subsets of the configuration space of interest. The need for human intervention in the curation of training sets makes their generation labor-intensive and time-consuming. Here, we present a generalization of a previously developed method based on the automated maximization of the information entropy of the descriptor distribution. The method is applied to train ML potentials for W and Be, primary candidates for divertor and first wall material applications in fusion reactors. The transferability of the potentials trained using the entropy-optimized training data is compared to that of traditional curation approaches, highlighting some desirable characteristics of optimal training data irrespective of the chemistry.

11:15 AM MD02.03.06
Application of Machine-Learned Potentials to Accurately Model Polymer Materials Mohammad Atif Faiz Afzal, Shaswat Mohanty, James Stevenson, Andrea Browning and Mathew Halls; Schrödinger Inc, United States

Polymers are widely and increasingly used in a variety of industries, for example, in aerospace, electronics, and automotive. This popularity is due to polymer materials being easy to process and able to make the devices lighter and flexible. Furthermore, we can obtain desirable mechanical and thermophysical properties for specific applications by changing and controlling polymer chemistry. However, the scope of chemical space exploration and testing in an experimental setup is limited. Modeling and simulation of polymer systems provide an accelerated means of characterization and design of new polymer materials. Designing new polymers requires a careful understanding of the interactions between polymers and also with other components in a formulated material. Polymer systems are typically modeled using molecular dynamics (MD) techniques, but using classical force fields in MD has several shortcomings, especially for properties dependent on the polymer chain dynamics. We built scalable and generalizable machine-learned (ML) potentials that accurately capture the dynamics of polymer chains. Using the ML potentials, we can precisely calculate the polymer properties, including dynamical, thermophysical, and mechanical properties. In this presentation, I will present several case studies demonstrating the key benefits of using ML potentials in modeling polymeric materials.

11:30 AM MD02.03.07
Scalable and Generalizable Neural Network Potential for Polymers: Application to Ethylene Glycol and its Oligomers Shaswat Mohanty[1], James Stevenson[2], Andrea Browning[2], Leif Jacobson[2], Karl Leswing[2], Mathew Halls[2] and Mohammad Atif Faiz Afzal[2]; [1]Stanford University, United States; [2]Schrodinger Inc., United States

Developing accurate force fields for studying polymer systems through molecular simulations is of growing interest and use across industries. Understanding and predicting their properties are vital in being able to develop tailored polymer molecules for desired applications. However, classical force fields fail to capture key properties such as the dynamics of a majority of polymer systems. As a potentially scalable solution, we present a charge recursive neural network (QRNN) model trained on DFT calculations made on smaller atomic clusters using the ωB97X-D3BJ/def2-TZVPD theory, that generalizes well to oligomers comprising larger atomic clusters or longer chains.

We demonstrate the validity of the polymer QRNN workflow by modeling the oligomers of ethylene glycol. We apply two levels of active learning and implement a novel model training approach that uses the initial partial charges from a semi-empirical method. Our developed QRNN model for polymers produces stable molecular dynamics (MD) simulation trajectory and captures the dynamics of polymer chains as indicated by the striking agreement with experimental values. The energy landscape predicted by the QRNN model is also demonstrated to be in closer agreement with the reference level theory than the classical MD force field. Our model allows working on significantly larger systems than allowed by DFT simulations, at the same time providing a more accurate force field than classical force fields which provides a promising avenue for large-scale molecular simulations of polymeric systems.

11:45 AM MD02.03.08
Dynamic Responses of Nanoparticle Heterogeneous Catalysts using Machine-Learned Force Fields Cameron J. Owen[1], Nicholas Marcella[2], Yu Xie[1], Anatoly I. Frenkel[3], Boris Kozinsky[1] and Ralph Nuzzo[2]; [1]Harvard University, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]Stony Brook University, The State University of New York, United States

Quantitative understanding and control of interfacial reactions between the gas-phase and solid surfaces are crucial for improving numerous catalysis and energy conversion systems. Examples of these interfacial phenomena include H_2 exchange and CO adsorption on nanoparticles, both of which are important industrial processes and lead to markedly different particle behaviors.

While important for device performance in catalytic applications, these dynamic responses are not quantitatively understood from the atomistic level. Hence, this work demonstrates a collection of robust, Bayesian machine learned force fields (MLFFs) trained with an on-the-fly active learning framework implemented using Gaussian Process regression in the FLARE code to uncover these dynamic phenomena. Molecular dynamics (MD) simulations are used to sample atomic configurations and density functional theory is only called upon when the Bayesian uncertainty exceeds a threshold. The MLFFs retain first principles accuracy, are fast, and are uncertainty-aware. These MLFFs are then used to perform MD simulations for freestanding metal nanoparticle systems, as well as to study reaction mechanisms under gaseous exposure (e.g., H_2 and CO).

Particular emphasis is made on comparison of these simulations to experimental x-ray measurements (e.g., extended x-ray absorption fine structure (EXAFS)), from which the effect of gaseous exposure can be relatively compared across Pt-systems of various length-scales. The method is first benchmarked using bulk-Pt simulations and experimental EXAFS data, and applied to more complicated nanoparticle systems (e.g., Pt_{55}, Pt_{147}, and spanning to much larger particles (> 5nm)) afterwards, as well as extended surfaces. Ultimately, we uncover the atomistic mechanisms driving disparities in particle shape, and reactivity as a function of gaseous exposure, and correlate these dynamic observations to electronic effects inherent in the adsorption of these gasses on the particle surfaces.

Linear Versus Nonlinear Machine Learned Potentials for Transferability and Property Prediction Andrew Rohskopf, Aidan Thompson and Mitchell A. Wood; Sandia National Laboratories, United States

Machine learned potentials have proven useful in molecular modelling, but their construction and deconstruction remain a challenge for many researchers. We therefore created FitSNAP, an extension of the LAMMPS Python interface, to aid in the construction of potentials and then immediately deconstructing, or testing their viability in large-scale simulations, in LAMMPS. We generally approach the molecular machine learning problem by abstracting software components required for calculating descriptors, and then using these descriptors in machine learned models such as linear regression or neural networks. The modularity of these components allows convenient customization, and the various options allow users to find the best descriptor/model combinations for their systems of interest. Seamless integration to LAMMPS ensures a one-to-one agreement with the trained model and its end use in high-performance molecular dynamics simulations. The ability to easily and rapidly prototype different model and descriptor combinations allows for the study of how different models (e.g. linear regression or neural networks) influence accuracy and performance on any dataset.

This talk illustrates the usefulness of rapidly prototyping different machine learning models for interatomic potentials development. We overview linear regression models and the newer addition of rapid force training with general atom-centered neural networks. The latter feature makes use of automatic differentiation frameworks such as PyTorch and JAX to generally approach the atomistic machine learning problem in a performant manner. Finally, we overview the LAMMPS interface to show how we use the final models in LAMMPS simulations, to deconstruct our models and test their viability in their end use.

1:45 PM MD02.04.03
Anharmonic Thermo-Elasticity of Tungsten from Accelerated Bayesian Adaptive Biasing Force Calculations with Data-Driven Force Fields Manuel Athenes, Anruo Zhong, Clovis Lapointe, Mihai-Cosmin Marinica, Alexandra Goryaeva and Jacopo Baima; CEA, France

The elastic properties of tungsten, a ubiquitous material in future energy systems, are investigated up to its melting temperature by means of a data-driven approach. The proposed workflow combines machine learning of the force field and enhanced sampling of the crystalline structure. While the machine learning force field achieves the accuracy of {\it ab initio} calculations, its implementation in sampling methods is often limited due to its high computational cost, which is commonly a few orders of magnitude larger than that of traditional potentials. To overcome this limitation, we propose a fast and robust Bayesian sampling scheme aiming at estimating the fully anharmonic free energy of crystalline solids with the help of an improved adaptive biasing force method. This method performs a thermodynamic integration from a harmonic reference system, wherein zero frequencies associated with the periodic boundaries are screened off. The proposed sampling method drastically improves the speed of convergence and overall accuracy. We demonstrate the efficiency of the improved method by calculating the second order derivatives of the free energy, such as the elastic constants, which are performed almost 100 times faster than with the standard methods. The proposed method enables the prediction of the elastic properties of tungsten in the range of temperatures that cannot be investigated experimentally, from 2\,100 K to the melting temperature. Accuracy and numerical efficiency of the proposed strategy open up many avenues for the reliable predictions of finite-temperature properties of materials, like the relative stability of structural defects, elastic constants, etc.

Enabling Long Timescale Molecular Dynamics Simulation with *Ab Initio* Precision Jan Janssen and Danny Perez; Los Alamos National Laboratory, United States

Classical molecular dynamics (MD) is in principle an ideal tool to investigate the long-time evolution of materials, as ab initio-based MD simulations remain limited to very short time. While modern machine learning MD potentials report errors on the order 1 meV/atom, these errors are only typical of configurations that are similar to those found in the training set used to fit the potential, and transferability to genuinely new configurations remains limited. This poses a challenge to the accuracy of long-time MD simulations for two reasons: i) transition rates are exponentially sensitive to energy barriers, and ii) saddle configurations form a very small subset of the whole configuration space and so are very unlikely to appear in traditional hand-crafted datasets, or even as part of conventional active-learning approaches based on MD.

We propose a large-scale automated workflow to develop and validate transferable machine learning potentials for long-time simulations. Starting from an information-entropy optimized training set with over 7 million atomic environments, fitted potentials are benchmarked on a very large set of transition states to characterize their transferability. We also assess different practical strategies for enriching the training set so as to improve the accuracy for long-timescale simulations. The workflow is developed using the pyiron integrated development environment for computational materials science and executed with the Exaalt infrastructure.

A Multi-scale Percolation Model of Initial Passivation of FCC Binary Alloys John D. Cavin[1], Alex Tai[1], Ian McCue[1], Karl Sieradzki[2] and James M. Rondinelli[1]; [1]Northwestern University, United States; [2]Arizona State University, United States

Corrosion costs $2.5 trillion globally, which is equivalent to roughly 3.4% of the world's gross domestic product. The susceptibility of an alloy to corrosion depends on its ability to form a thin, protective layer, often an oxide, that prevents electrochemical degradation of the metal in its environment. In aqueous environments, for example, corrosion is primarily mediated by the electrochemical dissolution of metal ions at the anodic regions of local-action galvanic cells. Designing alloys that better protect against corrosion requires a deeper understanding of the interplay of oxidation and dissolution that occurs in the initial stages of passive oxide formation. Beyond the establishment of an initial oxide layer, these processes are also critical for the "self-healing" nature of corrosion resistant alloys that allow them to reform protective oxides if local abrasion exposes the underlying alloy. Recent work has shown that percolation theory can be used to gain a deeper understanding of the compositional dependence of corrosion resistance in BCC and FCC, Fe-Cr and Ni-Cr alloys [1]. Utilizing percolation theory to build predictive models, requires determining the connectivity of chromium oxide networks after selective dissolution of iron. In this work, we study the Cu-Rh system as a use case for FCC binary alloys, where Cu selectively dissolves. Using first-principles calculations of Cu-Rh supercells, we trained cluster expansion models that can be used to quickly determine the energies of large-scale alloy models. We then use to Monte Carlo methods with these cluster expansions to obtain thermodynamic ensembles to analyze short-range order in the Cu-Rh system and to study the connectivity of Rh oxide networks in the context of percolation theory. Additionally, preliminary results on training machine learning interatomic potentials to predict transition barriers to perform adaptive kinetic Monte Carlo simulations of the dissolution and oxidation process are discussed. We conclude by comparing our results in FCC binary alloys to available experiments.

Regression-Based Projection for Learning Mori–Zwanzig Operators Yen Ting Lin, Yifeng Tian, Danny Perez and Daniel Livescu; Los Alamos National Laboratory, United States

More than half a century ago, Mori and Zwanzig (MZ) developed a mathematically rigorous formalism for constructing reduced-order models for dynamical systems using functional projection operators. Formally, a pre-specified projection operator is used to map any function which depends on both resolved and unresolved variables to a function that only depends on the resolved variables. As the latter does not depend on unresolved information, one can then prescribe a set of evolutionary equations for the resolved variables. Theoretically speaking, there are infinitely many choices of the projection operators. Several recent studies have established that with Mori's linear projection operator, it is possible to adopt a data-driven approach to learn the MZ operators using the time series of the resolved dynamics. We also showed in a recent study (Lin et al., SIAM Applied Dynamical Systems, 2021) that these methods provide higher-order and memory-dependent corrections to existing data-driven learning of the approximate Koopman operators.

In this talk, I will present our latest proposition of using regression analysis to define the projection operators, and a data-driven method for learning the associated MZ operators using time-series data. Interestingly, the resulting algorithm is very similar to statistical boosting, but with an intuitive structure prescribed by the MZ theory. We identified that the proposed learning is identical to our published method for Mori's linear projector, when the projector is defined by a linear regression. The newly proposed method can be considered as a generalization of the previously proposed one because it is not restricted to linear regressions. As we gradationally increased the complexity of the regression models (linear, polynomial, spline, to neural networks), we observed a consistent improvement of the learned reduced-order models on a few test examples. We still observed considerable improvements by including the MZ memory effect in these nonlinear projections, justifying the necessity of accounting for the past histories of under-resolved systems. We believe that the proposed method for learning MZ operators is promising because it is applicable to most data-driven methods (e.g., approximate Koopman and SINDy) for learning dynamical systems.

Progress in Equivariant Deep Learning Interatomic Potentials—Allegro and NequIP Albert Musaelian[1], Simon Batzner[1], Anders Johansson[1], Lixin Sun[1], Nicola Molinari[1], Cameron J. Owen[1], Mordechai Kornbluth[2] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch LLC Research and Technology Center, United States

The utility of atomic-scale simulation of materials systems can be greatly expanded by machine learning interatomic potentials (MLIPs), which use small numbers of computationally expensive quantum chemistry calculations to enable simulating larger length- and time-scales than those quantum methods can achieve alone. A central challenge in such efforts is building model architectures that respect the symmetries of the underlying physics, namely permutation of atoms, rotation, translation, and inversion.

This talk discusses recent progress, both in methods and applications, with Allegro and NequIP, our "E(3)-equivariant" machine learning architectures for MLIPs. Most existing MLIPs respect the invariance of the true potential energy to symmetry transforms like rotations by operating only on already invariant scalar input encodings such as distances, angles, or even systematic basis expansions. Our models, in contrast, operate directly on 3D geometry: their inputs, internal latent representations, and predictions can contain not only scalars, which are invariant under symmetry transformations of the input, but also "equivariant" geometric vectors and higher-order tensors, which transform correspondingly when the input is transformed. This approach yields remarkable real-world improvements in accuracy, geometric and chemical extrapolation, simulation stability, and data efficiency as demonstrated in organic molecules, ionic liquids, catalysts, biomolecules, and other systems. Finally, the Allegro model further enables scaling these desirable traits to simulations at large very length-scales and high speeds.

Proper Orthogonal Descriptors for Complex Chemical Systems Ngoc-Cuong Nguyen[1], Andrew Rohskopf[2], Dionysios Sema[1] and Yeongsu Cho[1]; [1]Massachusetts Institute of Technology, United States; [2]Sandia National Laboratories, United States

We present the proper orthogonal descriptors for efficient and accurate interatomic potentials of multi-element chemical systems. The potential energy surface of a multi-element system is represented as a many-body expansion of parametrized potentials which are functions of atom positions, atom types, and parameters. Proper orthogonal decomposition is employed to decompose the parametrized potentials into a set of orthogonal basis functions. The orthogonal basis functions are used to construct proper orthogonal descriptors based on the elements of atoms, thus leading to multi-element descriptors. For a system of M elements, the number of multi-element proper orthogonal descriptors increases as M^3, while the computational cost is independent of M. We compose the multi-element proper orthogonal descriptors to develop two different interatomic potentials. The first potential expresses the energy of each atom as a linear combination of proper orthogonal descriptors, while the second potential expresses the energy as a linear and quadratic combination of the descriptors. The second potential is shown to provide a significant increase in accuracy relative to the first potential, while having the same computational complexity as the first potential. The POD potentials are demonstrated on a wide variety of materials including InP, GaN, TiO2, HfB2, and HfO2, and compared with the spectral neighbor analysis potential (SNAP), atomic cluster expansion (ACE), Allegro potentials, as well as DFT calculations and experiments.

Uncertainty Aware Active Learning of Coarse Grained Free Energy Models Blake Duschatko, Jonathan Vandermause, Nicola Molinari and Boris Kozinsky; Harvard University, United States

Coarse graining techniques play an essential role in accelerating molecular simulations of systems with large length and time scales. Theoretically grounded bottom-up models are appealing due to their thermodynamic consistency with the underlying all-atom models. In this direction, machine learning approaches hold great promise to fitting complex many-body data. However, training models may require collection of large amounts of expensive data. Moreover, quantifying trained model accuracy is challenging, especially in cases of non-trivial free energy configurations, where training data may be sparse. We demonstrate a path towards uncertainty-aware models of coarse grained free energy surfaces. Specifically, we show that principled Bayesian model uncertainty allows for efficient data collection through an on-the-fly active learning framework and open the possibility of adaptive transfer of models across different chemical systems. Uncertainties also characterize models' accuracy of free energy predictions, even when training is performed only on forces. This work helps pave the way towards efficient autonomous training of reliable and uncertainty aware many-body machine learned coarse grain models.

A First Principles Approach to Spectral Phonon Transport in Heterostructures Jackson R. Harter[1], Cameron Chevalier[2] and Alex Greaney[2]; [1]Idaho National Laboratory, United States; [2]University of California -- Riverside, United States

Understanding thermal transport across interfaces which give rise to a thermal resistance (also known as Kapitza resistance) is a critical issue affecting the development of nanotechnologies. Much modern and emergent nanotechnology consist of adjacent materials, and phonon mediated heat transfer governs thermal behavior across internal interfaces in these devices. The physics of thermal transport in solids are governed both by phenomena occurring at the atomic scale and interactions with the material's microstructure. The forecasting of fundamental quantities such as temperature, heat flux and thermal conductivity typically employs the semi-classical Boltzmann transport equation to predict the macroscopic behavior of materials in terms of the microscopic dynamics of its heat carriers.

Kapitza resistance was first discovered in liquid helium experiments and has led to a fundamental research thrust in micro and nano-scale heat transport, the behavior of thermal carriers across internal interfaces. Thermal interfacial resistance (TIR) is a widely studied phenomenon, first engaged by Swartz and Pohl through their development of the acoustic and diffuse mismatch methods, then continued through myriad efforts with varying methods and approaches in an attempt to resolve carrier behavior at thermal interfaces.

Many of the fundamental approaches to TIR have been at the nanoscale, and research is conducted with molecular dynamics (MD) and density functional theory (DFT) methods. The limitations of these methods is system size; atomistic methods tend to be limited to system sizes of 100,000 atoms or less. Larger length-scale methods have also been pursued, based on the principles of acoustic or diffuse mismatch, but not all include simulation of TIR using a full phonon band spectrum, or temperature dependent methods.

Our approach to enabling phonon transport in layered materials draws upon our previous work of demonstrating spectrally coupled phonon transport in homogeneous and heterogeneous materials. We use a semi-analytical approach in which the Bose-Einstein (B-E) statistics set the strength of the phonon radiance in a frequency group, but the B-E statistics are informed with information from the transport system. The B-E statistics in a single frequency group feels the influence of all the groups through the spatial temperature. We also include a new field term which is an indicator of the amount of non-equilibrium behavior of the phonon spectrum---this is added to the phonon source term in all groups to ensure closure and conservation of energy, as the phonon groups in the transport system and the analytical systems are coupled.

This work builds upon our previous approach by adding a phonon coupling term at an internal interface, using the principles of the DMM through transmission and reflection coefficients. In this work, the coefficients are determined through computing a common temperature at the interface, influenced by the phonon band structure of both materials, in effect, providing mixing between the two material systems and using the common temperature to set the strength of the phonon radiance at the boundaries on either side of the interface. Our approach uses material properties computed along various crystallographic orientations, and while some isotropy is built into the interface condition, the material properties weight the phonon distributions in the proper crystalline direction. Geater resolution of phonon behavior in proximity to an interface, and more accurate predictions of TIR are obtained. While it is true the assumption of diffuse mismatch can yield inconsistent results compared to experiment especially at low temperatures, this work focuses on room temperature and beyond effects, for future applications in nuclear fuel, or thermoelectric devices; a modified mismatch approach may be feasible if applied properly. Additionally, our methods focus on bridging mesoscale to engineering scale.

SESSION MD02.05: Materials Design I
Session Chairs: Soumendu Bagchi, Victor Fung, Jan Janssen and Haoran Wang
Thursday Morning, April 13, 2023

Graph Neural Networks for Materials Chemistry Victor Fung; Georgia Institute of Technology, United States

Graph neural networks (GNNs) are a rapidly expanding class of machine learning models with exceptional potential for materials chemistry problems across a wide range of spatial and time scales. A key strength in GNNs lies in their high expressivity and capacity for learning from large datasets over traditional feature engineering approaches in the materials sciences. Here, we develop a GNN-based software platform, MatDeepLearn, which offers broad customizability in data processing, model construction, hyperparameter selection and post-processing for materials informatics applications. In particular, we show the importance of the large hyperparameter space offered by the MatDeepLearn framework towards obtaining high performance in materials property predictions. We also demonstrate the viability of GNNs for the prediction of atomistic to macroscopic quantities, and across a large range of applications, including in catalysis, gas capture, and for molecular dynamics.

Artificial Intelligence Assisted Gas Diffusion Electrode Development for Carbon Dioxide Reduction Sang-Won Lee[1,2], Bjørt Joensen[1,3], Joel Jenny[1,4], Dong Un Lee[1] and Thomas Jaramillo[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Technical University of Denmark, Denmark; [4]Swiss Federal Institute of Technology Zurich, Switzerland

Intergovernmental panel on climate change (IPCC) presented the 6th IPCC report that the temperature of Earth is likely to exceed the 1.5 °C rise. The IPCC forecasts 2025 will be the tipping point at which greenhouse gas emissions must turn to a decreasing trend, otherwise preventing global warming after 2030 below the 2 °C limit will be difficult. We are coming to the point where we must not only switch to renewable energy, but also remove already emitted greenhouse gases.[1]
Electrochemical carbon dioxide (CO_2) reduction has been investigated since 1980s-1990s as a promising greenhouse gas elimination method. The activity of CO_2 reduction in aqueous electrolytes is far lower than economically viable minimum. The low solubility (< 30 mM) and diffusivity of CO_2 in aqueous electrolyte limits reduction current approximately to 30 mA in ambient condition. The fact that the majority of feedstocks in the real world of greenhouse gases are in the gaseous state has also fueled technological innovation. [2]
The gas diffusion electrode (GDE) emerged to address this problem and enable current densities a few orders of magnitude higher than planar electrode.

The development of GDEs has been investigated by applying materials with various properties, such as porosity, hydrophobicity, mechanical strength, and conductivity. However, the complex GDE structures and various roles of each layer in GDEs cause difficulties in theory-based development of the optimal GDE.
In order to overcome the aforementioned complexities of developing the optimal GDE, this study focuses on utilizing a structure data-based machine learning to optimize the structures in the GDEs. Imaging of GDEs can be performed using characterization techniques such as scanning electron microscopy and commutated tomography to obtain the structural information.[3] Relationship between CO_2 reduction performance and structural characteristics of GDEs are used as training data for 3D convolutional neural network. AI unsupervised learning, such as Affinity Propagation and MiniBatch k-Means cluttering, are utilized to reveal unknown GDE design parameters.
We provided method for dealing with complexities involved in the GDE development through 3D structure information measurements, segmentation, learning and clustering. The method presented in this study can be applied not only to the development of GDEs for electrochemical CO2 reduction but also to many other applications in the energy fields.

Data Science-Driven Bulk Electronic Structures Descriptors in Cubic Perovskite Oxides for Oxygen Evolution Reaction Activity Oguzcan Dedeci, Cigdem Toparli and Irmak Sargin; Middle East Technical University, Turkey

The discovery of new materials has been accelerated using machine learning in electrocatalysts in which the main performance criterion is the work function of oxides. It is possible to predict the work function and reveal quantitative information regarding its dependence on the structure by machine learning models. However, the experiments and calculations required to obtain the work function are costly and challenging. As a result, many descriptors based on geometry and bulk electronic structure have been offered for predicting the work function of new compositional candidates, especially for the perovskite oxide family. Among many alternatives to replace noble metals in electrocatalytic applications, perovskite oxides have been extensively studied, and promising candidates have been suggested from this class of materials for better performance. However, due to their complex electronic and crystal structure, a generally applicable descriptor to cover all possible compositional candidates is still lacking. The compositional dependence of the relationship between the most frequently used bulk electronic structure descriptor, O2p band center, and work function limits its use, verifying the need for a new descriptor. Consequently, the lack of such a descriptor is the barrier to the accelerated discovery of new simple and complex compositions by machine learning. In this study, we have investigated the potential of new bulk electronic structure descriptors for characterizing the work function of the BO_2-terminated surfaces in cubic perovskite oxides using a dataset from the scientific literature, including 583 different simple perovskite compositions with 26 different A-site and 23 different B-site elements. We have first identified the bonding-related reasons that cause the composition dependence of the relationship between the O2p band center and work function by univariant exploratory data analysis. The bonding-related features that cause the compositional dependency are electronegativity, ionicity, covalency, ionization energy, valence orbital energy, orbital radii, band-filling, bond hybridization, and charge distribution. We have generated several new descriptors by combining these features with the O2p band center in varying mathematical forms. A new descriptor that is a function of O2p band center, valence orbital energy, d-orbital radii, bond hybridization, and charge distribution has been found to have a Pearson correlation coefficient of 0.82 with the work function that is 30% higher than the previously suggested and widely used bulk electronic structure descriptor O2p band center. The strategy suggested here is exemplified for the cubic perovskite oxides with a definite surface termination; however, it is general enough for application to other crystals and surface terminations as well as other materials and application areas showing the strength of combining data science with domain knowledge.

9:30 AM MD02.05.04
Deep Learning of Multi-Component Cathode Electrochemistry from Experiments Peichen Zhong[1,2], Bowen Deng[1,2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Disordered rocksalt materials are the most promising earth-abundant cathode materials for Li-ion batteries, and as such can enable scaling of Li-ion energy storage to many TWh/year production. However, the computational modeling for DRX is difficult as such modern battery materials can contain a large number of elements with substantial site disorder.

Instead of approaching from *ab-initio* modeling, we will demonstrate a novel approach to the modeling and prediction of electrochemistry (discharge voltage profile) of DRX materials. We applied a deep neural network (DNN) trained directly on a large amount of experimental results. The DNN is trained with an end-to-end learning scheme, that includes the redox information appropriately regularized. The DNN can interpolate and make predictions for compounds that have not yet been tested, which can accelerate the exploration of DRX and other electrode materials.

9:45 AM MD02.05.05
Ternary Oxides of Pre- and Post-Transition Metals for Photocatalytic Solar-to-Hydrogen Conversion Simon Gelin[1], Nicole Kirchner-Hall[1], Rowan Katzbaer[1], Monica Theibault[2], Yihuang Xiong[1], Matteo Cococcioni[3], Iurii Timrov[4], Quinn Campbell[5], Hector Abruna[2], Raymond Schaak[1] and Ismaila Dabo[1]; [1]The Pennsylvania State University, United States; [2]Cornell University, United States; [3]University of Pavia, Italy; [4]Ecole Polytechnique Federale de Lausanne, Switzerland; [5]Sandia National Laboratories, United States

Green hydrogen produced via photocatalysis is a promising sustainable energy source. However, many of the known water-splitting photoactive semiconductors are costly or of low efficiency due to their high electronegativity which impedes the transfer of electrons from the catalyst to chemisorbed/hydrated protons. To address this issue and expand the list of known water-splitting photocatalysts, we build on previous studies [1,2] which showed via data-intensive screening that inserting pre-transition (s-block) metals in binary metal oxides can lower electronegativity while maintaining appealing light absorption properties. Starting from a family of post-transition (p-block) metal oxides used in optoelectronics, we analyze how adding pre-transition metals in these materials impacts the electronic couplings between their constituents and may improve their photocatalytic properties. Then, we screen 109 of these ternary metal oxides using band gaps and band edges predicted at both the semilocal DFT and DFT+U levels of theory. Pourbaix diagrams are also used to assess the stability of the materials in water. Based on the screening protocol, we identify seven ternary oxides among which two appear to not have been previously proposed as water-splitting photocatalysts.

Design of High-Entropy Hydrides for Reversible Hydrogen Storage Vitalie Stavila, Matthew Witman, Sapan Agarwal and Mark Allendorf; Sandia National Laboratories, United States

Hydrogen is a promising energy carrier that can be produced with zero-carbon emissions and is expected to play a key role in future energy systems. However, storage and transportation of hydrogen in a safe and cost-effective way is challenging. One promising method is to store hydrogen in a solid metal hydride; compared to high-pressure hydrogen storage, the metal hydride technology offers potential safety advantages (due to low pressure operation), with the additional benefit of higher volumetric density. We developed a machine learning approach to design high entropy alloys (HEAs) with a high hydrogen-to-metal ratio and tunable equilibrium plateau pressures. We used a gradient boosting tree approach combined with SHapely Additive Predictions (SHAP) to elucidate simple physics-based design rules that dictate the thermodynamic properties of metal hydrides, then employed these models to screen HEA hydrides across a large compositional space (>21,000 distinct candidate compositions). We demonstrated how feature importance uncovers the strong dependence of the metal hydride equilibrium H_2 pressure on a volume-based descriptor that can be computed from just the elemental composition of the alloy material. This in turn permitted rational targeting of high-hydrogen capacity HEAs by their descriptor values. We used high-energy ball milling and arc melting approaches to synthesize dozens of HEA materials which cover a wide range of pressure and temperature regimes for reversible hydrogen uptake and release. The HEA materials were characterized by X-ray diffraction, scanning and transmission electron microscopy, and X-ray photoelectron spectroscopy. Hydrogen storage properties were measured using the Sieverts techniques, and Pressure-Composition-Temperature measurements were used to determine the enthalpy and entropy of hydrogen uptake and release in the case of most promising HEAs. We show that frustrated chemical environments found in HEA materials composed of 4-, 5-, or 6- different atom types lead to important changes in the thermodynamics and kinetics of chemical processes, which can be leveraged for sustainable hydrogen storage applications..

Data-Driven Learning and Interpretable Model Reduction of Chemical Reaction Networks Qian Yang[1], Carlos A. Sing-Long[2], Enze Chen[3] and Evan Reed[4]; [1]University of Connecticut, United States; [2]Pontificia Universidad Católica de Chile, Chile; [3]University of California, Berkeley, United States; [4]Stanford University, United States

Complex reactive chemistry such as that occurring in catalytic systems and energetic materials are complicated nonlinear dynamical systems that are difficult to model and interpret. While *ab initio* molecular dynamics (MD) is a key computational method that can be used to interrogate reactive chemistry, many challenges remain due to its computational limitations in time and length scales. In this talk, we will first discuss how it is possible to use the wealth of data generated by a few expensive MD simulations to statistically learn fast kinetic Monte Carlo (KMC) models of chemical reaction networks. Our KMC models can not only extrapolate the behavior of the chemical system by as much as an order of magnitude in time, but can also be used to predict the dynamics of entirely different chemical trajectories. With this framework, one can imagine a future where MD data will be routinely archived to form a "chemical genome" that can be used to quickly simulate new chemical systems. Second, we will consider the question of how to build reduced models of these chemical reaction networks, both to build understanding and to accelerate simulations. We have developed a data-driven method utilizing L_1-regularization for model reduction of nonlinear dynamical systems, which can handle large-scale systems with as many as thousands of reactions in a matter of minutes. Our method uses minimal parameterization and produces a family of reduced models that exhibit a trade-off between model complexity and estimation error. Finally, we will conclude with a discussion of how machine learning can be used to adaptively reduce the reaction network under different initial conditions and enable long-time scale extrapolation of reduced-order models. Our methods can be easily interfaced with existing simulation software to enable automatic, interpretable reduced-order modeling of complex reactive chemistry.
