Soft materials are ubiquitous in nature and everyday life. The first part of the talk is focused on a general strategy to design soft materials possessing extreme properties. The second part of the talk is specifically focused on the toughening of soft materials. The ratio between fracture toughness and intrinsic fracture energy of a soft material defines its toughness enhancement. Soft materials' toughness enhancement has been long attributed to their bulk stress-stretch hysteresis induced by dissipation mechanisms such as Mullins effect and viscoelasticity. With a combination of experiments and theory, here we show that the bulk dissipation mechanisms significantly underestimate the toughness enhancement of soft tough materials. We propose a new mechanism and scaling law to account for extreme toughening of diverse soft materials. We show that the toughness enhancement of soft materials relies on both bulk hysteric dissipation, and near-crack dissipation due to mechanisms such as polymer-chain entanglement. Unlike the bulk hysteric dissipation, the near-crack dissipation does not necessarily induce large stress-stretch hysteresis of the bulk material. The extreme toughening mechanism can be universally applied to various soft tough materials, ranging from double-network hydrogels, interpenetrating-network hydrogels, entangled-network hydrogels and slide-ring hydrogels, to unfilled and filled rubbers.

Designing Gels to Absorb Impact—How a Thin Gel Can Protect an Egg from Breaking Mahima Srivastava[1], Sairam Ganesh[1] and Nikhil Subraveti[2,1]; [1]University of Maryland, United States; [2]Princeton Center for Complex Materials, United States

In recent years, several routes have been devised to make hydrogels that are strong, flexible and bendable, with prominent examples being the double-network hydrogels. This work investigates whether such strong and flexible gels can absorb impact. That is, can such a gel be wrapped around a brittle or fragile object (such as an egg) and protect the object if it is dropped onto a hard surface. We have studied a range of gels, including gels made by either physical cross-linking (e.g., gelatin) or chemical cross-linking (e.g., acrylamide, AAm) or both (double network gels of AAm and alginate). None of these bare gels are able to absorb impact. We also studied the same gels with various particulate additives, including iron-oxide, carbon-black, and graphene: again, none of these particles improve the protective abilities of the bare gels.

The central result from our work is that the addition of starch granules greatly enhances the protective abilities of any gel. This is observed both with gelatin and AAm gels. When a load strikes a gel containing 20% starch, the peak impact force is reduced by 25% when compared to a bare gel without the starch. Correspondingly, the coefficient of restitution (COR) is also lowered by the presence of starch (i.e., a ball bounces much less on a starch-bearing gel). An egg covered with a starch-bearing gel survives impact on a hard surface from a height of 25 inches. Similarly, a blueberry covered with the gel resists being crushed when a weight is dropped on it.

We correlate the impact-absorbing effects of starch granules to their ability to shear-thicken water. When starch granules are gelatinized by heat, they no longer give rise to shear-thickening, and in turn, their protective ability in a gel is also eliminated. Our research can guide the rational design of protective coatings or armor for fragile objects, which could be applied in the sports, defense, and consumer sectors.

A Multiscale Model for Reversible, Thermally Activated Chain Scission and Healing in Polymer Networks and Interfaces Rui Huang; The University of Texas at Austin, United States

Rate-dependent fracture and healing have been observed for many polymer networks and interfaces. Here, we propose a multiscale approach to modeling reversible chain scission as a mechanism for rate-dependent fracture and healing, considering the energetics of bond stretching, the entropic effect of long molecular chains, the kinetics of thermally activated chain scission, and the statistical distributions of chain lengths. These multiscale features are seamlessly assembled to formulate a rate-dependent model, linking the macroscopically measurable properties (e.g., toughness and strength) to the underlying molecular structures of the polymer network, while the rate dependence results naturally from the kinetics of damage evolution as a thermally activated process. Through this model we seek to answer the following questions: (1) What is the enery barrier for the thermally activated chain scission, and how does it change with continuous loading or deformation? (2) Under what conditions can the broken chains heal? (3) Can such a model simulate a dynamic polymer network under cyclic loading?

Molecular Stiffness Cues of Interpenetrating Hydrogel Networks for Cell Adhesion Bin Li, Arzu Colak, Johanna Blass, Mitchell Han, Aránzazu del Campo and Roland Bennewitz; Leibniz Inst for New Materials, Germany

The response of cultured cells to the mechanical properties of hydrogel substrates depends ultimately on the response of single crosslinks to external forces exerted at cell attachment points. We performed single-molecule force spectroscopy experiments using AFM to probe the mechanics of single cross-links which mediate the cell attachment and spreading. We compared hydrogels of varying elastic modulus which exhibited significant differences in fibroblast spreading and derived an effective spring constant for the displacement of single cross-links at the hydrogels' surface. A factor of ten in the elastic modulus E of the hydrogel corresponded to a factor of five in the effective spring constant k of single crosslinks, indicating a transition in scaling with the mesh size ξ from the macroscopic $E \propto \xi^{-3}$ to the molecular $k \propto \xi^{-2}$ [1].
We also prepared an interpenetrating network (IPN) design based on a stiff PEGDA host network interlaced within a soft 4-arm PEG-Maleimide/thiol (guest) network. The IPN presents different mechanical cues at the molecular scale, depending on which network is linked to the probe, but the same mechanical properties at the macroscopic length scale as the individual host network. Cells attached to the interpenetrating (guest) network of the IPN or to the single network (SN) PEGDA hydrogel modified with RGD adhesive ligands showed comparable attachment and spreading areas, but cells attached to the guest network of the IPN, with lower molecular stiffness, showed a larger number and size of focal adhesion complexes. The observations indicate that cell adhesion to the IPN hydrogel through the network with lower molecular stiffness proceeds effectively as if a higher ligand density is offered [2].

10:15 AM SB07.04.05
Effect of Crosslink Homogeneity on the High Strain Behavior of Elastic Polymer Networks Victoria Kong and Jennifer Laaser; The University of Pittsburgh, United States

The topology of polymer networks affects critical material properties such as elastic modulus and toughness. While the effects of crosslink homogeneity and topological defects are well understood in low strain regimes, quantifying their effects in the high strain regime has proven difficult because of premature network fracture. Here, we address this problem using a double network approach, in which the network of interest is swollen in a mixture of monomer and crosslinkers that is then polymerized to generate a secondary network that helps dissipate stress. We examine the effect of crosslink homogeneity by comparing the low and high strain behaviors of randomly and regularly crosslinked butyl acrylate networks. Regularly crosslinked networks are synthesized via coupling of n-butyl acrylate star polymers, while randomly crosslinked networks with comparable moduli are synthesized by free-radical polymerization. We find that the randomly crosslinked networks exhibit a much earlier onset of non-Gaussian strain stiffening behavior than the comparable regularly crosslinked networks, indicating the importance of strand length distribution, and particularly the shortest strands, in determining the high strain behaviors of elastic polymer networks.

WITDRAWN (NO SHOW) 5/5/23 SB07.04 Design Rationale for Polymer Networks—From Stimuli Responsive Hydrogels to Dual-Cure 3D Printable High Performance Polymers Xiao 'Matthew' Hu; Nanyang Technological University, Singapore

This presentation aims to discuss the design rationale of a class of thermally responsive semi-IPN hydrogels and a series of photo and thermal dual curable liquid monomers that are fit for high resolution precision 3D printing via projection micro-stereolithography (PμSL), leading to 3D printed polymers that are of high strength, stiffness and glass transition temperatures. In the former case, systematic investigation was carried out and discussed on how swelling and deswelling ratios and their kinetics are uniquely tunes and controlled in these stimuli responsive semi-IPN hydrogels. Furthermore, the semi-IPN structure turns out to be ideal for surface deposition of highly robust and conformal polyamide layers onto these hydrogels via interfacial polymerization. In the latter case, the discussion focuses on design dual cure high Tg and high strength polymer networks. Their photo curability and low monomer viscosity allow high resolution stereolithography 3D printing to be readily carried out via a free radical polymerization. Their subsequent thermal curability allows the formation of an extra network via a ring opening reaction. Although unlike the reported double-network systems, these dual network structure endows these polymers with not only extra-robustness such as thermal resistance, high strength and stiffness, but also intrinsic flame resistance among other attributes. Both polymer systems have potentials for various functional and engineering applications.

Shape-Morphing Liquid Crystal Elastomer-Based Tissue Adhesives Mahjabeen Javed, Yoo Jin Lee and Taylor H. Ware; Texas A&M University, United States

Current tissue adhesives for wound management face ongoing challenges and limitations such as insufficient adhesion strength to soft and wet tissue and poor mechanical properties. Chemical-based adhesives, such as cyanoacrylates, provide high bond strength but can elicit an inflammatory response due to toxic monomers. Alternatively, mechanical systems are commercially available for clinical applications, such as sutures and staples, but these approaches can cause excessive penetration trauma. Recently, microneedle (MN) array adhesives have been developed. These mechanical adhesives offer enhanced tissue adhesion while reducing trauma and clinician time. We are developing shape-morphing liquid crystal elastomer (LCE) based microscale tissue adhesives, capable of providing strong fixation to soft and wet tissue through mechanical interlocking. The key advantage of this approach is that we can create sub-millimeter scale polymeric structures with controlled forms that can be used as MN adhesives. We employ thiol-ene click chemistry to synthesize liquid crystal elastomers capable of crystallizing after polymerization. The combination of liquid crystallinity and semicrystallinity enables these microneedles to not only exhibit large and programmable deformation strain but also high elastic modulus and toughness. Directed self-assembly is used to spatially pattern the molecular orientation of the material prior to crosslinking. This orientation dictates the shape of the polymer at body temperature. In this manner, flat sheets are able to morph into their programmed out-of-plane bent state when released from the underlying glass carrier without requiring an external stimulus. These curved needles are then inserted into the model tissue of interest. The relationship between microneedle curvature and adhesion will be discussed. The semicrystalline LCE-based MN arrays have sufficient strength to first be able to puncture and then mechanically adhere to both agarose tissue model as well as chicken tissue. The maximum pull-out force of an LCE-based microneedle is 9.6 ± 0.9 mN force per needle in an agarose tissue model. We expect that by leveraging this class of stimuli-responsive polymers, we can enable microneedle arrays to provide a safe and effective strategy for high-strength tissue adhesion.

1:45 PM SB07.05.02
Color and Shape-Switchable Biocatalytic Liquid Crystal Elastomers Responsive to Multiple Classes of Biomolecules Albert Velasco Abadia, Grant E. Bauman, Timothy White, Daniel K. Schwartz and Joel L. Kaar; University of Colorado Boulder, United States

The incorporation of enzymes into stimuli-responsive materials has the potential to sensitize their response to specific biomolecules, providing unique materials for applications such as coatings, smart textiles, drug delivery, or sensing. Among stimuli-responsive polymers, liquid crystal elastomers (LCEs) have emerged as a leading actuator platform due to their inherent programmability, realizing shape transformations and large strains upon exposure to stimuli. The immobilization of enzymes in LCEs presents an unprecedented opportunity to create polymers that undergo shape reconfigurations in response to specific biosignals. In this presentation, we will discuss the immobilization of the enzymes *Candida rugosa* lipase, glucose oxidase, and trypsin into acid-responsive LCEs. This imparted the LCEs with sensitivity to chemical signals that belong to different major classes of biomolecules, such as carbohydrates, lipids, or peptides. Enzyme-containing LCEs doped with methyl red readily switched color from yellow to red upon exposure to their enzymatic substrate. Multiple processing methods, such as twisted nematic patterning or 4D printing, were used to showcase the versatility of biocatalytic LCEs, which transformed from flat films or disks into curls or cones, respectively. Multiplexed responsiveness was demonstrated using a connected array of disks, each containing a different enzyme, highlighting the excellent chemical selectivity of enzymes. This work presents a novel platform of versatile bioresponsive color-switchable actuators that may have application in a wide range of biological fields.

2:00 PM SB07.05.03
Mussel-Inspired Strain-Responsive Adhesive Microcapsules for Self-Regulatable Antibacterial Therapy Yun Kee Jo; Kyungpook National University, Korea (the Republic of)

Bacterial infection of a wound is a major complication that can significantly delay proper healing and even necessitate surgical debridement and other complications. Conventional non-woven fabric dressings, including gauzes, bandages and cotton wools, often fail in treating wound infections in a timely manner due to their passive release mechanism of antibiotics. Here, we propose adhesive mechanically-activated microcapsules (MAMCs) capable of strongly adhering to a fibrous matrix to achieve a self-regulated release of antibiotics upon uniaxial stretching of a non-woven fabric dressings. To achieve this, a uniform population of polydopamine (PDA)-coated MAMCs (PDA-MAMCs) are prepared using a microfluidics technique and subsequent oxidative dopamine polymerization. The PDA-MAMC allows for robust mechano-activation within the fibrous network through high retention and effective transmission of mechanical force under stretching. By validating the potential of a PDA-MAMC-laden gauze to release antibiotics in a tensile strain-dependent manner, we demonstrate that PDA-MAMCs can be successfully incorporated into a woven material and create a smart wound dressing for control of bacterial infections. This new mechano-activatable delivery approaches will open up a new avenue for a stretch-triggered, on-demand release of therapeutic cargos in skin-mountable or wearable biomedical devices.

2:15 PM SB07.05.04
Fabrication of Bendable Microstructures Using Chiral Liquid Crystal Elastomers Yoo Jin Lee, Mustafa Abdelrahman and Taylor H. Ware; Texas A&M University, United States

Dynamic microstructures that respond to changes in environmental conditions such as temperature, light, and chemical stimuli are ubiquitous in nature. For example, wheat awn undergoes reversible bending in response to humidity to propel seeds into the ground. To synthesize synthetic materials with such controlled shape change at the microscale, processing strategies that control the microstructure of shape changing polymers are required. In this work, we will discuss controlling the reversible bending of arrays of microactuators made from liquid crystal elastomers (LCEs). Directed self-assembly of liquid crystal monomers with controlled chirality within a 3D micro-sized mold results in a gradient in the molecular orientation. We varied the concentration of chiral dopants to adjust the pitch and induce an asymmetric molecular orientation inside the microactuators. When doped with a certain value of chiral dopants, one side of the actuator expands, and the other side contracts, resulting in bending. When heated up to 150 °C, the microactuators produced an average bending angle of 28.8 ± 9.6 °. We were able to confirm the asymmetric molecular alignment inside the 3D structure by sectioning the actuators using a microtome and observing those sections with a polarized optical microscope. Our new platform to synthesize microstructures utilizing chirality allows the fabrication of bendable actuators on a microscale and can further be applied in soft robotics and healthcare devices.

2:30 PM SB07.05.05
Photo-Switchable Hydrogel Friction Allison Chau, Sophia J. Bailey, Kseniia Karnaukh, Javier Read de Alaniz and Angela A. Pitenis; University of California, Santa Barbara, United States

Stimuli-responsive hydrogels have a wide range of applications spanning drug delivery to soft robotics. Hydrogel mechanics and swelling are often tuned via external stimuli such as temperature and pH, but there is an increased need for bio-orthogonality in order to improve the biocompatibility of these hydrogels. Recently, light has been used as a stimulus through the incorporation of photo-responsive molecules that isomerize in response to light irradiation. One common photochromic molecule is water-soluble spiropyran, which is copolymerized into hydrogel networks to control the swelling and deswelling kinetics, resulting in light-induced actuation and bending. However, the tribological properties (e.g., friction and lubrication) of these photo-switchable hydrogels remain largely unknown. In this work, spiropyran-methacrylate was conjugated with acrylamide to form a copolymerized hydrogel network (p(SP-*co*-AAm)). In visible light, the photoswitch is hydrophobic in its spiro form (ring-closed). Once irradiated with UV light, the photoswitch isomerizes to its hydrophilic merocyanine form (ring-open), inducing macroscopic hydrogel swelling. Using a custom-built microtribometer, we characterized the friction coefficient before and after irradiation and demonstrated spatiotemporal control over the tribological properties of these hydrogels. In comparison, light-responsive spiropyran-based surfactants (SP-DA-PEG) were introduced in solution to the interface of self-mated poly(2-hydroxyethyl methacrylate) (pHEMA) hydrogels, which typically possess high friction. Under UV light irradiation, we demonstrated a decrease in friction coefficient. Based on these findings, we hypothesize that the increase in hydrophilicity with light irradiation is responsible for changes in the tribological properties of photo-switchable hydrogels and surfactants, leading to decreases in friction coefficient. Additionally, incorporation of these photo-switchable molecules at the sliding interface may be all that is necessary for friction reduction rather than incorporation into the bulk material.

3:15 PM SB07.05.06
Effect of Porosity on Silk's Water-Responsive Actuation Yeojin Jung[1,2], Maheen Khan[1,2], Darjan Podbevsek[2], Raymond S. Tu[1,2] and Xi Chen[1,2,3]; [1]City College of New York, United States; [2]Advanced Science Research Center, United States; [3]The Graduate Center of the City University of New York, United States

Water-responsive (WR) materials that mechanically swell and shrink in response to changes in relative humidity or water gradient have shown capability to exert higher energy than conventional actuators and artificial muscles, and thus hold potential to be used as high-energy actuating components for various engineering applications, including robotics, shape morphing, and smart structures. Despite the growing interest in this emerging category of WR materials, the underlying mechanisms of their significant performance are still not fully understood, hampering any rational design. One common feature of high-performance WR materials, such as bacteria peptidoglycan, is that they consist of hierarchical and stiff structures with nanoscale pores. Here, we systematically varied the porosity of *Bombyx (B.)* mori silk and tested the effect of porosity on silk's water adsorption and WR performance. To fabricate porous silk, blends of regenerated silk fibroin and Poly(ethylene glycol) solutions were cast on thin polyimide substrates, and subsequently treated with methanol and immersed in water to extract PEO. The porosity was varied by controlling the volume concentration of PEO from 0 to 60%. We found that *B. mori* silk's WR actuation energy densities increased first with increasing PEO concentration, and then decreased when the PEO concentration is higher than 20%. Notably, when silk is processed with 20%PEO, the silk showed extremely high WR energy densities of ~3 MJ m^{-3}, which is about four hundred-fold higher than that of mammalian muscles (~8 kJ m^{-3}). Further studies on silk's secondary structures, water adsorption, and water structures using scanning electron microscopy (SEM), dynamic water vapor sorption (DVS), and Fourier transform infrared spectroscopy (FTIR) showed that increasing silk's porosity can lead to dramatic changes in water-silk interactions and the structure of water confined within silk's nanopores. Our finding suggests that the pore structure-dependent water properties could play a crucial role in silk's WR performance.

3:30 PM SB07.05.07
Dynamic Device Based on Stimuli-Responsive Materials for Urethral Support: Potential Treatment for Stress Urinary Incontinence Seelay Tasmim[1], Zuha Yousuf[2], Farial Rahman[2], Mario Romero-Ortega[2], Philippe Zimmern[3] and Taylor H. Ware[1,1]; [1]Texas A&M University, United States; [2]University of Houston, United States; [3]University of Texas Southwestern, United States

Stress Urinary Incontinence (SUI) is the involuntary leakage of urine in response to increased intra-abdominal pressure such as during coughing or sneezing. This condition affects nearly 50% of adult women. Bothersome SUI can be treated with the insertion of a synthetic or autologous sling underneath the urethra to provide needed support. A limitation of current mid-urethral slings is their fixed level of support, which cannot be modulated to adjust for voiding. Here, we report the design and fabrication of a dynamic sling based on stimuli-responsive materials such as liquid crystal elastomers or magnetic elastomers. These devices are capable of achieving shape change to adjust urethral support in response to safe stimuli such as transcutaneously delivered infrared light or magnetic field in physiologically relevant environments. A scar-tissue phantom model was developed to characterize the shape change of these devices. An *in vitro* urinary tract model was designed to study the efficacy of these stimuli-responsive devices on continence and flow. Both devices achieved significant shape change in response to IR light or magnetic field when embedded in an agar gel with 100kPa stiffness, mimicking scar tissue. Furthermore, both devices increased urethral resistance to flow, and allowed unimpeded voiding upon activation, thus affecting the sphincteric mechanism. When illuminated with IR light, the LCE-based device significantly decreased ($p<0.0001$) time to void 20mL of water from 5.2min ± 1min to 2min ± 0.5min. Likewise, the magnetic elastomer-based device reduced abdominal pressure by 0.51cmH_2O ± 0.14cmH_2O in the presence of a magnetic field, thereby reducing time to void in this in vitro model. Future work will focus on further analysis of the mechanical properties of these materials and testing for biostability. The devices will be implanted in rabbits, a viable animal model for SUI, to test the devices *in vivo*.

3:45 PM SB07.05.08
Improving the Redissolution Kinetics of Thermoresponsive Hydrogels for Biomedical Applications in Higher Temperatures Mahsa Rezaiyan, Frances Yau, Darius A. Shariaty and Mark E. Thompson; University of Southern California, United States

Stimuli-responsive materials that respond to specific triggers, such as thermoresponsive hydrogels, are in high demand for biomedical applications. Due to their biocompatibility and water content similar to tissue, they have been used as contact lenses, wound healing bioadhesives, and drug delivery platforms. Biocompatible thermoresponsive sealant (TRS) is of great interest in the wound management of those injuries that risk substantial impairment with delayed treatment, such as open globe ocular injuries. TRS exhibits non-adhesive behavior at cold temperatures and is easily deployed; however, it becomes viscous and adhesive at body temperature and is capable of sealing penetrating injuries. Fast and reversible phase transitions of TRS upon cooling are required for their application after storage in variable temperatures. The kinetics of redissolution of a thermally treated TRS is slower for high molecular weight materials.

Herein we present a unique strategy for significantly increasing the redissolution kinetics of thermoresponsive hydrogels via the utilization of a high surface area host material. As an example of any other injectable in-situ forming hydrogels, which have suitable mechanical strength but slow transition times, the increase in the redissolution kinetics of hydrophobically-modified poly(N–isopropyl acrylamide) (pNIPAM) in the presence of a high surface area, open cell foam host is demonstrated. The recovery measurements show enhanced recovery (74-99%) across a range of foam types and pore sizes when compared to samples stored without a host (9% recovery). Maximizing a host surface area with an open cell foam demonstrated the greatest increase (~ten-fold) in TRS recovery after storing the TRS solution at 50 °C and cooling for ten minutes. The rheological analysis revealed that the viscosity, storage, loss modulus, and mechanical strength are not significantly affected by storage over a foam host.

This work is supported by the US Army Medical Research and Materiel Command under Contract No.W81XWH-16-C-0086, and partially was supported under Research Project Award MTEC-20-14-Ocular-006 as executed by Delivery Order No. W81XWH-21-9-0003.

4:00 PM SB07.05.10
Probing Temperature-Responsivity of Microgels by Superresolution Microscopy Xhorxhina Shaulli[1], Rodrigo R. Barbosa[2], Maxime J. Bergman[1], Chi Zhang[1], Nicoletta Gnan[2], Frank Scheffold[1] and Emanuela Zaccarelli[2]; [1]University of Fribourg, Switzerland; [2]Sapienza University of Rome, Italy

The ability to observe microgel morphologies at nanometer scale and its response to temperature changes opens exciting opportunities to design and precisely control the behavior of microgels for various applications [1]. In this context, super resolution microscopy is a well-established tool used to investigate colloidal systems e.g. poly(N-isopropylacrylamide) (pNIPAM) microgels [2]. An important role when performing advanced microscopy experiments on such particles plays the interface where the microgels are established, as they have to be fixed during the experiment. We use super resolution microscopy and molecular dynamic (MD) simulations to investigate how individual microgels anchored on hydrophilic and hydrophobic surfaces change morphology with temperature. Super resolved images of individual microgel particles at different collapsing stages are analyzed and their density profiles are obtained. The results suggest that the anchoring parts of the microgel stick to the surface as the temperature is increased. For these surfaces the experimental data and the MD simulations are in very good agreement. Such study is relevant to establish a technique for the investigation of more complex systems along lower critical solution temperature (LCST), where molecules of interest can be incapsulated in the microgel network and controllably released with temperature.

Multi-State Hydrogel Device Programmed by DNA Sequence Instructions Ruohong Shi, Kuan-Lin Chen, Joshua Fern, Siming Deng, Yixin Liu, Noah Cowan, David H. Gracias and Rebecca Schulman; Johns Hopkins Univerisity, United States

Living systems can convey information and drive complex chemomechanical processes such as metamorphosis using biomolecules as signals. Yet, synthesizing macroscale soft structures that can likewise interpret and respond to such signals by undergoing chemomechanical changes has been challenging. Here, we create a new family of programmable polymeric materials, DNA polymerization gels, whose shape change can be programmed by DNA sequence instructions. The growth and shrinking of these DNA polymerization gels are driven by the polymerization and depolymerization of DNA via hybridization chain reactions. The actuation mechanism was studied in-depth for optimized sequence design to perform high-degree growth and reliable reversibility. We developed a multi-step photolithography process that enables the fabrication of centimeter-scale gel devices consisting of multiple micro-segments. Several orthogonal DNA systems that can selectively execute “grow” or “shrink” instructions were designed to direct material transition repeatedly between different configurations. Finally, we introduced a machine learning-assisted design method for creating “seed” structures, which in response to different DNA instructions, could transform into one of a large set of functional target configurations: four different letters and either every even or every odd Arabic numeral. Our work offers a general architecture for manipulating polymeric materials by dissipative chemical cycles, programming functions into the structures by molecular designs, and encoding complex, continuous transformations of curved mechanical structures into precise molecular instructions and protocols.

SESSION SB07.06: Sustainable Polymer Networks

8:00 AM SB07.06.01
High-Performance, Low-Cost, and Recyclable Photopolymers via Dual-Cure 3D-Printable Polyesters Grant Musgrave and Chen Wang; The University of Utah, United States

Among the 3D printing technologies available for polymers, vat photopolymerization or stereolithography (SLA) is promising for future manufacturing because it uses photopolymers to print parts with incredible speed and complexity. The material properties of traditional, filament-fabricated 3D-printed parts are often inferior due to their inherent brittleness and poor interlayer bonding. Similarly, 3D-printed photopolymers are also often weaker than traditional polymers due to their structural heterogeneity. To dramatically reduce the heterogeneity, latent chemistries will be introduced into the resin that will re-organize the molecular structures to homogenize the photopolymer. This will result in photopolymers with robust properties that will enable the implementation of vat photopolymerization in mainstream manufacturing. These “dual-cure” polyesters reduce the structural heterogeneity of 3D printed photopolymers, and thus, improve material properties, decrease costs, and enable recyclability of the photopolymer. Herein, “dual-cure” refers to an initial "photo-cure" mediated by UV-light, followed by a secondary "heat-cure" where a thermal-meditated reaction takes place. This unconventional network enables a new direction of high-performing polymers for 3D printing and chemical recyclability via ester-based chemistry.

8:15 AM SB07.06.02
Upcycle Commodity Plastic Waste to Fully-Recyclable and Self-Healable Polymers Qiming Wang; University Southern California, United States

Over 300 million metric tons of plastics are created globally every year but more than 79% of the plastic waste goes to landfills, but only a small fraction (~9%) is recycled and most of the recycled plastic is down-cycled to low-value products such as garden furniture or pots. The accumulation of unrecycled plastics has become a huge global challenge. Here we present a general strategy to upcycle commodity plastic waste to a class of fully-recyclable and self-healable polymers. The idea is that we functionalize the commodity plastic powder with photosensitive dynamic chemical groups can enable light-activated self-assembly of plastic powder into a polymer composite. Thanks to the light-controlled reversible association and cleavage reactions, the mechanical properties of the polymers can be on-demand tuned by the external light. Besides, the interfacial crack can be healed by light-activated re-association reaction. Furthermore, the synthesized polymer can be ground into powder and then reprocessed back to a solid polymer with rebuilt mechanical properties. We show our strategy is universal to various commodity plastic wastes, such as PS, PP, PET, and PE.

8:30 AM SB07.06.03
Simple Upcycling of Virgin and Waste Polyethylene into Covalent Adaptable Networks—Catalyst-Free, Radical-Based Reactive Processing with Dialkylamino Disulfide Bonds John M. Torkelson, Logan M. Fenimore and Boran Chen; Northwestern University, United States

Polyethylene (PE) is a ubiquitous commodity polymer that faces significant barriers to efficient recycling despite its thermoplastic nature. PE can be permanently cross-linked to enhance its properties and expand its applicability, but conventionally cross-linked PE (PEX) is not reprocessable in the melt-state and thus cannot be recycled for high-value use. Here, we have transformed thermoplastic PE into PE covalent adaptable networks (CANs) via reactive radical-based, melt-state processing with 1 wt% dicumyl peroxide and 5 wt% bis(2,2,6,6-tetramethyl-4-piperidyl methacrylate) disulfide (BiTEMPS methacrylate), a dynamic covalent cross-linker. The simple, catalyst-free, one-pot reactive process employing dialkylamino disulfide dynamic chemistry was used to upcycle both commodity and waste thermoplastic PE into thermally stable and reprocessable PE CANs, and the thermomechanical properties of resulting CANs are tunable without sacrificing their recyclability. Low-density PE CANs and high-density PE CANs fully recover cross-link densities and associated properties after multiple reprocessing steps, resist creep deformation at elevated temperature relative to their thermoplastic precursors, and, like PEX but unlike some PE vitrimers, exhibit no phase separation. This novel procedure opens the door to the development of CANs based on reactive processing of ethylene-based copolymers as well as cross-linked PE nanocomposites and foams.

8:45 AM SB07.06.04
Modeling Erosion of Polymer Networks with Stimuli-Responsive Degradable Bonds Olga Kuksenok and Vaibhav Palkar; Clemson University, United States

Understanding and controlling degradation of polymer networks on the mesoscale is critical for a range of applications ranging from regulating growth of complex tissues and neural networks to controlled drug delivery. Degradation that can be controlled by external stimuli, for example photo-controlled degradation, permits spatially-resolved dynamic control of materials properties. We develop a dissipative particle dynamics (DPD) approach that captures degradation and erosion of hydrogels at the mesoscale. To overcome unphysical topological crossings of bonded polymer chains, we utilize a modified Segmental Repulsive Potential (mSRP) formulation. We focus on hydrogels formed by the end-linking of multi-arm polyethylene glycol macromolecular precursors. We track the degradation via measuring the fraction of the degradable bonds intact and spatial distributions of network fragments or clusters. We demonstrate that the dispersity and the fraction of broken-off fragments scales with the relative extent of reaction. Reduced weight average and reduced z-average degrees of polymerization allow us to identify the reverse gel point. We characterize the erosion process in solvents of various qualities via tracking the mass loss that accounts for the broken-off fragments remaining in contact with the percolated network. We quantify the dependence of the mass loss on the extent of reaction and on the hydrogel properties. These results elucidate the main features of degradation and erosion on the mesoscale and could provide guidelines for future design of degrading materials with dynamically controlled properties.

Circularity in Plastics via Understanding and Controlling Polymer Reactivity Across Scales Brett A. Helms; Lawrence Berkeley National Lab, United States

Polydiketoenamine (PDK) is an emerging class of plastics that can be efficiently deconstructed to the original triketone and amine monomers using low intensity chemical processes. Controlling the rate at which bonds in the polymer are hydrolyzed in strong acid is an emerging area of interest, enabling chem. recycling of complex products made from several classes of PDK resins. Likewise notable is the impact of formulation on recycling rates, hlghlighting the importance of examg. the foundations of polymer reactivity beyond the bond. I discuss this multi-lengthscale perspective, where a convergence of experiment, theory, and advanced characterization bring into focus design rules. I will discuss how to minimize parasitic losses in chem. recycling, toward infinite recyclability. I will also discuss how such considerations can be applied to the chem. recycling of polymers with a broad range of useful and advantaged properties. As most PDK resins can be produced from biorenewable raw materials, the platform appears well poised to address the sustainability of plastics as we transition to plastics as a service in a circular economy.

9:15 AM SB07.06.06
Bio-Renewable Feedstock for Circular Polydiketoenamine Networks Jeremy Demarteau[1], Benjamin Cousineau[1], Zilong Wang[2], Baishakhi Bose[1], Corinne Scown[1,2], Jay D. Keasling[2,1] and Brett A. Helms[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]Joint BioEnergy Institute, United States

Bio-synthesized plastics and durable goods thermosets are usually difficult to pair with circularity because of their various application fields, opposite lifetime and different chemistry. Here, we show that circular polydiketoenamines (PDK) vitrimers are produced with aromatic biorenewable monomer. Odd-even effects over different PDK spacer length are translated in a change of density and tensile modulus values. Chemical recycling is realized in a low intensive acid process with large monomer recovery variations through PDK series due to an increased degradation occurring in formulations featuring shorter spacers. While reaching high monomer recovery in powdered PDKs, PDK plastics with longer spacers enable higher monomer recoveries. Bioproduction of aromatic monomer is achieved from both glucose and glycerol in engineered *E. coli* using non-native thiolase BktB under fed-batch fermentation. System analysis scaling-up of the monomer production provides the estimated cost and greenhouse gas emission with different scenarios. Our results demonstrate the versatility of the circular PDK platform incorporating aromatic biorenewable synthons and potentially opening the way to chiral circular polymers.

Superabsorbent 'Gel Sheets' with Fabric-Like Flexibility—A 'Better Picker-Upper' for Water and Blood Hema Choudhary, Christine Zhou and Srinivasa R. Raghavan; University of Maryland, United States

Materials that can absorb aqueous liquids have evolved along two parallel tracks for the past millennia. On the one hand, there are flexible, foldable materials like cloth or paper towels that are convenient to use but not very absorbent. On the other hand, we have superabsorbent polymer hydrogels (SAPs) with the ability to absorb more than 100x their weight in water, but in dry form these become fragile solids. Here, for the first time, we report the synthesis of **'gel sheets'** that combine the above properties in the same material. The sheets are prepared at macroscopic sizes (e.g., 10 x10 cm) by foam-templating (polymerizing monomers around the bubbles of a foam), followed by addition of a plasticizer (glycerol) and ambient drying. The dried sheets are macroporous (pore sizes ~ 240 µm, porosity > 80%), flexible, soft, and robust; they can be folded, rolled up, and cut with scissors to desired sizes, much like fabrics. At the same time, they can rapidly absorb substantial amounts of water, like hydrogels. Remarkably, these sheets ***expand as they absorb water***, which is unlike any sponges or absorbents made from fabric or paper. The sheets are also able to absorb viscous liquids like blood as well as viscoelastic, non-Newtonian liquids like polymer or surfactant solutions. Absorbed liquids are retained within the gel sheet when it is lifted up whereas with typical commercial controls, excess liquid drips down. Due to their unique properties, these gel sheets could be useful in cleaning up spilled liquids in a variety of locations, including homes, labs, and hospitals. They could also be useful tools for absorbing biological fluids during surgeries or other medical procedures.

Mechanical and Electrical Properties of Polyelectrolyte Elastomers in Bulk and at Interface Baohong Chen and Shu Yang; University of Pennsylvania, United States

Unlike conventional polyelectrolyte solutions and gels and conventional elastomers, polyelectrolyte elastomers are both solvent-free and ion-conductive. We developed polyelectrolyte elastomers and investigated their unique mechanical and interfacial properties. With collaborators, the tunability of ion transimission in the polyelectrolyte elastomer and the rectification of ionic current across their interfaces are reported. Recently, we observed a novel electrical manifestation of polyelectrolyte elastomers. In a preciously engineered reversible mechanical process, the polyelectrolyte elastomer transforms the mechanical loss into an electrical gain. This phenomenon depends on the appropriate design of the electro-mechanical-chemical responsive network of the polyelectrolyte elastomer. We experimentally and theoretically bridged the molecular picture of a polyelectrolyte elastomer to quantifiable characteristics. In addition to inheriting the benefits of the parent ionic liquids and elastomers in various applications, polyelectrolyte elastomers lead to advanced applications in areas including energy harvesting, sensors, and soft robots.

Rubbery Organic Frameworks-Tuning the Gaz-Diffusion through Dynameric Membranes Mihail Barboiu; Institut Europeen des Membranes, France

High permeability whilst keeping a reasonable selectivity is the most important challenge in developing membranes for gas separation. Valuable performances are usually obtained with membranes for which the gas transport is controlled by the gas-diffusivity in glassy polymers and by gas-solubility in rubbery polymers. During the last decade, important advances in this field are related to the molecular control of the gas separation properties. The combination/replacement of classical glassy polymers with metal-organic frameworks (MOFs, ZIFs, zeolites…) embeded in polymeric matrixes provided reasonable permeability through porous free volume network and high selectivity due to so-called "selectivity centers", specifically interacting with the gas molecules. Despite the impressive progress, important difficulties are observed to get dense mechanically stable thin layer MOFs on various supports. Taking advantage of high permeabilities observed with the dynamic covalent rubbery polymers and to their flexible casting properties, there should be very interesting to build rubbery organic frameworks-ROFs, as alternative for molecularly controlled membranes for gas separation. Here we use low macromolecular amino-functional connectors and aldehyde core centers in order to constitutionally generate such adaptrive dynameric ROFs. Differently to classical rubbery polymeric membranes the ROFs performances depend univocally of diffusionl behaviors of gas molecules through the network. For all gases, a precise molecular composition of linear and star-type macromonomers generates an optimal free volume for a maximal diffusion through the matrix. These results should initiate new interdisciplinary discussions about highly competitive systems for gas separation, constitutionally controlled at the molecular scale.

Photodegradable Hydrogel Materials for Encapsulation, Isolation and Recovery of Functionally Rare Bacteria from Complex Microbial Communities Ryan Hansen, Niloufar Fattahi, Niloy Barua, Mohammadali Masigol, Esther L. Radaha, Andre J. van der Vlies, Prathap Parameswaran and Tom G. Platt; Kansas State University, United States

Photodegradable hydrogel materials can be used for cellular encapsulation and for spatiotemporally-controlled cell release, and therefore have been explored as materials for use in cell isolation applications. While most studies have focused on mammalian cells, here we extend the use of photodegradable polyethylene glycol (PEG) hydrogels towards isolation of bacteria with rare or unique function from complex microbial communities, which often contain thousands of unique species. Hydrogels are formed using the photocleavable macromer, PEG *o*-nitrobenzyl diacrylate, which is crosslinked into a hydrogel through thiol-acrylate Michael-type addition reactions with PEG-tetrathiol macromers. PEG molecular weights are selected to form hydrogels with a 10 nm mesh size, enabling physical encapsulation and immobilization of bacteria cells while also allowing for the transport of nutrients, chemical cues, and waste products throughout the material for culture. A patterned illumination tool is used to expose the hydrogel to user-defined 365 nm light patterns at 5-mm spatial resolution to selectively release desired cells from the hydrogel interface after phenotypic observations for recovery, genomic characterization, and application.

With this foundational approach, three applications will be highlighted. The first involves screening bacteria mutant libraries for phenotypically rare cells. Cells from mutant libraries are directly encapsulated into the hydrogels for high-throughput, microscopic observation. After identification of the desired cellular phenotype, rare cells are released with patterned light and recovered for whole genome sequencing, enabling one to link phenotype to genotype. Second, these materials are integrated into microdevices containing microwell arrays for bacteria co-cultures. These devices are designed to screen thousands of different co-cultures to uncover microbe-microbe interactions that impact beneficial or pathogenic bacteria. Finally, photodegradable hydrogels have been functionalized with lectin proteins, enabling high-affinity capture and removal of bacteria from young biofilms on host surfaces. After capture, bacteria can be sectioned from the hydrogel using patterned light for sequencing and characterization. We have applied this approach to study membrane biofouling in wastewater treatment systems, and specifically to identify early-colonizing bacteria from wastewater that accelerate the membrane biofouling process. Current and future work involves investigating the use of upconversion nanoparticles in these hydrogel systems for release of cells using near infrared light.

11:00 AM SB07.07.04
Flexible Porous Gels Synthesized by Templating Organofoams—Ability to Selectively Absorb Oil from Water Hema Choudhary, Christine L. Zhou and Srinivasa R. Raghavan; University of Maryland, College Park, United States

Porous absorbents are being explored rigorously for recovering volatile organic solvents and oils from water bodies. However, most existing synthesis techniques are limited to the fabrication of small-size absorbents. These techniques are based on modifying polymer sponges towards a greater affinity to organic solvents. For large-scale manufacturing, these methods turn out to be arduous, energy-intensive, and expensive. Here, we devised a simple strategy to create porous absorbents, using an inherently hydrophobic polymer, that can be easily scaled up. Our approach involves the generation of foams in an organic monomer solution by mixing it with an aqueous acidic solution and sodium bicarbonate. The acid-base reaction produces CO_2 gas bubbles, and simultaneously, oil-in-water type emulsions are formed, with the monomers being the oil phase. Both the emulsion and bubbles are stabilized by a silicone surfactant present in the monomer solution. This foamed-emulsion solution is quickly polymerized to give a porous solid named ‘oleosponge’ or ‘oleosheet’. It retains the interconnected pores from the foam, which have an average size of 277 µm. The material is flexible and mechanically robust, withstanding several cycles of deformation. It can sustain more than 90% compression and 35% tensile strain and has a tensile modulus of 40 kPa. The material also shows a contact angle of ~130° with water and 0° with oils. When immersed in a toluene-water mixture, it selectively absorbs the toluene and expands by ~75% linearly. In solvent absorption, the oleosponge outperforms commercially available polyurethane sponges, which have been used for designing hydrophobic absorbents in many previous studies. Our material shows very high absorption for a wide range of organic solvents (> 50 g/g), and it can be reused for more than 100 cycles without showing a significant reduction in its selective absorption capacity. For large-scale clean up, we have created oleosheets with dimensions of 10 x 7 cm and a thickness of 4 mm. The sheet instantly absorbs solvent and expands when spread over a large spill. The expanded sheet is robust enough to be picked up by hand and holds solvent within when held vertically. Compared to commercial oil-absorbing sheets, our oleosheets absorb and retain a much higher volume of organic solvent. Another exciting aspect of our synthesis technique is that we can attain additional interesting properties in the oleosponge simply by adding nanoparticles of interest to the monomer solution. We have created a magnetic responsive oleosponge that can be remotely lifted up by a magnet after solvent absorption. Lastly, we designed a hybrid sheet of two distinct layers with opposite wettability for water: one side can absorb solvents and oils while the other absorbs only aqueous fluids. This type of hybrid sheet could have applications in cosmetics and household use in addition to oil spills.

Regenerative Repair of a Critical-Size Rat Femoral Segmental Defect Guided by a Chemically Crosslinked Degradable Shape Memory Polymer-Hydroxyapatite Composite Scaffold Jordan D. Skelly, Xiaowen Xu and Jie Song; UMass Chan Medical School, United States

Facile surgical delivery and stable fixation of synthetic bone graft substitutes play roles just as critical as osteoconductivity and osteoinductivity in ensuring successful scaffold-guided bone regeneration. Shape memory polymers (SMPs), when engineered with a multitude of appropriate characteristics, may serve as smart synthetic bone graft substitutes to meet these challenges. We previously showed that rigid polyhedral oligomeric silsesquioxanes (POSS) nanoparticles could be covalently integrated with urethane-crosslinked polylactide (PLA) to prepare high-strength, degradable POSS-SMP nanocomposites that exhibit stable temporary shape fixation at room and body temperatures, and efficient shape recovery with a safe thermal trigger. By crosslinking star-branched POSS-PLA building blocks with hydrophilic polyethylene glycol diisocyanates (PEG-DI), we recently prepared amphiphilic POSS-SMPs in the presence of 20 wt% osteoconductive mineral hydroxyapatite (HA). The resulting amphiphilic mineral composite exhibited desirable surgical handling characteristics (compliance, toughness) and excellent shape recovery (>95%) at a safe triggering temperature. The incorporation of HA mitigated the negative impact of the composite’s acidic hydrolytic degradation products on the proliferation and osteogenesis of bone marrow derived stromal cells. Here we further examine the *in vivo* efficacy and safety of macroporous 20 wt% HA/POSS-SMP composite scaffolds, tailored for a 5-mm rat femoral segmental defect and fabricated using 3D printed sacrificial molds, in guiding long bone regeneration with or without 400-ng recombinant human osteogenic bone morphogenetic protein-2 (rhBMP-2). These compliant macroporous scaffolds may be conveniently press-fit within the defect and allowed to recover to their pre-programmed shape at body temperature and/or upon hydration *in vivo,* resulting in stable graft fixation within the femoral segmental defects in skeletally mature SASCO SD rats. Using a combination of longitudinal microCT analyses over 16 weeks and terminal femoral histology analyses, we demonstrated robust new bone formation throughout the defect, guided by the macroporous degrading amphiphilic scaffolds in the absence of exogenous rhBMP-2. With the addition of 400-ng rhBMP-2, new bone formation, new bone remodeling, and scaffold resorption were significantly accelerated, resulting in complete bridging of the defects as early as 5 weeks after implantation. Histological analyses confirmed scaffold-guided osteointegration and coordinated osteoblastic/osteoclastic remodeling by 8 weeks in both treatment groups. Systemic organ pathology did not reveal any detrimental effects of the degrading nanocomposites. To further accelerate the full resorption of the scaffold and functional restoration of the mechanical integrity of regenerated long bone, an amphiphilic scaffold with larger macroporosity and/or more expedited degradation rates may be considered. These findings combined support this amphiphilic osteoconductive degradable SMP composite as a promising class of next-generation synthetic tissue grafts.

11:30 AM SB07.07.06
Additive Manufacturing of Polymer Networks Based on Dissociative and Associative Dynamic Covalent Bonds Francesca Furia, Aleix Costa Cornellà, Guy Van Assche and Joost Brancart; Vrije Universiteit Brussels, Belgium

Additive manufacturing (AM) techniques allow rapid prototyping of complex 3D shapes and custom-made products, in fact they attracted soon the interest of many researches and the range of materials that can be used is rapidly expanding. Curing and melting are the two main characteristics taken into account when deciding which techniques used, but recently polymers networks based on dynamic covalent bonds have been introduced into this world. Two main mechanism can be differentiated: associative and dissociative covalent chemistries. In the former, the crosslink density of the network stays constant with temperature, but the speed at which these dynamic covalent bonds exchange increases. In the latter, the crosslink density changes as a function of temperature. The main drawback for additive manufacturing of dissociative networks is the sharp and drastic change from a rubbery network to a low viscosity liquid at temperatures above their gel transition. In recent work, this limitation has been overcome by the addition of fillers that allowed the printing of overhangs and eventually the addition of other properties to the network. The fillers improved the printability of these materials, but at the same time they had a stiffening effect of the mechanical properties and obtaining a homogeneous dispersion is challenging.

In this study, dissociative and associative dynamic bonds were combined in the same network, providing the dissociative network the thermal and mechanical support needed during the AM processing at high temperatures.

Thermoplastics polymers such as PLA and ABS are usually printed taking advantage of the melting temperature or the devitrification of the polymer to have a high viscous flow in material extrusion AM. When using a polymer network based on dissociative thermoreversible Diels-Alder (DA) bonds, the gel transition temperature (T_{gel}) is used. When heated above T_{gel}, the dynamic equilibrium shifts towards the dissociation of the DA adducts to the extent that the polymer can flow through the nozzle as a viscous melt. Once in contact with the printing bed at a temperature below T_{gel}, the dynamic equilibrium shifts back to the formation of the adducts, reforming the polymer network structure. Differently from PLA or ABS, this is a reactive type of printing based on the reaction kinetics of the DA bonds, which are not fast enough to hold the shape of the object and cure before starting to flow on the print bed.

Associative covalent networks present different types of exchange reactions. Recent studies showed that in presence of the transesterification reaction it proved possible to extrude at high temperatures and pressures, though with a rough surface finish. There is no net change in the crosslink density, but the exchange speed is fast enough for the material to flow and they also present thermal stability.

When combining DA bonds and esters in the same network, it is possible to print objects with sharps edges and smooth finish using material extrusion AM. When heated at a temperature higher than the T_{gel}, the materials behave like a high viscous melt because the DA part of the network is completely dissociated and, once it reaches the bed, the network is hold together by the associative bonds present due to the vitrimers. Differential scanning calorimetry was used to verify the absence of degradation and side reactions when printing at temperatures much higher than the Tgel. Rheology measurements, such as small amplitude oscillatory shears, have been conducted on the materials and on commercial PLA used as a reference. The shear thinning behavior at high shears ensure extrudability and printability. Different percentages of the two dynamic bonds have been tested to evaluate the effect on the printability and to find the optimum composition. The healing property is also preserved after printing, the healing temperature is far from the printing temperature.

Mechanically Robust Mechanically Interlocked Polymers Xuzhou Yan; Shanghai Jiao Tong University, China

Due to the unique topological structures and controllable mechanical motions under external stimuli, mechanically interlocked polymers have gained widely attention from the scientific community. Nevertheless, it is still a significant challenge to elucidate the influence of microscopic mechanical motion of mechanical bonds on the macroscopic mechanical properties of their aggregates. In this talk, we will firstly present a class of mechanically interlocked networks carrying densely rotaxanated backbones as a model system to understand macroscopic mechanical properties stemmed from the integration and amplification of intramolecular motion of the embedded [2]rotaxane motifs. Subsequently, we will introduce the coupling of dynamic covalent bond and mechanical bond to understand the dynamicity and reprocessability of mechanically interlocked vitrimers. Finally, we will showcase how we use densely mechanical bonds to realize the applications of mechanically interlocked networks in the fields of stretchable materials, aerogels, soft actuators. Our work promotes the development of mechanically interlcoked materials, especially on the understanding of the underlying mechanism of the relationship between microscopic mechanical motion and macroscopic mechanical performance.

8:30 AM SB07.08.02
Hygroscopic Tunable Multi-shape Memory Polymers Siya Huang; Shenzhen University, China

Tunable multi-shape memory polymers offer intriguing opportunities for memorizing multiple temporary shapes with tunable transition temperatures from one material composition. However, such multi-shape memory effects have been exclusively correlated with the thermoresponsive behaviors of materials, significantly limiting applications in heat-sensitive scenarios. Here we report on a nonthermal tunable multi-shape memory effect in hygroscopic cellulosic polymers, which exhibit a broad, reversible hygromechanical response at ambient temperatures. The polymers present a unique moisture memory effect, enabling diverse multi-shape memory behaviors (dual-, triple- and quadruple-shape memory effects) with excellent performance under highly tunable and independent control of humidity alone. Owing to the tissue-like mechanics and bio-benign triggering conditions, bio-adaptive medical devices such as self-deployable stents and self-tightening sutures were successfully demonstrated under physiological circumstances, exhibiting autonomous shape recovery in a fast and programmable fashion while supplying a biocompatible recovery stress that can be further tailored to tissue-specific requirements over a broad range (0.1 to 4 MPa). Such hygroscopic tunable shape memory effects with great design flexibility readily extend the implications of shape memory polymers beyond the conventional thermomechanical regimes.

8:45 AM *SB07.08.03
Polymer Networks with Embedded Reactivity Stephen Craig; Duke Univ, United States

The physical limits of polymer networks are determined by the physical limits of its constituent molecular strands: the energy a strand absorbs before breaking, the force at which it breaks, and the extension it achieves at that force. In many case, polymer strands are typically viewed as structureless entropic springs. In this talk, we discuss the consequences of treating strands as being both structurally active and chemically reactive, and of viewing macroscopic mechanical events such as crack propagation as a moving chemical reaction vessel, in which molecular strands undergo conformational and covalent chemical reactions that are tied to their specific molecular structure.

9:15 AM SB07.08.04
Mechanochromic Liquid Crystals and their Polymer Blends Kris Senecal[1], Paola A. D'Angelo[1], Todd E. Alexander[1], Walter Zukas[1], Christina Tang[2], Hong Zhao[2] and Timothy Lawton[1]; [1]U.S. Army DEVCOM SC, United States; [2]Virginia Commonwealth University, United States

The long term goal of this research is to understand the influence of structure and properties of polymer blends with cholesteric liquid crystals (LC) to facilitate the design of adaptive/responsive optical color change to mechanical strain. Cholesterol ester liquid crystals form into periodic helical structures and give these liquid crystals their unique responsive optical properties. The color of the light reflected depends on the pitch length of the liquid crystal and can be influenced by external stimuli like mechanical deformation or temperature. Temperature-dependent properties depend upon a transition between the smectic and twisted nematic mesophases. If the smectic phase exists, temperature dependent reflecting properties are observed. Temperature-insensitive formulations can be achieved by ensuring the absence of the smectic mesophase transition. Such mixtures reflect a single color below its clearing point. Practically, this has been achieved using mixtures of components that have a smectic A mesophase (e.g. cholesteryl perlagonate and/or cholesteryl oleyl carbonate) with a component that does not form a smectic A mesophase (e.g. cholesteryl chloride). Such formulations are expected to change color in response to mechanical shear while remaining relatively unaffected by temperature changes. To achieve these mechanochromic LC formulations, we are investigating ternary mixtures of cholesteryl benzoate (CC), cholesteryl pelargonate (CP), and cholesteryl oleyl carbonate (COC). Through investigations of the formulation space using a ternary diagram, the broadest range of colors (reflected wavelengths) can be achieved by varying the COC concentration at a 1:1 ratio of CP:CC. Formulations that appear blue, green, and red were selected and mechanochromic behavior was demonstrated when applying a shear stress using a doctor blade with an estimated strain rate of 180 s^{-1}. However, the fast relaxation times associated with the liquid nature of the LC formulations meant a rapid return to the original color. To both lengthen the relaxation times and incorporate the formulations into practical structural materials, various methods were employed to combine LC formulations with an aromatic polyether-based thermoplastic polyurethane (TPU). Long term stability of separate layers of LC and TPU proved physically questionable. Initial efforts to combine LC formulations with TPU in tetrahydrofuran showed good compatibility in cast films and wet-spinning of fibers. A series of TPUs with varying physical properties is currently being investigated. Characterization of the mechanochromic response of these blends and the relationship of the TPU properties to the LC structure will be presented.

9:30 AM SB07.01.01
Controlling the Thermomechanical and Viscoelastic Properties of Polymer Networks by Combining Associative and Dissociative Dynamic Covalent Bonds Aleix Costa Cornellà, Joost Brancart, Guy Van Assche and Francesca Furia; Vrije Universiteit Brussel, Belgium

Introducing dynamic bonds into polymer networks can produce materials that can be more easily processed, applied, and recycled than their permanent counterparts. Moreover, they show improved toughness, stretchability, and the ability to heal physical damage. This dynamicity can be introduced into polymers by means of supramolecular interactions, dissociative dynamic covalent bonding, or associative dynamic covalent bonding (vitrimers).
The behavior of these polymer networks heavily depends on the kinetics and thermodynamics of the dynamic bonds, which are entirely different for each mechanism. On the one hand, the viscosity of vitrimers show a linear behavior (Arrhenius behavior) as a function of inverse temperature. On the other hand, dissociative networks can exhibit abrupt changes in viscosity above a critical temperature. Both systems have their strengths and weaknesses, but both suffer from the same compromise. Having to choose whether to be able to self-heal/reprocess at mild conditions or to not creep at operation temperatures.
Here, we tackled this intrinsic problem by developing a strategy to engineer the relaxation time regime in dynamic polymer materials. We achieve this control by combining, in a single network, Diels-Alder and β-hydroxy ester bonds. Diels-Alder bonds based on furan and maleimide are dissociative dynamic covalent bonds and show an abrupt change in viscosity above a critical temperature. β-hydroxy ester bonds are associative dynamic covalent bonds and show an Arrhenius behavior. By tuning the ratio between Diels-Alder bonds and β-hydroxy ester bonds it is possible to access the complete range of relaxation times between the two mechanisms. The polymer network that is crosslinked exclusively by Diels-Alder bonds becomes liquid above its gel transition temperature of around 100 °C, with viscosity as low as 0.45 Pa.s at 125 °C. As the proportion of associative bonds increases, the gel transition temperature of the system increases until a point where it no longer degel, which means that the β-hydroxy ester bonds have a concentration high enough to create a network. For the network crosslinked only by β-hydroxy ester bonds, it remains solid and doesn't relax a measurable amount of stress at a time scale of >750 minutes at 130 °C. Even after the point where the material doesn't degel, healing of completely cut tensile specimens remains possible at a reasonable temperature of 90 °C for 30 minutes, without any external pressure. These conditions are notably milder conditions than the ones normally needed to self-heal materials based on transesterification.
The materials are also designed following the 12 principles of green chemistry. They are synthesized using 100% bio-based raw materials, based on fatty acids, without using any solvent, and are potentially (bio)degradable. As all the components have a similar backbone, the mechanical properties of the materials don't vary much between materials with different ratios of associative and dissociative bonds. The Young's modulus of the whole range of materials sits around 1.5 ± 0.5 MPa at room temperature.
With this strategy, the design of the mechanical properties is decoupled from the relaxation dynamics. Combining two types of dynamic bonds with very dissimilar relaxation dynamics empowers a range of applications where the materials can be tailored according to their application, processing, as well as the timescale of their use. Additionally, this approach is not exclusive to our system but can be generalized to any compatible pair of dissociative and associative dynamic covalent bonds.

Opportunities for Materials Chemistry in Haptic Interfaces Charles Dhong; University of Delaware, United States

Haptic devices have wide ranging applications, from entertainment in virtual reality, to accessibility aids, and even to advance basic knowledge in sensory biology. Here, show approaches from materials chemistry could be used to improve the quality, range, or portability of haptic devices. We highlight some of our work which show that humans are sensitive by touch to molecular scale changes in surfaces and also examine opportunities for materials innovation from the stimuli responsive and wearables community. We also introduce goals and research overlaps for the symposium to connect members of the materials research community to the haptics community.

10:45 AM *SB08.01.02
Effective Levels of Haptic Signal Complexity for Texture Rendering Across Diverse Displays Rebecca Friesen; Texas A&M University, United States

Our ability to assess and discriminate a vast variety of surface textures relies on densely packed mechanoreceptors embedded in our fingertips, which are exquisitely attuned to both temporal and spatial changes in skin deformation. Texture perception is critical for our ability to identify and evaluate the quality and material of every surface we touch, and dynamic changes in texture can also serve as an intuitive way to haptically communicate information such as finger location or changing dial settings. This range of utility suggests diverse and realistic texture rendering is an important modality to consider for any haptic display. Yet what exactly constitutes "diverse and realistic enough," balancing ability to render a wide breadth of realistic textures using a given haptic display while maintaining efficient signal representation and accommodating actuator limitations?
My recent research focuses on texture rendering for a diverse set of displays, from friction-modulated touchscreens to wearable vibrotactile rings and watches. These devices differ broadly in site of actuation, actuator bandwidth, and concurrent visual displays, but all rely on a vibration applied to the hand during movement as the primary method of texture rendering. We explored various methods of designing new vibration patterns, such as increasing the amount of spectral content or scaling different aspects of the vibration as a function of finger speed.
The impact of these texture design choices were evaluated via psychophysical ratings of both perceived haptic texture differences and similarity to real textures. Results indicate that for higher frequency vibrations, people can differentiate only a very limited amount of spectral complexity, and are also increasingly less sensitive to speed-dependent shifts in frequency. This suggests the set of fine texture sensations achievable via applied vibration alone can be composed using a manageably small set of design parameters and rendered with a few narrow bandwidth actuators.

11:15 AM *SB08.01.03
Multiphysics in the Human-Machine Interface—Impact on Friction and Haptic Perception M Cynthia Hipwell, Xinyi Li, Changhyun Choi, Sitangshu Chatterjee and Aditya Kuchibhotla; Texas A&M University, United States

Haptics is the field that deals with technology that stimulates the sense of touch and motion. Haptic researchers are working to create the same level of fidelity in touch-based recording and display that we currently have in audio and video. Why is this so complicated? One of the many reasons is the complexity of the finger-device interaction and the role that this plays in the generation of touch perception in humans. The finger-device interface is complex and variations with environment and person-to-person can cause finger material property changes that impact device performance and human perception of it. Multiphysics modeling of interfacial phenomena such as capillary forces and surface tension, electrowetting, electrophoresis, multiphase flow, and soft tissue contact mechanics can help predict friction under various conditions and enable purposeful design for consistent or enhanced performance. Examples of design for consistent performance with humidity, design for consumer preference, and consideration and use of temperature will be explored. Additionally, we will consider how human finger property changes can be used as bioinspiration for material design for active friction modulation in clutches and robotic grasping.

11:45 AM SB08.01.04
Skin Biomechanics and the Role of Neural Stimulation in Tactile Perception Sebastian Hendrickx-Rodriguez, Omar Elsafty and Reinhold Dauskardt; Stanford University, United States

Human skin regulates tactile perception of the world around us through interplay of the tissue's material properties and a system of cutaneous mechanoreceptors. However, the relationship between these properties, influenced by skin's hierarchical structure, and how we perceive sensations remains unclear. In this work, we establish a fundamental link between mechanical stresses in the top layer of skin, the stratum corneum (SC), and feelings of skin tightness [1]. We further show that these sensations can be dampened or enhanced via application of various cosmetic formulations [2].

Biomechanical changes in the stratum corneum (~20 m) stimulate cutaneous mechanoreceptors and sensory neurons in softer, underlying layers. Activated afferent neurons send signals to the central nervous system that are interpreted as perceptions. Dehydration of the SC is particularly relevant since water loss results in stiffening (from ~2 MPa to ~100-200 MPa) and contraction (by ~1.5%) of the SC, propagating strain fields into lower layers where they trigger sensations of tightness. Topical skin treatments can either augment tightness by driving more water loss (such as with cleansers), or reduce tightness by helping retain water in the SC (such as with moisturizers). Thin film characterization can measure SC mechanical stresses *in vitro*. Finite element simulations can model the resulting strain fields in full-thickness skin, and predict neuronal firing rates *in silico*. Results can then be compared to consumer perception scores gathered *in vivo*. We show a linear correlation between scores reported by volunteers up to 12 hours post application of cleansing and moisturizing formulations, and SC stresses measured in the lab. Predicted firing rates also correlate remarkably well with consumer scores. This framework can now aid in the development of novel formulations that carefully tune SC stresses for a desired sensation.

In this study, we establish a fundamental link between the SC's biomechanical state and tactile perception, and use this to quantitatively understand the mechanism underlying sensorial perception of our skin in response to topical treatments. This psychophysical framework can be extended to a full range of stimulations provided by haptic devices including wearable actuators and sensors. It also provides a novel way to study the body's sensing system which could serve as inspiration for the design of soft robotics and stimuli responsive materials.

1:30 PM *SB08.02.01
Thermo-Responsive Conducting Polymers Based on PEDOT:PSS Laure V. Kayser; University of Delaware, United States

Designing conductive materials for human-machine interfaces, robotics, and/or haptics requires materials with good electronic properties and mechanical properties close to that of biological tissues. Electronically-conductive hydrogels, composites of crosslinked and water-swollen polymers with a conducting material (polymer or inorganic nanoparticles), can address these requirements. But, two common issues arise from the traditional synthesis of conductive hydrogels. First, the elastic modulus of the hydrogels is increased at the high loadings necessary to achieve electronic conduction. Second, the crosslinking process is irreversible, making it difficult to process the materials in different form factors, inject them for implantable electronics, or remove the hydrogels after use. To address these issues, we have developed conducting polymers that undergo a sol-gel transition close to physiological temperatures: thermo-responsive conducting polymers. We focused on the polyelectrolyte complex of poly(3,4-ethylene dioxythiophene) and poly(styrene sulfonate) (PEDOT:PSS) as our conducting polymer for its high conductivity, low impedance, low toxicity, and dispersibility in water. To achieve thermally-gellable PEDOT:PSS, we used controlled radical polymerizations to create block copolymers of PSS with a thermo-responsive polymer, poly(N-isopropylacrylamide) (PNIPAm), and complex it with PEDOT. At the adequate ratio of each component, the PEDOT:PSS-*b*-PNIPAm block polyelectrolyte complex thereby synthesized gels in water at 37 °C. The gel displays both ionic and electronic conductivity of 0.13 mS cm^{-1} and 0.05 mS cm^{-1}, respectively. The thermal gelation process is completely reversible, providing exciting new opportunities in actuation for robotics or haptics, or injectable conductive hydrogels.

2:00 PM SB08.02.02
Electrically Driven Liquid Crystal Elastomer Actuator Matrix for Haptic Surfaces Giulia Spallanzani[1,2], Pengrong Lyu[2], Danqing Liu[2], Dirk Broer[2], Roel Kusters[1], Darragh Walsh[1], Charlotte Kjellander[1] and Peter Zalar[1]; [1]Holst Centre - TNO, Netherlands; [2]Technische Universiteit Eindhoven, Netherlands

Haptic surfaces are a flourishing research topic at the intersection of electronics, robotics, and biomedical sciences, aimed at the development of thin and flexible devices that mimic human-environment interactions. Liquid crystal elastomers (LCEs) have great potential to drive this innovation, thanks to their unique ability to reversibly actuate to high strains with light or heat exposure. Here, an electrically driven LCE actuator matrix with the potential to be scaled up to large area production is developed. The device functions by LCE thermal actuation driven by the Joule heating of a resistive element. The multilayer actuator array consists of series of active LCE elements coupled with an electronic layer used to interconnect the elements and operate the device. These two layers are then embedded within a flexible substrate which shields them from the external environment and simultaneously amplifies out-of-plane actuation. Such a device can produce local on-demand deformation with no foreseen limitation on the overall size of the matrix. The presented concept shows great potential for applications in texture-changing surfaces or surface-driven object motion, examples of which include self-cleaning surfaces or soft touch massage mats.

2:15 PM *SB08.02.03
Topography via Topology—Localized Stimuli-Response of Liquid Crystalline Elastomers Timothy White; University of Colorado, United States

Liquid crystalline elastomers (LCEs) are functional materials capable of undergoing large, complex deformations in response to stimulus. These deformations are attributed to order disruption between liquid crystalline mesogens incorporated within the polymer network. By controlling the orientation of mesogens during material fabrication, 3D shapes can be programmed into these actuating materials. This talk will detail our strategies for locally programming mesogen orientation to realize complex 3D shapes and topographical surfaces in LCEs.

In order to program mesogen orientation, the liquid crystalline moieties can be oriented before crosslinking the polymer network. One approach that we have taken in this respect is the use of photopatterned substrates as command surfaces for the liquid crystalline monomers. This method enables high resolution programming of local mesogen orientation, enabling a broad range of targeted 3D actuations to be patterned.

In addition to investigating routes to programming orientation during network synthesis, we have also recently explored opportunities for *re*programming the crosslinked materials using dynamic covalent chemistry. Using these LCEs with dynamic bonds, we demonstrate multi-stage programming that combines surface patterning with dynamic bond reconfiguration to realize additional levels of complexity in 3D actuated shapes.

2:45 PM SB08.02.04
Controlling Fine Touch Sensations with Polymer Tacticity and Crystallinity Abigail Nolin and Chun-Yuan Lo; University of Delaware, United States

Fine touch sensation is a critical source of information, especially for those with low vision or blindness. Tactile aids (e.g. braille reader) and surface-haptic interfaces typically produce fine touch sensation by using physical features, such as surface patterned bumps and pins, to alter frictional forces on the user’s finger. However, when interacting with everyday objects, frictional and adhesion forces arise not only from surface topography but also from the chemical properties of a material itself. This work aimed to generate tactile sensations by altering the materials chemistry and microstructure of thin film polymer surfaces with minimized variations in physical roughness. We demonstrated that humans are sensitive to the microstructure of chemically-similar, semi-crystalline polystyrene films due to the influence on mesoscale friction. Through dynamic friction testing with a custom mock finger mechanical test set-up, custom signals analysis, and human psychophysical testing, we demonstrated how materials phenomenon alone may be used to influence fine touch. These material phenomena may extend to broader classes of materials for design of higher graphic haptic technologies and tactile aids.

3:00 PM *SB08.02.05
Progress in the Design of Distributed Electroadhesive Haptic Displays James E. Colgate; Northwestern University, United States

Imagine an interface device that can be programmed to feel like burlap or velvet in much the same way that pixels on a screen can be arranged to look like one of those fabrics. Extending this analogy, we might reasonably ask what information a tactile pixel would need to encode, what pixel density is needed, how an "image" of a texture might be recorded, and of course how the tactile pixels ("taxels") could be designed and made to work. In this talk, I'll review the progress that our group has made in answering these questions.

Our work has been done in the context of "surface haptics." Here, a fingertip – either bare or outfitted with a wearable device – is swept across a physical surface. Virtual textures are created by using electroadhesion (i.e., electrostatic attraction) to modulate the friction at the sliding interface. I will present a simple model of electroadhesion and explain how it can be used to modulate friction at a very high rate, in excess of 50kHz.

Until recently, most of our haptic devices might be considered "single taxel": electroadhesion, although high-bandwidth, occurred in synchrony over the entire finger-surface contact patch. There is a logic to the single-taxel approach: almost a century ago, David Katz proposed the "duplex theory" of tactile perception, suggesting that texture depends upon a "spatial sense" for coarse textures and a "vibration sense" for fine textures, and modern neuroscience has supported the idea that fine textures are encoded temporally, not spatially. In other words, it is reasonable to expect that high-bandwidth control of a single tactile taxel would suffice to recreate realistic fine textures. Unfortunately, this turns out to be wrong. A recent study performed in our lab demonstrated that recording of the skin vibrations caused by sliding over a fine texture followed by precise electroadhesive playback, did not result in realism. Texture playback was perceived to be much weaker and qualitatively different.

In that study, vibrations on the side of the finger were carefully matched, but the mechanics of contact patch interaction may have been quite different between the physical and virtual cases. In particular, some degree of spatial inhomogeneity almost surely occurred during contact with physical textures, even though they were fine. If this is the source of the perceptual discrepancy, then it sheds some doubt on the duplex theory (to be fair, the theory is qualitative in nature and does not establish strict conditions for either fine or coarse texture). A follow-up study performed with a high-bandwidth pin array showed that inhomogeneity does, in fact, play a significant role in subjective experience: greater inhomogeneity leads to greater subjective intensity. Simulations further suggest that two different mechanoreceptor populations are involved: Meissner corpuscles respond strongly to spatiotemporal variation within the contact patch, while Pacinian corpuscles respond to surface waves that propagate up the side of the finger. Single taxel electroadhesion would address only the Pacinian population while physical textures would excite both.

The path to texture realism therefore, appears to require more taxels, even in the case of fine texture. While development of a rigorous specification is ongoing, we are currently targeting 2.5mm taxel spacing and a bandwidth of 300Hz. To realize this in a compact device, we are developing a wearable array of electroadhesive taxels (also known as "pucks"). A 4x4 array has been built on a latex backing with printed silver ink electrodes addressing each taxel. The taxels themselves are made from a commercially available conductive finger cot material, which is a nitrile doped with carbon nanotubes. Puck and fingertip behavior can be imaged through a transparent countersurface (glass with and ITO electrode, coated with SiO2). I will report on preliminary physical and psychophysical results.

3:30 PM BREAK

4:00 PM SB08.02.06
Octopus-Inspired Adhesive Skins for Intelligent and Rapidly Switchable Adhesion Michael D. Bartlett[1], A B M Tahidul Haque[1], Ravi Tutika[1], Chanhong Lee[1] and Eric Markvicka[2]; [1]Virginia Tech, United States; [2]University of Nebraska-Lincoln, United States

Emerging applications in soft robotics and haptic devices demand strong adhesives which can be easily removed on-demand and subsequently reused. This requires new paradigms in adhesive science and engineering to create new classes of multifunctional switchable adhesives. Nature can provide inspiration for these challenging adhesion scenarios. For example, the octopus couples controllable adhesives with intricately embedded sensing, processing, and control to manipulate underwater objects. Current synthetic adhesive–based manipulators are typically manually operated without sensing or control and can be slow to activate and release adhesion, which limits system-level manipulation. Here, we couple switchable, octopus-inspired adhesives with embedded sensing, processing, and control for robust underwater manipulation. Adhesion strength is switched over 450× from the ON to OFF state in <50 ms over many cycles with an actively controlled membrane. Systematic design of adhesive geometry enables adherence to nonideal surfaces with low preload and independent control of adhesive strength and adhesive toughness for strong and reliable attachment and easy release. Our bio-inspired nervous system detects objects and autonomously triggers the switchable adhesives. This is implemented into a wearable glove where an array of adhesives and sensors creates a biomimetic adhesive skin to manipulate diverse underwater objects.

4:15 PM SB08.02.07
Multimodal Sensing and Haptic Feedback to Improve Minimally Invasive Surgery Arincheyan Gerald, Rukaiya Batliwala, Patra Hsu, Jonathan Ye and Sheila Russo; Boston University, United States

Minimally invasive surgical (MIS) procedures suffer from limited haptic feedback to the surgeon and manufacturing limitations for embedded sensing capabilities on surgical instruments. The lack of sensing and haptic feedback results in the application of excessive forces on the tissue. This is exacerbated in instruments such as endoscopes where the tool's flexibility affects transmissions of friction forces, resulting in severe adverse advents (SAEs), such as bleeding, perforation, or splenic injury. Multimodal sensing, such as force monitoring or bleeding detection, combined with direct haptic feedback could be useful in reducing SAEs in colonoscopy. Similarly, haptic feedback combined with multimodal soft sensing could be beneficial in other MIS scenarios such as remote palpation or robot-assisted laparoscopies.

Previously, we created a force sensing soft robotic sleeve to mitigate excessive forces exerted on the colon wall. The sleeve contains optical waveguides and can be mounted directly onto the colonoscope. We further extended our work to develop biosensors that can detect bleeding in the colon. This is particularly important because the surgeon is often unable to detect bleeding as their field of view is limited to the endoscope's distal end camera. It is crucial that these sensors are integrated in a seamless manner that does not impede the functioning of the colonoscope or alter the clinical workflow. Thus, these sensors are designed to be soft and flexible with a low vertical profile (~1 mm). The sensor can easily be mounted onto the colonoscope at multiple points to provide bleeding detection. The sensor is manufactured by molding PDMS onto photolithographically patterned silicon wafers. The sensor contains micron scale soft optical waveguides that interface with a microfluidic channel allowing intake of blood. Presence of blood in the channel causes attenuation of the incident light thereby allowing detection.

To improve MIS, it is important to convey sensing modalities to the surgeon in an intuitive manner. It is essential to develop a comprehensive system that can accurately sense forces and other physical phenomena on the surgical tool, and then directly alert the surgeon through haptic feedback. Thus, we augmented the force sensing capabilities of the soft robotic sleeve by interfacing it with a pneumatic haptic feedback glove. The pneumatic actuators of the glove inflate proportionally to the incident forces on the soft robotic sleeve. Thus, the haptic feedback glove allows the endoscopist to feel the magnitude of forces exerted by the colonoscope onto the colon wall. Additionally, a comprehensive sensing and haptic feedback system can be beneficial in other MIS scenarios. Currently, we are developing a soft sensing and haptic feedback system for robotic palpation of tissue. Since the operator cannot physically feel the palpated tissue, it is difficult to detect the presence of tumors. The palpation sensor can be mounted onto a robot arm, which presses on tissue to detect tumors. The sensor consists of silicone layers of varying hardness embedded with waveguides. As the sensor presses onto tissue, the layers deform around harder areas that may be tumorous. The deformation of the layers causes a change in the waveguide signal. The sensor interfaces with a haptic glove consisting of silicone actuators mounted onto the fingertips. The sensation of tissue palpation can be translated to the user via actuator inflation.

The safety and efficacy of MIS must be improved by not only embedding sensors on the surgical tools but also developing solutions to convey the complex sensing data to the surgeon in an intuitive manner. This highlights the need for haptic feedback to enable the surgeon to process multimodal sensing cues in a manner that complements the clinical workflow. Future works that seek to embed sensing on robotic tools must evaluate optimal methods by which the sensing data is best relayed to the surgeon.

4:30 PM SB08.02.08
A Low-Voltage Electroadhesive Clutch for Untethered Wearable Devices Based on Ionoelastomer Heterojunctions Owen Lee[1], David Levine[2], Gregory Campbell[2], James H. Pikul[2], Kevin Turner[2] and Ryan C. Hayward[1,1]; [1]University of Colorado Boulder, United States; [2]University of Pennsylvania, United States

Electroadhesive clutches (EAclutches) in which frictional blocking forces can be modulated by an applied potential have recently enabled lightweight, compact wearable devices such as haptic clothing, soft exoskeletons, and controllable prosthetics. However, typical EAclutches based on electronic conductors with insulating dielectric layers suffer from low force capacities (1-25 N/cm^2) and operate using large working potentials (> 100 V), requiring tethers to specialized high-voltage circuitry. These performance limitations, along with safety concerns regarding the use of high voltages, have limited the practical implementation of EAclutches for untethered wearable devices. Previous work has sought to reduce EAclutch operating voltage by decreasing the thickness of the dielectric (< 10 µm), however, these devices are challenging to fabricate and are prone to short circuits due to defects or damage. Recently, our group developed a novel class of low-voltage electroadhesives based on oppositely charged polymerized ionic liquid elastomers (termed "ionoelastomers"). The large electric field developed across a nm-scale ionic double layer (IDL) allows for robust and reversible adhesion between two ionoelastomers at comparatively low working potentials (~ 1 V) even with overall layer thicknesses of ~ 100 µm. Despite this promise, high off-state adhesion and poor environmental stability have so far prevented the integration of ionoelastomers into practical EAclutch devices. In this work, a low-voltage, environmentally stable EAclutch based on ionoelastomer electroadhesives is demonstrated. Here, the integration of a perfluorinated comonomer enables enhanced delamination in the off-state by reducing the surface energy of the junction without significantly affecting the capacitive behavior of the IDL. Ionoelastomer EAclutches exhibiting high force capacities (60-80 N/cm^2) at low voltages (5-9 V) are fabricated. The ionoelastomer EAclutch is combined with a soft elastomer, allowing for electroprogrammable stiffness in an untethered kinesthetic haptic device. These findings provide a fundamental understanding of the mechanism of electroadhesion in ionoelastomer adhesives and broaden the scope of EAclutch integration into untethered wearable devices.

4:45 PM SB08.02.09
Poly(ionic liquid) Fillers for Dielectric Elastomer Actuators with Low Driving Electric Fields and High Actuation Performance Hui Wang, Matthew Tan, Wei Church Poh, Dace Gao and Pooi See Lee; Nanyang Technological University, Singapore

Dielectric elastomer actuators (DEA) have commonly been used as haptic devices because of their high actuation strain, quick response, large energy densities and low weight. However, the driving electric field is high, which leads to danger to users and incompatibility with portable power sources. In this work, a soft, stretchable, adhesive, transparent and all-solid-state poly(ionic liquid) (PIL) is introduced as filler into VHB to fabricate DEA. As a result, the dielectric constant increases from 4.8 to ~15 at 1 kHz and Young's modulus decreases to 0.11 MPa. Unlike liquid fillers, possibility of filler leakage reduces, minimizing short circuit which is dangerous to users. DEA with PIL filler delivers high area strain of 137% at 17 V/µm, exceeding that of most DEAs at similar electric field. The unimorph DEA with PIL filler shows a bending angle change of 38.6° under an electric field of 12.6 V/µm, which is over twice the value of the DEA without PIL. Finally, an unimorph DEA integrated with alternating-current electroluminescent layer is demonstrated. This work provides a promising strategy for building a high-performance and safer DEA for haptics.

5:00 PM SB08.03.01
Tunable Soft Optical Sensors for Shape Sensing in Soft Continuum Robots and Multi-Modal Contact Sensing End Effectors Max D. McCandless, Frank Julia Wise and Sheila Russo; Boston University, United States

The design, control, and functionality of soft robotic manipulators and grippers are a growing area of research interest. Recent advancements are pushing toward closed-loop control via embedding proprioceptive and exteroceptive sensing into these soft platforms. Different soft sensing technologies have been explored, i.e., resistive, capacitive, and magnetic. Fully soft optical sensors are useful for both shape sensing and contact force recognition and have been utilized for a variety of soft gripper applications. However, these grippers are often attached to rigid robotic arms, which highlights the need for soft continuum robots with embedded sensing. Soft continuum robots can benefit from the integration of tunable soft optical sensors that provide the systems with real-time 3D shape sensing. The combination of shape sensing soft continuum robots and contact sensitive soft robotic grippers presents exciting application scenarios in minimally invasive surgery (MIS) and high-precision pick-and-place tasks.

Recently, we have developed a roughness tuning strategy for the fabrication of soft optical waveguide sensors (WG) to achieve shape sensing and contact recognition within a single multi-modal sensor. We integrated the sensors into a fully soft continuum robot consisting of a multi-directional bending module and a gripper. The robot module integrates two WGs for 3D shape sensing and three soft pneumatic actuators to steer the robot in all directions. The gripper embeds two soft pneumatic actuators to deploy itself, two soft pneumatic actuators to control grasping, and two WGs, one in each jaw of the gripper, with tuned roughness to monitor both gripper tip positions and subsequent occurrence of contact with an object. The deployment and grasping motions of the gripper cause measurable losses in optical power through the WGs. These losses are utilized to track the tip position of the gripper. Alternatively, when an object is contacted, we observe a distinct increase in the output power of the WG through the system, which allows us to distinguish the tip position tracking from contact recognition and thus create a multi-modal sensor. The proposed system simultaneously tracks the real-time shape of the robot body and the tip positions of the gripper via a graphical user interface (GUI). Furthermore, upon contact with an object, the GUI alerts the user of the successful grasping of an object. The robot module is calibrated so that the shape of the robot is mapped with an electromagnetic tracker throughout its entire workspace. This data is used to determine the true shape of the robot by using a constant curvature model, and then the WG signals are fit to a surface based on the data collected to predict the shape of the system in subsequent testing and controls. The surface fits implemented to use the WGs to predict the robot module shape had an average error of the tip position of less than 4 mm.

Our soft continuum robot can be utilized in a variety of pick-and-place applications where the integration of soft optical sensors can improve the accuracy of the control of soft robotic arms. Further, we have determined that proper tuning of the sensors can result in increased sensitivity across a large range of curvatures and enable a multi-modal sensor response, which allows for a reduced number of total sensors in the robot. These advancements in the tunability of soft optical sensors pave the way toward miniaturized devices and better closed-loop control of soft robots. Providing contact force recognition to continuum robots also pushes toward improving the capabilities of haptic feedback systems that can be integrated with soft sensors and soft continuum robots. Lastly, the low cost and scalable nature of the system presents opportunities for incorporation into a variety of MIS procedures where enhanced dexterity and sensor feedback is valuable for surgeons.

5:00 PM SB08.03.02
MXene-Silver Ink-Based 3D Printed Flexible Haptic Figure Tip Sensor—From Macro Sensing to Micro Sensing Jiaoli Li[1], Yun Li[2], Adam Sawyer[1], Mingyuan Sun[2], Bo Li[2] and Chenglin Wu[1]; [1]MST, United States; [2]Villanova University, United States

Soft sensors have been widely accepted and used in many fields. However, a technological breakthrough is still needed to gain a wider sensing range, faster response speed, and longer durability. In this work, we successfully fabricated an MXene-sliver ink-based interdigitated electrode via direct-ink-writing (DIW) 3D printing technology and assemble it into robotic gloves. Test results have shown the following advantages: (1) ultrafast response time (within several seconds) for surrounding detection at the macro level; (2) extremely accurate detection and object recognition; (3) ultrasensitive detection of omicron virus up to 110^{-22} molar at the micro level; (4) remarkable extension of the sensing range and targets. The 3D printed interdigitated MXene-sliver electrode could work as a figure tip sensor, as a result of being able to feedback continuously output impedance changes for any approaching objects. When functionalized with single-strand probe DNA, it can also work as a virus sensor and captures the target DNA in the environment by collecting signal changes through electrochemical response. This successful demonstration elucidates the broad prospects of MXene-based soft sensors for soft robotic devices.

5:00 PM SB08.03.03
A Self-Powered Triboelectric Tactile Sensing Device Shujia Xu[1,1], Shengjie Gao[1,1] and Wenzhuo Wu[1,1,2]; [1]Purdue University, United States; [2]Regenstrief Center for Healthcare Engineering, United States

Triboelectric sensors has been widely used for tactile sensing due to its self-powered attribute, low cost, and facile fabrication process. High-resolution tactile devices relying on densely arranged sensing units impose significant challenges to fabrication and signal readout for practical applications. Here we demonstrated a new touch-sensing mechanism for triboelectric tactile sensors. A trackpad with 9 sensing units was fabricated using an additive manufacturing method. The device can continuously track 25 touch locations on the panel based on a machine-learning algorithm. We also demonstrated the potential application of such device for user identification based on keystroke dynamics with random touch other than a predefined input sequence. The proposed new triboelectric sensor provide a new direction for TENG-based tactile sensing development leveraging artificial intelligence to boost the sensing performance.

5:00 PM SB08.03.04
Actively Increasing Force Transmission of a Millimeter-Scale Soft Robot for Tissue Interactions in Minimally Invasive Surgery Daniel Van Lewen, Taylor Janke, Harin Lee, Ryan Austin and Sheila Russo; Boston University, United States

Interest in soft robotics is rapidly growing in large part due to the ability to safely interact with humans. The use of soft materials allows for scalable fabrication processes that can combine various degrees of freedom into monolithic structures. Miniaturization enables soft robots to navigate in tortuous, narrow, and difficult-to-reach areas, allowing for broad applications ranging from exploration to minimally invasive surgery. However, force output scales with the robot's cross-sectional area, thus hampering significant robotic tasks and interactions with the surrounding environment at smaller scales.
Here, we present a 3.5 mm diameter soft robot that increases force transmission and, consequently, broadens the potential interactions that may be achieved within similarly scaled environments. These capabilities are accomplished by designing three fluidic-actuated, independent degrees of freedom. The proposed robot consists of a continuum body constructed out of two polymers with differing elasticity and an attached 3 mm linear bellows actuator. The continuum body contains actuation mechanisms for steering via a bending degree of freedom and for stabilization via a radially-expansive actuator. Fabrication of the continuum body is performed through a series of molding processes in which the stiffer of the two polymers, DragonSkin 10, forms the base of the body. Dowel pins run axially along the body for alignment and masking the cross-sectional off-center bending chamber. A 3D masking technique combined with the molded shape of the base are utilized for the creation of the radial stabilization actuator through the over-molding of the less stiff polymer, Ecoflex 00-30. The linear bellows actuator utilizes a layer-by-layer fabrication technology in which the application of heat and pressure bonds each bellow at predetermined locations. The bellows actuator is adhered to the tip of the continuum body to act as an end-effector deployment mechanism enabling the robot to utilize any increase in force transmission provided by the anchoring of the stabilization mechanism.
The increase in force transmission is measured through mechanical characterizations of the robot in states with stabilization activated and unactivated. An increase in the effective stiffness of the system of about five times is measured as a result of stabilization, demonstrating that, for displacements less than 2 mm, the robot can transmit up to 0.75 N of force to the deployment mechanism located at its tip. Characterization of the deployment mechanism further confirms the need for stabilization with blocked forces measuring up to 1.1 N. Results of both stabilization and deployment force measurements validate models that guided the robot design. To characterize dexterity of the robot, bending of the continuum body is measured displaying full retroflexion with a maximum bending angle of 196 degrees. Linear expansion of the deployment mechanism is also measured showing a range of 9.3 mm. The deployment mechanism is assembled with a needle to demonstrate the feasibility of the robot to be used as a platform for minimally invasive tissue biopsy in bronchoscopy procedures. Compared with typical surgical forces, characterizations of the robot verify its ability to puncture stiffer tumor tissues while maintaining safe levels of force on healthy tissue. An in-vitro setup places the robot within a lung model to demonstrate its ability to steer into a desired lung branch, stabilize within the chosen branch, and deploy a needle for tissue biopsy. The proposed soft robot demonstrates the potential benefits of more forceful interactions between miniaturized soft robots and their environments paving the way for the creation of soft robots as advanced surgical tools.

5:00 PM SB08.03.05
Tunable Actuation Response of Humidity-Driven Artificial Muscles by Means of Nanofillers Sevketcan Sarikaya[1], Frank Gardea[2], Hannah Strong[1], Jeffrey T. Auletta[3], David Mackie[3] and Mohammad Naraghi[1]; [1]Texas A&M University, United States; [2]DEVCOM Army Research Laboratory South, United States; [3]DEVCOM Army Research Laboratory, United States

Soft actuators can be driven via environmental humidity and provide biomimetic adaptation to environments. Humidity may serve as a passive stimulus, i.e., the desired actuation may be caused by uncontrolled changes in the humidity of the environment, or active stimuli, i.e., promoting an actuation response by controlling the humidity. Here, we report a humidity-responsive axial actuator and walking robot of sulfonated polyether ether ketone (SPEEK), which shows greatly tailorable actuation performance upon embedding graphene nanoplatelets (GNP). Three cases of SPEEK with no GNP, SPEEK with 0.5 wt.% GNP and 1 wt.% GNP was tested. Adding only 0.5wt% GNP increases the actuation by 50% and provides a maximum actuation stroke of 24% and work capacity of 230 J/kg. In addition, 0.5wt% GNP promotes faster actuation, with significantly enhanced rates of both contraction and expansion. However, the addition of 1wt% GNP slightly decreases the actuation magnitude and rates. The non-monotonic actuation tunability by GNP was correlated to changes in ion exchange capacity (IEC), water uptake, and GNP dispersion. By utilizing actuation magnitude dissimilarity, the axial actuators were converted into a walking robot stacked of two active layers consisting of fibers of the same material system. The bilayer robot demonstrated self-crawling and locomotion ability in response to humidity changes. This study shows a uniquely tailorable humidity actuator that demonstrates both linear and bending actuation.

5:00 PM SB08.03.06
Complete Foldable, Resilient, and Fatigue Resistant Electrode Insic Hong, Seunggon Lee, Yeonwook Roh, Daseul Lim, Dohyeon Gong, Je-Sung Koh, Daeshik Kang and Seungyong Han; Ajou University, Korea (the Republic of)

Development of mechanically and electrically robust electrode that can be completely folded and crumpled without fatigue degradation in substrate and electrode material has been demanded as a core component of next-generation foldable electronics and soft robot. Here, we report a nanocomposite electrode that can be completely folded in half, crumpled, and endure tensile load (3 N/mm) without changing electrical resistance using a simple composite structure consisting of Elastomer, Kevlar, PET film and silver nanowires (Ag NWs). We performed rigorous experimental and theoretical investigations based on the neutral axis and strain engineering, suppressed the plastic deformation causing crease pattern by an unprecedented method encapsulating a plastic substrate with elastomers, and increased tensile strength of the electrode dramatically via aligned Kevlar fiber reinforced elastomer. Furthermore, by successfully applying developed nanocomposite electrodes to a foldable wrinkle-free display and multifunctional sensor, it is expected that our electrode presents a methodology and tool with vast potential for soft robotics and next-generation foldable electronics.

Investigating Sensation Mechanics and Improving Actuation of the Soft Robotic Tongue and Ear from Simulation Selena Rodriguez, Deepak Ganta and Joaquin Contreras; Texas A&M International University, United States

Hepatic-based simulation plays a key role in designing and developing sensors and soft robotics for improving human-like robot interaction and sensing. For example, there is a huge demand for electronic tongues and ears in the food and defense industries for sound or air pressure detection and chemical and flavor analysis. The lack of availability of soft robots with human-like sensory features has motivated us to investigate, design, and simulate a human tongue's complex motions, including that of a human ear.

Human anatomy was studied in detail to modify the standard designs of the human tongue and the human ear. In the tongue model, adding embedded chambers at strategic locations was used to replicate various 3D motions (rolling, groove, twist, and elongation) of the human tongue necessary for improving the bio-chemical sensing capabilities. The FEM (Finite element method) simulations using ABAQUS software showed the relation between pressure and deformation range for various motions in a human tongue, including stress vs. strain relation for investigating the mechanical properties. Similarly, a study was conducted to test the mechanical properties of the human ear, and a load was applied on the ear's outer rim in a downward direction. The behavior of the ear was simulated under various loads, both compressive and tensile testing, to determine the stress vs. strain relation.

High Performance and Deformable Ionic Sensory Platform by Tailoring Gelator Design Jin Han Kwon, Yong Min Kim and Hong Chul Moon; University of Seoul, Korea (the Republic of)

Here, we propose versatile ionic conductors for high-performance, deformable and functional ionic sensory platforms by tailoring the mechanical properties of ionic conductors. For instance, porous ion gels simply fabricated by sugar cube can be effectively deformed by closing pores even with small pressure, a broad variation in the contact surface area of the porous ion gel and electrodes is induced, leading to a dramatic difference in electrical double layer (EDL) capacitance. More interestingly, the functionality of the porous ion gel is extended to include electrochemiluminescence (ECL), resulting in the production of emissive ECL ionoskins. Furthermore, the deformability of ionic conductors is tailored by using binary polymer blends as the co-gelators. To reduce the polymer chain entanglement of polymer gelators and induce effective dissipation of applied stresses, flexible and low glass-transition temperature(Tg) polymer is additionally doped into the relatively hard and high Tg polymer based-ionic conductors. The optimized ternary blend ionic conductors exhibit outstanding stretchability, mechanical elasticity and durability, indicating high feasibility for strain sensory systems.

Bioinspired Vibration-Resistant Sweat-Tolerant Haptic Adhesion Interfaces Jinhyung Kim[1], Da Wan Kim[1,2], Gui Won Hwang[1], Hyeongho Min[2], Jihyun Lee[1], Dohyun Lim[1], Tae-Heon Yang[3] and Changhyun Pang[1,2]; [1]Sungkyunkwan university, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Korea National University of Transportation, Korea (the Republic of)

Polymeric adhesives, which are thin, soft and flexible, with skin conformal interfaces are attractive for haptic interface technology capable of transmitting sophisticated mechanical stimulation. However, conventional polymeric skin adhesives cannot maintain adequate shear adhesion to the haptic interface, such as repetitive vibrations or sweaty skin. Here, we report skin adhesive patches inspired by the hybrid architectures of frog toe pads' water-drainable hexagonal arrays and snail pedal muscles' energy dissipation layer with interlocked structures. Hybrid frog-snail-inspired adhesive (FSIA) patch exhibits remarkable shear adhesion in both dry and sweaty conditions (max. ~36.0 kPa in dry conditions, and max. ~26.8 kPa in sweaty conditions). Adhesion force enhanced by the stress distribution was analyzed as a simple theory based on the capillary, elastic, and dissipation stresses, and the finite element method simulation according to the geometric and material parameters. Furthermore, we showed that the microchannels between the hexagonal arrays effectively drains the liquid in sweaty conditions. Our patch could tolerate high-frequency vibrations (~60 Hz) while maintaining vibrational transmissibility on even sweaty skin. For potential application, we demonstrated an integrated system combining skin-attachable patches with thin vibration actuators. Our haptic adhesion interface may establish new strategies for developing VR/AR technology.

5:00 PM SB08.03.10
A Multifunctional Pressure and Strain Sensor for Tactile Compliance Identification Arielle E. Berman[1], Chengyi Xu[1], Rahul Singh[2], Levent Beker[2] and Zhenan Bao[1]; [1]Stanford University, United States; [2]Koç University, Turkey

The development of human-like tactile sensation is vital to the advancement of robotic manipulation and the completion of highly nuanced tasks. A fundamental way humans understand and interact with their surroundings is the classification of touched object compliance, or the inverse of stiffness, via the activation of mechanoreceptors in the skin. Specifically, slow adapting (SA) I and II receptors, which sense pressure and skin stretch, respectively, are both needed to perceive compliance. We propose that such a functionality can be replicated with a multifunctional pressure and strain sensor fabricated from digitally printed conductive structures impregnated into an elastomer, such as styrene-ethylene-butylene-styrene thin films. Here, we design a novel device structure that combines pressure and strain sensing at the same pixel location, which has the potential to improve spatial accuracy and enable increased taxel density in an array. Although existing literature has reported object identification technologies, these devices require a known and controlled force or displacement. On the other hand, this work proves that both inputs can be sensed independently and are, thus, inherently deconvoluted. Additional advantages over the state-of-the-art include this device's stretchability and thin form factor. When integrated with robotic systems or eSkins on prosthetics, this novel biomimetic sensor can provide sophisticated sensory feedback for force modulation, safer human-robot interactions, and natural sensation on artificial limbs.

5:00 PM SB08.03.11
Arbitrarily Shape-Manipulation of High Stiffness Electronic Composite through Shifting Neutral Surface of the Material Dohyeon Gong, Yeonwook Roh, Changhwan Kim, Suhyeon Hwang, Dongwook Shin, Daseul Lim, Insic Hong, Doohoe Lee, Je-Sung Koh, Daeshik Kang and Seungyong Han; Ajou Univ, Korea (the Republic of)

Transformation a sensor of 2D type into 3D structure can realize a differentiated function. A sensor for 3D structure must be consisted of a thin or low-stiffness material to avoid a failure of sensor's electrode. However, when the sensor was transformed the 3D structure, it requires additional tools to maintain the 3D structure, because the structural stiffness is not sufficient. In this study, we produced an electronic composite that can be flexibly bent and transformed into an arbitrary 3D shape and maintain the transformed shape due to sufficient structural stiffness after deformation using the principle of moving the neutral surface of Shape Memory Polymer (SMP). This sensor is a multi-layer composite in which SMP embeds a high sensitivity crack-based sensor. The SMP has low stiffness (2.2 MPa) at high temperature (60 °C), so the electrode is not broken during transformation, and has high stiffness (1200 MPa) at low temperature (25 °C), so it may maintain a 3D shape even after transformation. For this reason, the composite initially made in 2D form can be transformed into three 3D structures. Each structure is activated to detect external stimuli that are not detected in the initial form; Large strain (2 to 35%), Small pressure (1 to 30 kPa), Small bending (1 to 15 °). In addition, even after transforming to all 3D shapes and returning to the initial shape, there was also a reversibility in which the resistance didn't change at all. Based on these results, we demonstrate that high stiffness electronic composites that can transform into arbitrary 3D shapes and maintain the transformed shape.

5:00 PM SB08.03.13
Realistic Haptic Rendering Based on Piezoelectric Multimorph Actuators for Human-Interactive Tactile Communication System Yulim Min[1,2], hanbit Jin[2], YunJeong Kim[2], Jeongnam Kim[1,2], Osman Gul[3,2] and Hye Jin Kim[2]; [1]UST, Korea (the Republic of); [2]Electronics and Telecommunications Research Institute, Korea (the Republic of); [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In an immersive virtual interaction, realistic sensory devices allow users to provide richer experiences such as vision, hearing, touch, smell, and even taste. Recently, several haptic devices including tactile gloves [1], full-body haptic suits [2], and joysticks [3] are interesting and significant attention for human perception. However, most commercial haptic solutions are insufficient to fully immerse users in virtual environments due to the haptic feedback which is not similar to the real-like feeling. To enable sophisticated tangible interactions, it is essential to reproduce the realistic haptic signals using rendering technology in haptic interfaces between the sensor and actuator. In this study, we proposed a human-interactive tactile communication system using a piezoelectric multimorph actuator capable of both sensing and actuating functions simultaneously. The piezoelectric actuator was designed with multimorph structure with improved displacement (> 800 um) than the traditional PZT ceramic. Our actuator also exhibited uniform vibrations with input signals of frequencies ranging from 1Hz to 1kHz. which is within the perceivable frequency ranges of the human Pacinian corpuscle. To demonstrate the proposed system, 3 different textures are prepared to represent the smooth and rough feeling of the surface. While dragging the textures with the device attached to the fingertips, the signals obtained from the self-sensing actuator are classified by principal component analysis (PCA) with high accuracy of 96 %. Subsequently, rendered signals are generated by extracting key features such as the envelope of the waveform, main frequency, and amplitude based on the PCA. Finally, the actuator reproduces the rendered haptic feedback in real-time. The tactile sensing/actuating communication system is utilized in fields of artificial skin for robotics, and remote tactile communication in virtual reality.

5:00 PM SB08.03.14
Color-Changing Miniature Heater Array for Emotional Expression DooSeung Um[1], Se-jin Kim[2,3], Qiang Liu[2], Mi-Jin Jin[3] and Chang-Il Kim[2]; [1]Sejong University, Korea (the Republic of); [2]Chung-Ang University, Korea (the Republic of); [3]Institute for Basic Science, Korea (the Republic of)

Recently, attempts to connect the virtual reality world with the real world have been actively conducted. Haptic devices that make you feel like you are interacting with real objects are at the center of the metaverse technology because they can make virtual reality more realistic when you interact with objects in virtual space. In order to further enhance the sense of reality, it is important to transmit various sensations to the human skin. In particular, Warmth, which expresses feelings of comfort and love, is important for expressing emotions. Therefore, we developed a functional miniature heater array that changes color depending on temperature change. A miniature heater array was integrated through the patterning process of silver nanowires. A thermochromic liquid crystal film was stacked on the heater array to visually represent the change in temperature. Moreover, this device was integrated into a flexible substrate (polyimide) to attach to the human skin or gloves.

4D Printing of Liquid Crystal Elastomer Fibers with Programmable Bending Sasha M. George, Taylor H. Ware and Manivannan Sivaperuman Kalairaj; Texas A&M University, United States

Liquid crystal elastomers are a class of shape-changing polymers capable of undergoing reversible shape changes in response to changes in temperature. Our goal is to create fibers of liquid crystal elastomers with a nematic to isotropic transition temperature that is sufficiently low to enable use in wearable, active textiles. A two-step reaction is used for the synthesis of the fibers. The first reaction is the Michael addition of a nematic diacrylate monomer with a dithiol. The resulting thiol-terminated liquid crystal oligomer can be extruded, creating long fibers on a rotating mandrel. The diameter of the fiber can be tuned from 210 um and 750 um based on the different speeds of mandrel rotation. During the printing phase, the fibers undergo a photocuring process to crosslink the aligned oligomers by a thiol-ene click reaction with a triallyl crosslinker. By varying the intensity of UV light, we can achieve different amounts of bending of the fibers. With the lower values of UV intensity, we observed that one side of the fiber contracts more than the other side resulting in bending. Fibers with 36% ± 6 reversible actuation strain between the temperatures of 25°C and 60°C have been synthesized with higher contractions ratios achieved by combining this strain with the bending of the fibers. As these fibers have significant actuation around body temperature, these fibers may be used for biomedical applications and active textiles.

5:00 PM SB08.03.16
Haptic Interface Systems Based on Low-Voltage Ionic Polymer Actuators Hyeonseong Ham and Moon Jeong Park; POSTECH, Korea (the Republic of)

Ionic electroactive polymer (EAP) actuators are promising candidates for wearable electronics, including artificial muscles and flexible haptic devices owing to their low-voltage operability and flexible form factor. Yet, major challenges remaining are the slow switching speed, low blocking force and lacks of motion control in real-time. Herein, we report haptic interface systems based on a sensing glove and sensor-integrated ionic EAP actuators, allowing the teleoperation of soft grippers. By using bifunctional polymer electrolytes and soft-conducting electrodes, fast switching speed and high mechanical strength were achieved simultaneously under 1.5V conditions. This enabled the development of efficient haptic feedbacks at the finger without the need for high external voltage. With an aim at controlling the actuation motion in real-time, a liquid metal strain sensor was integrated into both the ionic EAP actuators and sensing glove. The sensor signal was changed according to the degree of bending of fingers wearing the sensing glove, and an algorithm was generated to synchronize the resistance change with the mechanical deformation of sensor-integrated actuators. The physical contact between the object and soft gripper fabricated with sensor-integrated actuators was simultaneously estimated through the sensor signal generated from the actuators, which was delivered to the fingertip as haptic feedback. Given that the haptic feedback system can be operated with small portable batteries, this will be a platform in soft robotics, wearable haptic devices and biomimetic devices.

5:00 PM SB08.03.17
Electrostatic Actuation of a Liquid Crystal Elastomer with Three-Dimensional Electric Field Modulation Choi Moon Young[1], Keumbee Kim[2], Suk-Kyun Ahn[2] and Jun-Hee Na[1]; [1]Department of Convergence System Engineering, Chungnam National University, Korea (the Republic of); [2]School of Chemical Engineering, Pusan National University, Korea (the Republic of)

Liquid crystal elastomers (LCE) have gained enormous attention in the recent past because of their facile fabrication and reversible shape morphing when exposed to external stimuli such as heat, light humidity, and magnetic or electric force. Especially among these, the electrostatic force has several advantages including fast response, easy control, and low power consumption. Mostly, Maxwell's stresses have been employed to control the shape morphing of LCE, but electrode patterning is limited. Therefore, we propose a new type of stimuli to control the LCE based on electrostatic forces generated because of charge transfer between electrodes and LCE. As a result, we demonstrated various types of operations with a high degree of freedom by applying electrostatic forces. The above result could be achieved through three-dimensional control of the electric field according to the structure of the electrode and the application signal without a pre-program in the LCE samples. We believe this study will be very useful for developing LCE-based actuators for various operations using electrostatic control methods with a variety of electrode designs and field modulation.

Role of Fingertip Friction in the Tactile Perception of Surface Materials Roland Bennewitz, Maja Fehlberg, Kim Michéle Jost, Sairam Saikumar and Victor Infante; Leibniz Inst for New Materials, Germany

Fingertip friction plays a key role in the stimulation of tactile perception upon sliding touch. We present psychophysical experiments with materials, whose tactile perception is dominated by their surface microstructure. Random roughness at the length scale of the finger ridge distance contributes more to the tactile perception of similarity than the resemblance of surface topography [1]. For micro-fibrillar surfaces, tactile perception follows the bending stiffness of fibrils rather than the elastic moduli or the length of fibrils [2]. The perception of frictional strength in sliding touch can be confused if the characteristic length scale of surface microstructure varies [3]. Finally, physiological characterization reveals the soft matter properties of fingertip skin and their influence on tactile perception of materials.

8:30 AM SB08.04.02
The Role of Rigidity in Soft Robotic Fabrics Rebecca Kramer-Bottiglio[1] and Xiaonan (Sean) Huang[2]; [1]Yale University, United States; [2]University of Michigan–Ann Arbor, United States

Fabrics are breathable, conformable, and compactible interlaced fiber structures, which makes them the perfect material for wearables, among many other everyday applications. Given their ubiquity, the possibility of "roboticizing" fabrics could lead to smart adaptive clothing, self-deploying shelters, and lightweight, stowable, shape-changing machines. Ideally, a robotic fabric's actuation, sensing, and structural support should be provided by fiber-based components, designed to integrate seamlessly with the fabric's soft and conformable nature. Variable-stiffness mechanisms are often used for the structural elements, functioning as "bones" that can be turned on and off as needed. However, many available fiber-based variable-stiffness mechanisms are passively rigid, only allowing the fabric to become soft when powered, and others require bulky external air or power supplies, making them untenable for untethered robots. In this talk, I will present a new electrically-driven variable-stiffness fiber that can provide a rigid load-bearing structure when powered, but remains flexible otherwise. The active variable-stiffness fibers are stable enough for a robotic fabric to lift and locomote with its own battery pack and onboard electronics, enabling a fully untethered locomoting robotic fabric. I will also present new fabric capacitive sensors that exhibit high strains, cyclic stability, and high water-vapor transmission rates, the latter of which allows for sweat evaporation, an important parameter of comfort in wearable applications. Finally, I will speculate on the combination of the fabric sensors with actuated and variable-stiffness fabrics for human motion monitoring and haptic feedback.

8:45 AM SB08.04.03
Enhancing Actuation Response in Haptic Displays Utilizing Nanoparticle-Based Magnetorheological Elastomers Ludovico Cestarollo[1], Shane Smolenski[2,1] and Amal El-Ghazaly[1]; [1]Cornell University, United States; [2]Bowdoin College, United States

Despite the importance of touch for humans, interactive tactile (haptic) displays can still be considered in their infancy. While several actuation techniques have been developed, all these methods still present major drawbacks either in terms of the power demanded for actuation or their large size, thereby discouraging their use in high-resolution haptic displays. *Magnetorheological elastomers* (MREs) constitute an ideal candidate for a low-power and compact solution to be integrated into a programmable haptic interface. MREs are smart composite materials made of a soft elastomeric matrix and magnetic micro-/nanoparticles. Few studies have focused on the actuation of MREs, and those that do, mostly report the use of relatively large magnetic microparticles inside of elastomeric matrices. In contrast, much smaller nanoparticles would be required to fabricate films on the order of hundreds of nanometers in thickness, able to actuate into sharp textures at the microscopic scale. This research project focuses on building *high-resolution* haptic interfaces by developing flexible magneto-responsive thin-films based on magnetic *nanoparticles*. In the future these materials will be integrated into a nonvolatile magnetic control system that can produce local magnetic fields to actuate the film and generate the desired resolution of three-dimensional shapes and textures.

In this study, we fabricated MREs composed of soft, low-remanence ferromagnetic iron nanoparticles with isotropic and anisotropic arrangement in an elastomeric matrix (Ecoflex 00-30) and optimized them by characterizing their magnetic and mechanical behavior. Films with nanoparticle concentrations varying between 2% and 8% by volume were fabricated. All films showed large visible deformations at the millimeter scale at small applied magnetic fields of only 100-300 mT. However, the magnetically-induced deformations increased with the nanoparticle concentration in the films up to 6 vol. % for both isotropic and anisotropic films. Furthermore, isotropic 6 vol. % films exhibited 1.6x the deformation of anisotropic films at the highest applied field (300 mT). These isotropic films were able to achieve deflections of 0.73 mm and 1.6 mm at 100 mT and 300 mT, respectively. Moreover, we characterized the morphology of magnetic particles from SEM cross section images of the optimal 6 vol.% isotropic and anisotropic films. While the isotropic films showed random dispersion of the nanoparticles in the matrix, the anisotropic ones confirmed preferential alignment of the nanoparticles along the magnetization direction. The magnetic hysteresis behavior of isotropic and anisotropic films was measured to visualize the difference in remanent magnetization between the two cases and a small but evident increase in magnetic anisotropy matched the particle arrangement of the anisotropic films.

To compare with the literature, identical MRE films were also fabricated utilizing soft iron microparticles. In comparison with the nanoparticle-based anisotropic MREs, at a field of 100 mT, the analogous microparticle-based films showed 25-30% lower deflection. The latter were only able to match the nanoparticle films' deflection at higher fields of almost 300 mT. This performance difference between nanoparticle and microparticle films was attributed to the increased anisotropic film stiffness resulting from the larger micrometer-size particles. Finally, the optimal nanoparticle-based isotropic MRE was utilized to create an enlarged programmable braille display which can be refreshed real time by actuating the deflection of specific buttons to construct different letters and words. In conclusion, this research showed for the first time the benefits of utilizing nanoparticles to engineer MREs with enhanced magnetomechanical response, enabling the realization of a reconfigurable haptic interface prototype with the potential for scalability and the promise of enabling numerous future haptic innovations.

9:00 AM SB08.04.04
A Monolithic Fabrication Strategy for Millimeter-Scale, Self-Sensing Actuators Hun Chan Lee, Nash Elder, Matthew Leal, Sarah Stantial and Sheila Russo; Boston University, United States

Advances in soft robotic technology helped to overcome many challenges in minimally invasive surgery by improving dexterity, flexibility, and safety. However, there are tradeoffs as well in using soft robots for surgical applications including complicated fabrication and assembly processes, low output force, poor controllability, and limited sensing functionality. The confined, tortuous workspace of minimally invasive surgery adds additional challenges, such as restricting the size of a robot to a millimeter scale and requiring a wide range of motion for navigation. Thus, the fabrication of these millimeter-scale soft robots becomes more delicate and convoluted, resulting in inconsistent fabrication outcomes. The manufacturing and assembly process becomes more onerous as the number of sensing and actuation elements increases. In addition, the control of these soft robots can be complicated due to the nature of their non-linear behavior, requiring computationally expensive control algorithms. Likewise, some aspects of mechanical performances (i.e., output force and torque) are limited due to the use of low elastic modulus materials. Bridging these gaps, we present the design, fabrication, and characterization of programmable composite actuators (PCAs). PCAs implement the concept of using an ionic solution as a working fluid for actuation and as a sensing medium for self-sensing. Unlike other soft robots, which require a manual assembly process to combine two discrete components, an actuator and a sensor, PCAs seamlessly integrate actuators and sensors into a single unit by embedding both self-sensing and actuation capabilities in a monolithic laminate structure. Leveraging a layer-by-layer fabrication method, PCAs are manufactured by stacking and bonding various types of films (i.e., rigid, flexible, soft, adhesive, and conductive films). PCAs include three components: 1) soft, inflatable Teflon balloons, 2) a rigid-flexible origami structure, and 3) conductive electrodes for self-sensing. The soft, inflatable balloons consist of adhesive films and Teflon films whose surface is chemically modified by using hydrogen plasma to promote adhesion. The Teflon films are selectively bonded to create multiple bellow-shaped actuation chambers. By fluidically inflating these chambers, the flat Teflon balloons can be transformed from 2D to 3D bellow shapes, producing motion. Similarly, the rigid-flexible origami structure is fabricated by selectively bonding rigid (i.e., fiber-reinforced epoxy laminate) and flexible (i.e., polyimide) films, and it surrounds the soft, inflatable Teflon balloons. Encompassing the soft, inflatable Teflon balloons, the origami structure helps to increase the output force of the actuator, and it mechanically programs the actuator to produce various types of motion and degrees of freedom in an actuator (i.e., extension, bending, and rotation). The conductive electrodes are composed of copper and graphene films embedded within the actuator to perform as a proprioceptive ionic sensor when the ionic solution is used as a working fluid. Thus, the position of the actuators can be sensed by measuring the change in impedance across the electrodes, which depends on the volume of the balloons. To further understand the performance of these PCAs, they are characterized in terms of the range of motion and output force. In addition, multiple PCAs are combined as a continuum robot to demonstrate their potential usage as a surgical robot for minimally invasive surgery.

9:15 AM SB08.04.05
A Self-Powered, Single Sensor for Both Dynamic and Static Pressure by Mimicking the Sensory Adaptation Behavior of Skin Ey-In Lee and Jin-Woo Park; Yonsei University, Korea (the Republic of)

The tactile sensor can be applied to various technical fields like electronic-skin technology, human-machine interface, prosthetics, and robotics. Particularly, the technology with feedback systems like haptic interfaces necessitates a sensitive, multimodal, flexible sensor for an actuator to give elaborate tactile sensations to the users. Pressure, one of the most important stimuli that the haptic interfaces should acquire, can be divided into two concepts: dynamic pressure and static pressure. To elaborately sense and apply the sensations of the pressure, it is crucial to detect the moment of the pressure application and whether the pressure application is continued. Like as mechanoreceptors of the human skin are divided into fast-adapting mechanoreceptors (Meissner corpuscle, Pacinian corpuscle) and slow-adapting mechanoreceptors (Merkel disc, Ruffini corpuscle), researchers integrate two sensors that detect dynamic and static pressure each into a single platform to discriminate the dynamic and static pressure. However, the integrated sensing system is inconsistent with the direction of the tactile sensing-related technology development that continues to develop as a system containing the sensing ability of various stimuli generated by the humans or external environment and the feedback control to interact with humans. While wearability and implantability of the system are developed for high compatibility with humans, a conventional integrated sensing system with batteries and signal processors is bulky, limits continuous operation with a fixed energy capacity, and restricts practical usage due to frequent charging. Accordingly, the integrated sensing system with energy issues and the volumetric problem is inadequate for human-linked technology. In this work, we propose a self-powered, single sensor with a compact structure using piezoelectricity and ionics as sensing mechanisms with mimicry of the sensory adaptation behavior of the human skin. Piezoelectricity is responsible for detecting dynamic pressure, and ionics is responsible for detecting static pressure and expressing the sensory adaptation behavior. Since the piezoelectric materials can only respond to dynamic pressure, we introduced the ions slower than the piezoelectric charges to sense the static pressure. Since the ions can hold the piezoelectric charges from moving to the electrode, they delay the charges from being measured by the instrument. The static pressure can be detected by analyzing a prolonged piezoelectric voltage output achieved from the introduction of the ions. We utilized the piezoelectric polymer, poly(vinylidene fluoride-*co*-trifluoroethylene) (P(VDF-TrFE)), and ionic liquid, 1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([EMIM][TFSI]) to achieve intrinsic mechanical flexibility and non-volatility of the sensing layer. Electrochemical impedance spectroscopy verified the stable sensor fabrication and the equivalent electrical circuit of the tactile sensor. Emulated systems based on EIS data proved the sensing mechanism and sensory adaptation behavior quantified by the decay constant. With sensory adaptation behavior, the sensitivity of the dynamic pressure increased about 4.4 times, and the sensitivity of the static pressure increased about 4 times. The tactile sensor with sensory adaptation behavior can detect the overlapped stimulus upon sustained pressure with higher sensitivity. The tactile sensor that can elaborately analyze the pressure and sense the overlapped stimulus is vital in a stimuli-flourishing environment where it is more important to detect newly applied stimulus than sustained one.

9:30 AM SB08.04.06
One Pot Multimaterial Photochemistries for Mechanical Gradients in Soft Wearable Tech Thomas Wallin; Reality Labs Research at Meta, United States

Seamless multimaterial construction, particularly joining soft, stretchable tissues with stiff, inextensible structures, is a common motif in animal physiology. Such continuous mechanical gradients remain challenging to reproduce in engineered systems as current resin chemistries typically result in a single fixed set of properties. As an alternative to single-property materials, we introduce a ternary sequential reaction scheme that produces multimaterials by profoundly altering the polymer microstructure from within a single resin composition. In this system, the photodosage during 3D printing sets both the shape and extent of conversion for each subsequent reaction. The different polymerization mechanisms of the subsequent stages allow our single photochemistry to exhibit a diverse range of soft (Young's Modulus, E ~ 400 kPa; ultimate elongation, dL/L0 ~ 300%) and stiff (E ~1.6 GPa; dL/L0 ~ 3%), providing the capability to match the mechanical properties of commercial polymers and biological tissues. Further, we successfully pattern photostable and mechanically robust modulus gradients (d[Er,stiff/Er,soft]/dx > 1000 mm-1) that exceed those found in squid beaks and human knee entheses. We demonstrate the ability to 3D print intricate multimaterial architectures by fabricating a soft, wearable braille display.

Soft Haptics for Virtual Reality and Tele-Operation Applications Femke van Beek; Eindhoven University of Technology, Netherlands

Humans are experts at using soft touch to efficiently manipulate a vast range of objects in a variety of situations. In several application domains, rigid robotic solutions such as exoskeletons and vibrotactile gloves have been designed in an attempt to tap into this human potential. In our lab, we are exploring soft robotic solutions for creating more comfortable and more compelling haptic displays. With these displays, we hope to enable a soft touch in Virtual Reality and tele-operation applications. In this talk, I will present our work on design, control and attachment strategies of these soft displays. I will also discuss our recent perceptual experiments in which we directly compare task performance of humans wearing rigid and soft haptic feedback displays.

10:30 AM SB08.05.03
Programming Complex Shapes in Soft Electrically-Active Materials Nakhiah Goulbourne; University of Michigan–Ann Arbor, United States

Electrically-activated elastomeric materials hold great promise to bring alive the dream of autonomous life-like soft robots. Fast actuation of materials that match the compliance and rheology of biological materials could enable breakthroughs in realistically mimicking the rippling fin motion of a cuttlefish, the dynamic acrobatics and dexterity of the bat wing membrane during flight, and even simulate the contractions and twists of arteries and the left ventricle of the heart. There have been several soft materials proposed to date ranging from very soft hydrogels to shape memory polymers whose shape change can be triggered by heat, magnetic field, electric field, and light. Of the soft active materials investigated to date, dielectric elastomers have garnered significant interest due to their nontrivial and reversible fast deformations in response to an external stimulus. Another soft elastomer demonstrating large deformations are liquid crystal elastomers via light and thermal actuation near their phase transition temperature, and more recently via electric field when configured as a planar capacitor. We discuss programming complex three-dimensional shapes using soft electrically-active elastomeric materials by controlling the anisotropy and mode of electric activation. The programming is achieved by patterning contractile fibers and selective activation. We introduce a computational model for simulating the shape-changing phenomena. The model is based on a new constitutive formulation within a finite viscoelastic framework. Computational implementation using a finite element user-subroutine allows us to simulate the complex shape response. Several examples of the achievable 3D complex shapes are demonstrated.

Soft Haptic Interfaces and Soft Surgical Robots Sheila Russo; Boston University, United States

Minimally invasive surgical (MIS) procedures, such as interventional flexible endoscopy, present several advantages to traditional surgery including shorter recovery time, less trauma, and lower risk of infections. However, MIS is more technically demanding for the surgeon, entailing limitations in visual (limited field of view, low spatial and chromatic resolution), motor (dexterity), and haptic (reduced perception and tactile information) functionalities.
This talk will highlight our recent work in the design, materials, manufacturing, and development of soft sensing technologies and wearable, textile-based, haptic interfaces that aim at restoring and amplifying sensor and haptic feedback directly to the surgeon's hand to facilitate navigation and improve safety during colonoscopy.
First, a new class of soft surgical robots (i.e., soft reactive skins) will be discussed. Soft reactive skins are thin, conformable robots with distributed sensing and actuation, that can be wrapped around traditional medical instrumentation to augment their functionalities. Our research group (the Material Robotics lab at Boston University) has explored these devices to sense and react to inputs like contact force, bending, shape, and bleeding during colonoscopy.
Second, our progress on soft robotic wearable haptic interfaces will be discussed. The talk will highlight our efforts in materials and manufacturing towards an ergonomic, lightweight, flexible, and comfortable-to-wear design. Through a user study, we assessed the mental workload and benefits of the haptic interface in a simulated colonoscopy scenario. The device is transparent while performing tasks, and could be worn and removed with minimal to no assistance.
The talk will conclude by discussing potential future applications of soft surgical robots and soft haptics in other minimally invasive surgical scenarios, like interventional bronchoscopy and endoscopic brain surgery.

Digital Light Processing 3D Printing Dielectric Elastomer Actuator for Haptic Device Peiwen Huang, Hongbo Fu and Pooi See Lee; Nanyang Technological University, Singapore

Haptic devices have attracted attention for application in automotive, telecommunication, braille communication, virtual reality, augmented reality, and medical healthcare. Dielectric elastomer actuators (DEAs), a kind of soft actuator based on electroactive materials, possess great potential for haptic devices because of the advantages of their lightweight, large displacement, fast response, and physical properties similar to skin. However, the force output generated by a single-layer DEA is limited, and can only be used in areas with high haptic sensitivity like the fingertips and the back of the hand. To expand the applicability, stacking multilayer DEA devices is a common approach to obtain larger actuation performance but can be tedious in preparation and are often low in device stability. Moreover, multiple actuators with various shapes and sizes are needed to be integrated into haptic devices for different applications, further extending the fabrication time and incurring difficulty in their fabrication. Hence, there is a compelling need for printing or molding processes that could address these challenges.
In our work, digital light processing (DLP) 3D printing is introduced to print the dielectric elastomer structure and realize the fast fabrication of multilayer cylinder DEAs. The printable elastomer resin is prepared by mixing epoxy aliphatic acrylate (EAA) and an aliphatic urethane diacrylate (AUD)-based material. The printed elastomer has a high dielectric constant of 7.3 and Young's modulus of 800 kPa at 10% strain. The DEAs can be fabricated by injecting carbon grease as the compliant electrodes into the designed cylinder channels made from the resin and sealing the ends with silver paste. The final cylinder DEA has 1 cm in diameter and 1 cm in height. The freestanding multilayer DEA has a blocked force of 120 mN and a free displacement of 50 µm under a voltage of 6 kV. The DEA can also maintain about 40 % actuation performance under a 100 Hz AC voltage, enabling a vibrotactile response perceivable through different body parts other than fingertips. In addition, the DLP 3D printing process allows multiple DEA devices to be prepared at the same time, which largely shortens the manufacturing time and enables the integration of multiple haptic devices. Overall, this process offers new opportunities for the development of haptic devices based on dielectric elastomer actuators.

Stimuli-Responsive, Morphing Liquid Crystal Elastomer Structures and Electronics for Intelligent Systems Xueju Wang; University of Connecticut, United States

Intelligent systems with capabilities of sensing, actuation, and closed-loop control are promising for many applications such as augmented reality, rehabilitation, and soft robotics. In this talk, I will present our work on stimuli-responsive materials, structures, and electronics toward this effort. I will start with our study on liquid crystal elastomers (LCEs), a type of smart material that has capabilities of soft elasticity and large, reversible shape-changing behaviors due to liquid crystal-polymer network couplings. Through introducing a versatile mechanical programming technique, previously inaccessible reconfigurable three-dimensional structures made of LCEs and their magnetic composites are created and their potential applications in soft robotics are demonstrated. I will further present our facile strategy to locally tailor the stiffness and the morphing behavior of these reconfigurable LCE structures by harnessing molecular-material-structure interactions, i.e., locally controlled mesogen alignment and crosslinking densities. Selective photopolymerization of spatially aligned LCE structures yields well-controlled lightly and highly crosslinked domains of distinct stiffness and selective permanent mesogen programming, which enables various previously inaccessible stiffness-heterogeneous geometries, as demonstrated in diverse morphing LCE structures via integrated experimental and finite element analysis. Furthermore, reprogramming of the non-photopolymerized regions allows for reshaping, as shown in a sequentially shape morphing LCE rod and "face". The heterogenous morphing LCE structures have the potential for many applications including in artificial muscles, soft robotics, and many others. In addition, a simple strategy for creating 3D thermochromic LCE structures with synchronous shape-morphing and color-changing capabilities for biomimetic robotics will also be introduced. I will conclude my talk with soft sensing devices for in situ pressure measurements, beyond the actuation capabilities enabled by LCEs. The introduced actuation and sensing strategies and concepts are promising for many intelligent platforms.

Haptic Biomaterials as Tools for Understanding and Manipulating the Tactile Sense Darren J. Lipomi; University of California, San Diego, United States

Most clinicians would not trade their sense of touch for even the most powerful imaging tool or surgical robot. Indeed, touch has played a critical role in diagnosis and treatment since prehistory, and is central to most branches of internal medicine. Clinicians rely on touch for all procedures performed by hand, e.g., tracheotomy, venous catheterization, routine orthopedic, obstetric, and urological procedures, most surgeries, and many forms of physical therapy. Despite the ubiquity of touch in medicine, haptic technologies are underdeveloped. For example, plastic and rubber models do not come close to mimicking the feel of biological tissue, and they cannot be reconfigured dynamically in a training environment. In robot-assisted surgery, limited forms of kinesthetic feedback have so far not led to improved patient outcomes. In telehealth appointments for individuals located in urban and rural "healthcare deserts"—or for most patients during a pandemic—medical touch is completely absent. Nevertheless, if tactile interaction with a high degree of realism were possible in these scenarios, the value of the technology which enabled it would be immense.

To implement feedback of a visual and auditory nature in a medical context is a simple matter: a digital display can render nearly any image and a loudspeaker can render nearly any sound. Implementing tactile feedback, on the other hand, is far more difficult. Whereas vision and hearing are localized to the eyes and the ears, touch and proprioception involve a range of structures distributed through the body. The reason that virtual medical training and remote care do not include touch is that existing haptic systems are incapable of recapitulating the surface texture and mechanical response of biological structures. This deficiency arises because most haptic systems rely on off-the-shelf mechanical actuators, which are limited to vibration, tingling, and other percussive effects: i.e., inaccurate proxies for sensations produced by soft, hydrated objects. In other words, these devices cannot mimic the texture, softness, wetness, thermal conductivity, adhesion, tack, and other near-surface properties of biological tissue.

Here, we describe several ways in which our group has explored the ways in which materials science can be used to understand and manipulate the tactile sense for applications in healthcare, VR, AR, and assistive devices. In this talk, I will discuss our major outcomes from this area of research, including (1) the development of a new type of conductive polymer that conforms to the skin and can be used to deliver haptic cues to the wearer; (2) elucidation of how the details of contact with the fingertip to materials surfaces contribute to the sense of softness, as well as (3) design rules for haptic surfaces that survive human contact in the real world.

3:30 PM SB08.06.05
Easy Fabrication of Stretchable Waveguide for E-skin Applications Lionel Fliegans, Sylvain Blayac and Marc Ramuz; MINES Saint-Étienne, IMT, France

For many years, a strong research interest has been oriented towards soft electronics for artificial skin applications. However, one challenge with stretchable devices is the limited availability of high performance stretchable electrical conductors and semiconductors that could remained entirely stable while stretched. Moreover, examples of such electronic skin embed excess amount of wires for addressing each sensors (pressure or temperature) in the conventional matrix structure.

Here, we present a new process for fabricating artificial skin consisting of an optical waveguide architecture allowing wide range of sensitivity to pressure [0 to 1KPa - 0.2 kPa $^{-1}$], strain, shear and/or temperature variation [20 to 100°C], in multi-level ultra-stretchable network. The manufacturing process allows for a simple and low cost design of 100% low Young's modulus polymer [<1GPa].
This new type of stretchable optical sensor is highly robust, transparent and present a large sensing area [10 x 10 cm^2] with limited amount of wires. Thus, this optical artificial skin presents far superior mechanical properties compare to current electronic skin.

3:45 PM *SB08.06.06
Transparent Soft Cutaneous Haptics Amir Firouzeh, Ayana Mizutani and Herbert R. Shea; Ecole Polytechnique Federale de Lausanne, Switzerland, Switzerland

Having clickable buttons that appear and disappear at will on any surface transforms how we interact with objects using our fingertips, be they touchscreens, furniture or a pair of binoculars. We report soft, compliant electrostatically driven actuators that pop up from a flat state to a curved shape in a few milliseconds and provide an intuitive click-like response to a user's fingerpress. The devices are completely transparent, allowing them to be mounted on an LCD or OLED display, while still using the multitouch finger position sensing of the display. The devices are HAXELs, a type of electrostatic zipping actuator that displaces fluid to a central elastomer region, creating a raised bump, when a high electric field is applied to electrodes at the devices' periphery. For a 2 cm x 2 cm device, we have strokes of 1.8 mm, and a holding force of 3 N, providing a haptic feel very much like a mechanical keyboard. The arrays are flexible, and can this be used on curved surfaces. Optical transparency is achieved using ITO for the electrodes and transparent polymers and oil for the other layers. We will report device fabrication, scaling, and use for cutaneous haptics, as well as self-sensing, illustrating several use cases.

4:15 PM SB08.06.07
Characterizing Acoustic Wave Propagation in Hydrogels Using Transient Grating Spectroscopy Melanie C. Adams, Allison Chau, Angela A. Pitenis and Bolin Liao; University of California, Santa Barbara, United States

Acoustic and thermal energy transport is critical for a wide range of applications, including biomedical diagnostics (e.g. ultrasound), renewable energy production, and building thermal management. Improving the performance of these technologies requires precise tailoring of acoustic and thermal energy transport, which remains a fundamental challenge. Understanding how to tune these materials and study them in real-time requires methods that can be used in varied environmental conditions. Hydrogels are of interest because they are easily fabricated, tunable, and have environment specific behavior. Our research investigates using transient grating spectroscopy, a method that employs acoustic wave signatures, to mechanically characterize hydrogels and other inhomogeneous materials. We provide a systematic approach across a range of polymer groups, to decompose the effects of crosslinking, swelling, and/or entanglements on Rayleigh wave speeds, which can then be related to a material's elastic modulus. Transient grating also presents a method for dynamic response measurements of hydrogels. Traditional characterization methods, such as indentation, result in large discrepancies in measurements, which indicates that mechanical properties of hydrogels differ significantly in dynamic and static conditions. These differences are the first step to developing models for the direct contribution of poroelasticity and viscoelasticity on hydrogel behavior. This project will show how we can model and subsequently develop hydrogels with the mechanical properties necessary for our desired applications. This work was supported by the UCSB Materials Research Science and Engineering Center (MRSEC) of the National Science Foundation under award No. DMR-1720256 (IRG-3). The development of the transient grating spectroscopy at UCSB is supported by a DURIP grant from the U.S. Army Research Office under the award number W911NF-20-1-0161. Allison Chau acknowledges support from the NSF Graduate Research Fellowship Program under Grant No. 1650114. Angela Pitenis acknowledges funding support from the NSF CAREER award (CMMI-CAREER-2048043).

4:30 PM *SB08.06.08
The Patterns of Skin Deformation That Encode Friction Michael Wiertlewski; TU Delft, Netherlands

Having a secured grip on an object fundamentally depends on controlling the amount of frictional force. Our sensorimotor system excels at estimating the frictional strength of the contact to anticipate the object's slippage, which in turn enables our remarkable dexterity. But how the tactile information about the state of friction is encoded within the mechanical deformation of the fingertips? Using a new setup that can image and modify friction in real-time, we show using that the skin undergoes specific patterns of deformation from the moment the skin first enters in contact with a surface all the way to sliding. The presence of these patterns of deformations is confirmed by a parsimonious model of the skin which captures the interplay of the visco-elastic nature of the skin and the frictional boundary layer.
Our finding suggests that the perceptual system uses these patterns of deformation as matched filters to rapidly estimate the frictional state, independently of knowing whether the contact has a large or small amount of friction.

SESSION SB09.01: Self-Healing Bioelectronics
Session Chairs: Lihua Jin, Jia Liu and Zhiyuan Liu
Monday Afternoon, April 10, 2023
Moscone West, Level 3, Room 3000

1:30 PM SB09.01.01
Exploiting Supramolecular Chemistry for Self-Healing Organic Semiconductors Megan Westwood, Peter Finn, Lewis M. Cowen and Bob C. Schroeder; University College London, United Kingdom

Material degradation is a primary concern to every material scientist and engineer, not only does degradation lead to failure, but results in the need for repair – a very costly endeavor. It is therefore of interest to develop self-healing materials that will make maintenance redundant. As opposed to inorganic semiconductors, organic semiconducting materials have low Young's moduli, which makes them ideal to be used in wearable electronic devices, which can be directly applied to the human skin.[1] Wearable electronics, however, are particularly susceptible to environmental stresses, such as mechanical damage, chemical attack, temperature fluctuations, and radiation damage. This constant stress can lead to the degradation of the chemical structure, resulting in the degradation and ultimately the loss of the material's physical properties.

Herein, we will discuss our approach to compensate for the loss of physical properties, by developing intrinsically self-healing polymers. This was achieved by exploiting supramolecular chemistry concepts such as intramolecular hydrogen bonds.[2-4] In order to gain a deeper insight into the effects of the hydrogen bonding on the viscoelastic, as well as on the electrical properties of the organic semiconductors, we developed two sets of materials; (1) a conjugated polymer with hydrogen bonding functionality and (2) a composite material comprised of a conjugated polymer embedded in a self-healing polysiloxane matrix. We will discuss the effects of the different approaches on the charge transport and self-healing capabilities and outline how we can take advantage of the observed differences to tune not only the electronic but also the self-healing and mechanical properties of the material depending on the field of application and its specific requirements.

1:45 PM SB09.01.02
Autonomous Self-Recognition and Healing in Multilayer Soft Electronics Using Orthogonal Dynamic Polymers Christopher B. Cooper and Zhenan Bao; Stanford University, United States

Can we design multilayer electronics that can spontaneously heal themselves after damage? Having this functionality would protect electronic devices from traditional "wear and tear" damages, improving product lifetime, as well as from intense mechanical damage that would otherwise cause product failure. Compared to the self-healing of a single polymer composite, the self-healing of complex, multilayered devices requires simultaneous healing between multiple layers with distinct functions. Currently, this is achieved by manual alignment of the layers after damage. In this work, we demonstrate a multilayer electronic device that can autonomously re-align and heal after damage using orthogonal dynamic polymers. We show that dynamic polymers with controlled orthogonality exhibit significant and predictable variations in interfacial healing dynamics, allowing for autonomous self-recognition. When misaligned after damage, these multilayer structures possess surface tension gradients that drive directional chain diffusion to enable realignment. We experimentally characterize the interface between different orthogonal dynamic polymers and compare our results to coarse-grained molecular dynamics simulations and self-consistent field theory. Using these polymers, we prepare conductive and high dielectric composites to create thin film capacitors that can autonomously heal with thicknesses below 100 microns. We also demonstrate macroscopic self-assembly of these polymers after damage using magnetic composites. This work provides the first proof-of-concept demonstration of autonomously self-healing multilayered devices and opens a pathway for future autonomous self-assembly in multi-component dynamic materials via pattern recognition.

2:00 PM SB09.01.03
Tough, Self-Healing and Somatosensitive Soft Robot Jaehoon Jung and Jiheong Kang; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

The physically compliant and gentle interactivity of soft robots has opened new possibilities of robot tasks like dexterous manipulation, soft material grasping, and human-interactive applications. However, the softness causes mechanical vulnerability to damage like puncture, tendon cuts, degradation, and delamination. To overcome the vulnerability, tough and self-healing elastomers are needed. However, it was very difficult to design tough and self-healing materials for somatosensitive soft robots due to the trade-off relationship between self-healing efficiency and mechanical toughness.
Here, we report a new molecular design of a self-healing elastomer with high mechanical toughness, and its application for a tough self-healing somatosensitive soft robot system. The designed polymer chain has two kinds of hydrogen bonding from isophorone diisocyanate (IP) and 2-ureido-4-pyrimidone (UPy) for self-healability and toughness respectively. Along with the autonomous self-healing at room temperature, the designed polymer shows unprecedented high toughness and high fracture toughness, which protects the soft robots from damage by sharp objects. The self-healing somatosensory system is composed of various stretchable self-healing sensors including temperature, pressure, damage and strain sensors. These somatosensory systems not only allow us to know the unknown environment but also recognize unexpected damage and respond immediately. The first demonstration of the tough self-healing somatosensitive soft robot would allow the autonomous soft robot system to be used in much more dynamic environments for a long time.

2:15 PM *SB09.01.04
Gold Nanowire-Based Electronic Skins and Tattoos Wenlong Cheng; Monash University, Australia

Sensitive, specific yet multifunctional tattoo-like electronics are ideal wearable systems for health monitoring anytime anywhere because they are virtually becoming parts of Human skins offering burdenless "unfeelable" wearing experience. Here, I will present our skin-like, multifunctional gold electronic skins and tattoos using standing enokitake mushroom-like vertically aligned nanowires. Among various materials of choices, gold has advantages of biocompatibity, chemical inertness, facile synthesis/Surface functionalisation and band-gap-matching with a lot of semiconductors materials. In this talk, I will briefly discuss our gold nanowire-based soft biosensing platform for applications in remote health monitoring.

2:45 PM SB09.01.05
Self-Healable and Stretchable Electronic Materials with Liquid Metal Composites Ravi Tutika[1], Aaron Haake[2], Gwyneth Schloer[1], Eric Markvicka[2] and Michael D. Bartlett[1]; [1]Virginia Tech, United States; [2]University of Nebraska–Lincoln, United States

Polymeric electronic materials with liquid metal (LM) droplets can enable new generations of self-healing soft electronics and robotics that can sense, stimulate and control biological systems. However, techniques to control local composite microstructure, which ultimately governs material properties and performance, is lacking. Current approaches to program LM droplet microstructure requires specific materials, lack spatial control, and only allow for programming of inclusions along a single axis. Further, integrating these polymeric electronic materials with current diverse rigid electronic components and materials is a significant challenge due to lack of adhesion control. Here, we introduce a new DIW 3D printing strategy to achieve on-demand programming of LM-composite microstructures throughout a printed part. This on-demand spatial control of LM microstructure (i.e., shape, orientation, and connectivity) has not been demonstrated with currently available casting, stretching, or patterning approaches. By systematically controlling the printing process conditions and LM droplet size, we can transform the initially spherical LM droplets into highly elongated and orientated ellipsoids on demand at any location with very high aspect ratios ≤ 40. The rapid formation of the surface oxide locks these droplets into the programmed shape and allows for systematic control of the LM droplet microstructure. The printed materials are soft (modulus < 200 kPa), highly deformable (>600 % strain) and highly thermally conductive. The initially isolated LM droplets can also be transformed into a connected network, enabling local creation of insulating or electrically conductive regions using a single ink and manufacturing system by controlling the process conditions. Additionally, using a chemical anchoring technique, the fracture energy can be enhanced up to 7800 Jm^{-2} (100x relative to untreated surfaces) which can further be tuned by controlling the liquid metal microstructures. The LM composite system and DIW 3D printing strategy will enable intrinsically stretchable electronic materials with tough bonding characteristics which provides opportunities to address the challenges in the integration of wearable electronics, implantable devices, and artificial skins with natural and engineered soft biological systems.

SESSION SB09.02: Implantable Bioelectronics I

Session Chairs: Lihua Jin, Jiheong Kang, Jia Liu and Zhiyuan Liu
Tuesday Morning, April 11, 2023
Moscone West, Level 2, Room 2022

10:30 AM SB09.02.01
Conformable Wireless Power Transfer System for Implantable Bioelectronics Based on Internal Ion-Gated Electrochemical Transistors Alexander N. Ranschaert and Dion Khodagholy; Columbia University, United States

Implantable flexible bioelectronics allow for high resolution recordings in animal and human models, which is needed for effective monitoring and clinical treatment. Currently, such implanted devices are powered using batteries, supercapacitors or silicon-based wireless solutions that are often bulky, non-biocompatible, non-rechargeable and require a rigid encapsulation. Furthermore, the threshold voltage of silicon-based field effect transistors lies close or beyond hydrolysis potentials, limiting the applicability in biological environments. In this work, we present a fully conformable inductive wireless power transfer system. The receiver coil and rectifier are integrated in the same substrate resulting in a compact design more suitable for surgical implantation. To accomplish this, enhancement mode internal ion-gated organic electrochemical transistors (e-IGTs) are employed, which can work at speeds beyond the limitations imposed by ion drift and mobility by creating local ion reserves inside the channel bulk. This ensures a large design freedom to optimize the operational frequency of the system to MHz ranges and achieve a high efficiency. We show that by carefully controlling the polyethylenimine (PEI) de-dopant concentrations and transistor geometry, the diode characteristic of the e-IGTs can be fine-tuned to avoid the point of hydrolysis and the power transfer efficiency can be optimized. A conformable high-density prototype is then fabricated and tested in-vivo in a freely moving rat to confirm that an implanted device can be efficiently powered over an extended period. This proves that IGTs are extremely versatile with respect to their applicability in bioelectronic devices. The designed wireless power transfer system is attractive in the context of powering bioelectronic devices, such as neural implants to treat epilepsy through responsive neurostimulation. Therefore, IGT-based devices are a promising platform for future high-performance neural implants.

10:45 AM SB09.02.02
Soft, Multichannel, Subcutaneous Electrical Junction for Long Term Ohmic Contact with Implantable Bioelectronics Hyung Joon Shim and Dion Khodagholy; Columbia University, United States

Implantable bioelectronics are becoming an integral part of modern medicine, from drug delivery systems such as insulin pumps to responsive neural interface devices. To minimize the adverse effects of such implants, all components of the device should be soft and conformable, including the access port to the outside world. However, conventional wires or connectors require a permanent transcutaneous portal which increases the risk of infection, inflammation, and mechanical disruption. For this reason, wireless communication is preferred to allow complete implantation of the device without tissue-extruding components. However, the complexity of wireless communication combined with the associated rigid radiofrequency electronics inevitably result in bulkier and higher power consumption implants with limited applicability. Here, we developed a soft, subcutaneous, multichannel polymeric junction as an alternative approach to provide on-demand ohmic contacts with implants for exchange of data and power. Insertion of a patterned needle into this self-healable connector enables transmission of power and multi-channel, high-speed data. When not in use, the connection can be easily removed completely with no exposed components. This access port is made out of a three-dimensional conductive polymer structure sandwiched in an insulating stretchable polymer matrix. The healable properties of the polymers allow repetitive connections for long-term use. The electrical as well as mechanical properties of the synthesized materials were analyzed. The feasibility of the access port for implantable bioelectronics was validated with long-term chronic implantations in freely moving rodents to exchange power and neurophysiological data at the resolution of single neurons. We anticipate this approach will have a broad applicability to a wide range of implants and offer possibilities to improve patient quality of life.

11:00 AM SB09.02.03
Using Electric Fields to Stick Hydrogels to Tissues—A Simple Way to Perform Suture-less Surgical Repairs Leah K. Borden[1,2] and Srinivasa R. Raghavan[1]; [1]University of Maryland, United States; [2]Massachusetts Institute of Technology, United States

We demonstrate electroadhesion, i.e., adhesion induced by an electric field, between cationic hydrogels, animal and plant tissues [1]. When gel and tissue are placed under an electric field (DC, 10 V) for 20 – 60 s, the pair strongly adhere, and the adhesion persists indefinitely thereafter. Applying the DC field with reversed polarity reverses the adhesion. Electroadhesion works with tissues of many mammals (cow, pig, chicken, and mouse), and is especially strong in the case of the aorta, cornea, lung, and cartilage. Electroadhesion is also achieved with plant tissues such as with carrot, onion and strawberries. Only cationic gels can be electroadhered to tissues, which suggests that the tissues have anionic character. These findings show the potential for using electroadhesion in surgery while obviating the need for sutures or staples. Advantages include the ability to achieve adhesion on-command, and moreover the ability to reverse this adhesion in case of error.

We then explore variables that contribute towards adhesion in these diverse types of tissues. For instance, the higher the fraction of anionic polymers (proteins and/or polysaccharides) in the biological material, the higher the electroadhesive strength. Interestingly also, because tissues often have anisotropic structure, adhesion by electroadhesion can be strong in one tissue orientation, but weak or non-existent in the perpendicular orientation. Last, we see that electroadhesion occurs in both soft and hard animal and plant tissues.

Reversible Electroadhesion of Hydrogels to Animal Tissues for Suture-less Repair of Cuts or Tears.
Nature Communications, 12, 4419 (2021)

11:15 AM SB09.02.04
Smart Multi-Sensory Capsule for Simultaneous Location Tracking and Inflammation Detection Sarath Gopalakrishnan, Sotoudeh Sedaghat, Rithu Thomas, Akshay Krishnakumar, Sina Nejati and Rahim Rahimi; Purdue University, United States

Inflammatory bowel disease (IBD) has gained a lot of attention in recent decades as it is increasingly prevalent in Western countries and steeply emerging in developing countries. IBD affects 7 million people worldwide and is characterized by chronic inflammation of the gastrointestinal tract (GI) which is manifested as Crohn’s disease, ulcerative colitis, and colon cancer if remained untreated. Existing methods widely used in hospitals include a combination of endoscopy, colonoscopy, and imaging studies. Endoscopy and colonoscopy are invasive and expensive and require a technician’s assistance. Similarly, MRI and CT scans require bulky equipment and manual assistance and cannot be made portable or automated.

To address the issues envisaged by these benchtop systems, ingestible capsules have emerged as an ideal portable wireless in-situ monitoring platform to perform around-the-clock measurements using contactless readout units. Although the existing ingestible capsules have gained popularity as miniaturized devices, the state-of-the-art active capsules are designed to sense a single parameter either for location tracking or inflammation detection but not for both parameters simultaneously. Single parameter sensing significantly limits traceability, targeted detection, and accuracy of measurements. Furthermore, the active capsules that contain electronic modules lack suitable sensor interfaces that can establish good contact with the tissues and biocompatible packaging to prevent leakage from the batteries and seepage into the electronics. To address these challenges, we report a multi-sensory smart capsule that can perform both targeted detection of inflammation using Oxidation Reduction Potential (ORP) sensing as well as location tracking of the device inside the GI tract using pH monitoring.

The device consists of a compartmentalized sensor interface, an electronic module, and a biocompatible encapsulation. The sensor interface consists of three compartments which include a pH sensing unit, an ORP sensing unit, and a common reference unit. The pH sensing unit is manufactured by dispensing carbon paste mixed with pH-sensitive ionophores. The ORP sensing unit is formed by dispensing carbon paste sensitive to redox reactions in the environment. The reference unit is made by mixing KCl particles, polyvinyl chloride, and cyclohexanone and is used for both pH and ORP sensors. This multi-sensory compartment is interfaced with the electronic module inside the capsule through reflow soldering. The electronic module consists of a microcontroller unit powered by batteries, separate buffer circuit boards for performing accurate potentiometric readings from the pH and ORP sensors, and an antenna to wirelessly transmit the collected data to an external reader. This heavily miniaturized electronic module of diameter 8 mm is secured inside a biocompatible 3D printed housing of outer diameter 9.5 mm and length 2.5 cm to prevent leakage and seepage.

To investigate the performance of the multi-sensory capsule, extensive characterizations are conducted on the pH and ORP sensors individually as well as collectively. A systematic study reveals that the sensors demonstrate the capability to detect pH within the range of 1-8 and ORP within the range of -500 mV to +500 mV. The capsule can provide successful passage through the GI tract at a polling rate of 30 min with an average power consumption of 110 μAh. As a proof-of-concept, we perform ex-vivo characterization on pig tissues to demonstrate the specificity, power consumption, and traceability of the capsule in a GI-tract surrogate environment. The multi-sensory smart capsule presented here provides a new avenue in addressing the emerging need for accurate IBD detection using a portable, wireless system and can be a successful alternative to the existing medical equipment.

11:30 AM SB09.02.05
4D Printing of Biomimicking Elastomers with Digital Light Processing (DLP) for Personalized Biomedical Device Fabrication Alireza Mahjoubnia and Jian Lin; University of Missouri-Columbia, United States

A real challenge to improving human health and quality of life is the gap between the growth in personalized medicine demand and the lack of cutting-edge biomedical technologies. The fabrication of complex medical devices that could respond to stimulation by biological signals implanted through minimally invasive surgery is facilitated by the innovative and promising 4D printing technique, which can be utilized to simulate numerous dynamic processes of living tissues. However, the 3d printing of biocompatible shape memory polymers (SMPs) that is frequently used produces structures with low printing resolution, unsuitable mechanical properties (relatively low toughness), and undesired transition temperatures (T_{trans}), which complicates implantation procedures. Herein, we demonstrate 4D printing of SMP poly(glycerol dodecanoate) acrylate (PGDA) and Poly(acrylic acid) (PAA) with a T_{trans} in a range of human body temperature(~37°C), making it appropriate for maintaining programmed shape at the room temperature and then shape deployment within the physiological temperature. Introducing the PAA network to PGDA has dramatically increased the toughness of the resulting PGDA-PAA elastomer, while the double crosslinked network has improved its chemical stability. In addition, Young's modulus (E) (40-170 MPa) and toughness (10-20 MJ/m^3) of the printed structures can be decreased by 90 and 25 times, respectively, due to the phase transition of PGDA over its T_{trans}. These mechanical properties make the implantation process more straightforward as it has shown enough stiffness to maintain the programmed shapes when used at room temperature. The low E above T_{trans} will make shape reprogramming easy. The drastic self-driven change of mechanical properties enables printed structures to mimic the natural tissue and maintain robust properties under cyclic deformations suitable for cardiovascular applications. Moreover, the pre-PGDA/Acrylic acid resin used as the ink for digital light processing (DLP) printing possesses suitable rheological properties to allow for the fabrication of a variety of high-resolution complex 3D structures such as "boat," "diamond," and "human hand," with the printing speed of 25-100 mm/h depending on model geometry, and slice thickness. Although printing tubular structures is challenging due to the over-curing of the residual resin inside the channel in vat photopolymerization (VPP)-based 3D printing techniques, we have been able to print sub-millimeter hollow tubes with a wall thickness of 200 mm. The printed 3D structures show shape memory properties, including a large fixity ratio of 98% at room temperature and a significant recovery ratio of 100% at 37°C. Furthermore, cell studies have shown cell viability of over 90%, proper attachment, and proliferation of cells over printed materials. Finally, Abdominal Aneurysm and Left Atrial Appendage were chosen as the target diseases. Devices were individually designed and printed for defects scanned from animal models and tested both in vitro and in vivo. The implantation of personalized devices demonstrated the geometrical and mechanical adaptivity of the printed constructs. This newly developed PGDA-PAA SMP-based 4D printing technology has the potential to pave a new route to the fabrication of shape memory scaffolds for personalized biomedical applications.

SESSION SB09.04: Poster Session I

Electropolymerized Organic Mixed Ionic-Electronic Conductors Arnel Besic and Connor G. Bischak; University of Utah, United States

Organic mixed ionic electronic conductors (OMIECs) are conjugated polymer systems that conduct both ions and electrons. They are promising materials for biosensors, neuromorphic computing platforms, and energy storage devices. An obstacle for these new materials is the lack of understanding of the fundamental processes that underlie operation, namely the coupled dynamics of ion motion, electron transport, and structural changes. This work presents the electropolymerization and characterization of thiophene-based polymers and copolymers. One advantage of electropolymerized materials is that they do not require bulky side chains to dissolve in organic solvents, allowing them to hold more charge per volume. Using electropolymerization, we synthesize several polythiophenes with different side chain chemistries. We investigate ion injection kinetics in these materials using spectroelectrochemistry and find that injection kinetics depend on the identity of the electrolyte. We also characterize their morphology with atomic force microscopy (AFM) and scanning electron microscopy (SEM). Electropolymerized OMIECs may play an important role in the advancement of OMIEC-based technologies due to their unique morphologies and ease of synthesis.

5:00 PM SB09.04.02
Switching Characteristics Enhancement of L-Tryptophan-Based Resistive Random-Access Memory by Plasma Treatment for Bio-Implantable Electronics Moon Ho Lee, Jong Bin An, Seok Gyu Hong and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

Because the COVID-19 pandemic spreads globally, interest in non-face-to-face treatment and bio-implantable electronics has increased. Unlike conventional electronic devices, which are rigid and have harmful properties to the body, bio-implantable electronics must have features that are flexible and harmless to the body. In addition, bio-information real-time sensing is essential for bio-implantable electronics. Among the various components of bio-implantable electronics, such as integrated circuits, displays, and batteries, a non-volatile memory storage device that can maintain data even in the absence of electrical power is one of the most important components. Due to its fast switching speed, simple structure, low power consumption, and low cost, resistive random-access memory (ReRAM) is one of the most promising non-volatile memory devices. However, an inorganic ReRAM has disadvantage such as relatively high fabrication cost and high temperature processes. To overcome these disadvantages, many biocompatible ReRAM devices composed of organic materials such as chitosan, egg albumen, sericin, glucose have been studied.

In this study, L-tryptophan, one of the essential amino acids that humans must ingest, was used as the switching layer of the ReRAM device. L-tryptophan is contained in foods such as milk, cheese, eggs, fish, and peanuts, and it is a precursor to the serotonin and melatonin, which are crucial for preventing insomnia, obesity, and depression. Because L-tryptophan is one of the essential amino acids that humans must ingest, it has been proven to be biocompatible property, thus it should be appropriate to be used as a switching layer material in bio-implantable ReRAM devices. In addition, for excellent memory characteristics the L-tryptophan-based ReRAM device, O_2 plasma treatment was performed prior to top electrode deposition. Through the following process, L-tryptophan-based ReRAM was fabricated. First, 2 × 2 substrates of heavily doped p-type silicon were cut to size. Second, L-tryptophan film was deposited at room temperature using the spin coating method on a cleaned silicon substrate. A 2 wt % L-tryptophan solution was synthesized by dissolving L-tryptophan powder (Sigma-Aldrich) in DI water. Before the top electrode deposition, an O_2 plasma treatment was performed under condition of 100 sccm, 50 W, and 10 min. Finally, a 150-nm-thick aluminum (Al) top electrode was deposited using an electron beam evaporator via a shadow mask.

In general, the resistive switching mechanism of ReRAM is attributed to the migration of oxygen ions in the interface oxide layer created between the top electrode and the organic material. We expect that hydroxyl functional groups in L-tryptophan react with the Al top electrode through redox reactions and the formation of conductive filaments because of oxygen ion migration at the interface between Al/L-tryptophan. Also, O_2 plasma treatment can increase the extra available oxygen ion in the switching layer of ReRAM. To increase these oxygen ions, we confirmed the switching characteristics change of L-tryptophan-based ReRAM after O_2 plasma treatment. The set and reset processes of non-treated and plasma-treated L-tryptophan-based ReRAM are performed at 2.7 V, -3.8 V, and 3.0 V, -2.9 V, respectively. At a read voltage of 0.2 V, plasma-treated L-Tryptophan-based ReRAM exhibited an improved resistive switching window from 10^4 to 10^6, defined as the ratio of high and low resistive, compared to non-treated L-tryptophan-based ReRAM. High-resolution transmission electron microscopy (HR-TEM) and X-ray photoelectron spectroscopy (XPS) analyses were performed to investigate the aforementioned Al oxide formation mechanism between the Al top electrode and L-tryptophan interface. Based on its superior switching characteristics, we confirmed that plasma-treated L-tryptophan-based ReRAM could be a candidate for bio-implantable electronics.

5:00 PM SB09.04.03
Photothermal Self-Healing, Magnetically Aligning Wearable Sensor System Jung Wook Kim and Jeong Sook Ha; Korea University, Korea (the Republic of)

Self-healing functionalities are studied actively in fields of stretchable electronics applications to improve the device lifespan, to gain economic feasibility, and ensuring environmental friendliness. However, the synthesis of high-efficient healing materials and specific application of these materials to actual devices are still in progress. In this abstract, we report on the fabrication of magnetic-aligning, light-responsive self-healing devices based on a custom-synthesized polyurethane(PU). Light-responsive self-healing PU was synthesized by reacting poly(tetramethylene ether) glycol, aminopropyl-terminated PDMS and aniline trimer. Aniline trimer inserted PU showed high photothermal property, increasing its temperature over 150°C when 808nm NIR laser is irradiated for several minutes. The glyoxime bond in PU chain dynamically regenerated when heated through NIR laser irradiation, exhibiting self-healing properties. Also, to acquire an automatic self-aligning property of self-healing devices, 5T-magnetized commercial ferrite rubber magnet was diced to 1mm-width rod shape and aligned to form in wanted magnetic flux. After patterning deformable magnet pattern in circular shape, the magnetic aligning layer was deposited into PU layer through liquid-casting method. After several hours of curing process, the magnetic pattern embedded in PU film was formed, showing self-aligning properties through attraction force between damaged magnetic patterns. Finally, the sensor device to measure biosignal and interconnection layer was embedded on polymer surface. The sensor system could be easily self-healed through magnetic-align and laser induced self-healing properties.

5:00 PM SB09.04.04
Optical Detection of Single Brain Cell and Neuron-Related Activities Using 3D Plasmonic Sensing Micro Antenna Array Yuxin Cai and Pengyu Chen; Auburn University, United States

Studies of brain activities have been conducted at the frontmost end of neuroscience. The brain is composed of billions of neurons and is in charge of the central nervous system, yet despite the main biological role of the brain, there still are many unknown structures, functions, and connections remaining unknown to us. Meanwhile, the development of medical and clinical research has been phasing in the *in vitro* inspection of brain cell and neuron-related mechanisms for preclinical studies. Specifically, the *in vitro* exploration of brain and neuron cell activities in preclinical studies has been conducted to mimic the central nervous system response to advanced new medicines or medical technologies and to assist deliver precision treatment for brain diseases.

Parallel to fluorescence methods, localized surface plasmonic resonances (LSPR) has become a particularly interesting technique for studying the chemistry of living cells. LSPR is a label-free, non-invasive technique, confined to subwavelength-size noble metal nanoparticles that possess large optical cross-sections which have been thoroughly studied. The nanoplasmonic structures propose remarkable potential in sensor sensitivity, tunability, miniaturization, and large-scale fabrication, which makes it possible to intrinsically record neural cell activity at a single neuron level by optical means.

Deciphering the mechanisms of brain and neuron-related activities requires the acquisition of detailed information from a wide range of different scales, ranging from neuron networks to single neuron cells. In our study, we directly measured the change of surface electron density on a gold nanoparticle that is induced by the local neural cell's electric field to monitor brain neural activity. A 1 cm^2 area sensing array of 100 um-high and 5 um-diameter antennas was used, which is large enough to analyze the collective behavior while offering high resolution to observe single neural cell activity.

Because of its low cost, easy processability, biocompatibility, and hydrophobic nature, polystyrene is widely used for biomedical research. First, we designed the desired basal face of the 3D structure and a silicone mode will be manufactured through lithography. By precisely manipulating the etching time, the photoresist layer, and the ultraviolet light source, we are able to control the height and shape of the pattern, and finally formed a micro-antenna array mode for unlimited polydimethylsiloxane (PDMS) microwell masks. Then, a polystyrene solution (20% w/v in toluene) will be cast onto the PDMS mask and covered with indium-doped tin oxide (ITO) coated glass. After degassing, processing, and evaporation of the organic solvent, the base layer of our micro-antenna sensing array will be subsequently coated with gold nanoparticles to serve the sensing purpose with the strong plasmonic coupling can be observed by our previous developed LSPR dark-field imaging technique.

Murine hippocampal cell line (H19-7) and dissociated hippocampal neurons were observed on our micro-antenna sensing array. After a common preparation of the sensing array surface, differentiated hippocampal cells and hippocampal neurons were transferred to the sensing surface and further cultured, forming a neuron-network-like *in vitro* cultured specimen and later treated with different formulations. Firstly, the baseline was set when there was rarely any scattered light change captured before any formulation was injected. However, after the formulation injection, spiking activities were spotted under the dark field microscope. According to the references, the shape of the signals is typical of results that would be obtained in extracellular electrode recordings. Within the microfluidic channel designed and applied, it will be easy to use the device to acquire real-time *in vitro* neural cell activity of any formulations of medicine.

5:00 PM SB09.04.05

Ecofriendly Transfer Printing for Biodegradable Electronics Seung-Min Lee[1], Woo-Jin lee[1], Jae-Young Bae[1], Joon-Woo Kim[2], Ju-Yong Lee[1], Jeonghyun Kim[2] and Seung-Kyun Kang[1,1]; [1]Seoul National University, Korea (the Republic of); [2]Kwangwoon University, Korea (the Republic of)

Biodegradable electronics, which serve biomedical sensing and treatment for a certain period yet degrade into biocompatible and bioresorbable byproducts after their usage, have drawn a great interest in the field of minimally invasive implantation and disposable biomedical devices. Although various demonstration of biodegradable electronics including electrical field generators, stimulators, drug delivery systems, and wireless sensors, their fabrication on biodegradable polymer substrates remains as a great challenge. Especially, high resolution photolithography process on typical biodegradable polymers is infeasible owing to their low glass transition temperature and active reactivity to the organic solvents. Therefore, transfer printing of fully formed device to a polymer substrate has been suggested. Early reported transfer printing technique, however, still have limitations as following: 1) contain removal process of a non-biodegradable inter-process layer, 2) limitation in size and resolution 3) risk of shape distortion during the removal process of a sacrificial layer. Here, we propose simple, reusable, and large scale transfer printing method for biodegradable electronics realized with biodegradable materials during the whole process. A delicate control of adhesion between Si wafer and biodegradable metals (Mg, Zn) via formation of a self-assembled-monolayer (SAM) allow serial deposition, photolithography, etching process to fabricate a metal trace on a temporary wafer, but readily released by peeling-off force of a biodegradable polymer stamp. Quantitative analysis of adhesion was conducted using scratch test and thermal conductivity test. Fabrication of temperature sensors, wireless heater, metal-oxide-semiconductor field-effect transistor (MOSFET) using silicon nanomembrane (SiNM) present a wide range application of this method for passive and active devices. Wafer scale fabrication of circuit components including resistors, inductors, and capacitors allow large scale, and mass production. Printed circuit board (PCB) presents the fabrication of high resolution, yet dissolvable integrated circuit board. Wireless hydration sensor for xerostomia diagnosis address the possibility of a real-time monitoring of a salivary level in mouth. A set of transfer printing technique and exemplary demonstrations of various electronics presented in this study provide a novel strategy for simple, large-scale, mass productive, and ecofriendly fabrication of biodegradable electronics.

5:00 PM SB09.04.06
Biodegradable Conductive Conduit and Electroceutical for Accelerating Peripheral Nerve Regeneration Jio Kim and Seung-Kyun Kang; Seoul National University, Korea (the Republic of)

Peripheral nerve injury that completely cut and damaged by traumatic injury causes loss of motor function and/or sensory function. Peripheral nerve generally regenerates naturally in some range, but natural regeneration is limited and functional recovery is incomplete when the nerve defect is longer than 10 mm. An autograft, one of gold standard in clinics, is needed for peripheral nerve amputation patients, however, treatment success rate of autograft does not exceed 50 %. Recent studies propose artificial nerve conduit as a new treatment method that can possibly replace autograft. A conductive nerve conduit that helps electrical signal exchange has been highlighted along with biodegradable nerve conduits. In addition, recent studies have shown that electrical stimulation of peripheral nerves not only accelerates nerve regeneration but also improves functional recovery.
In this study, we introduced electroceutical combined with the biodegradable conductive nerve conduit and electrical stimulator for accelerated regeneration of long defect gap of sciatic nerve in rodent model. We fabricated a composite type of nerve conduit using biodegradable polymer (PCL) and biodegradable metal particles (Mo Nanoparticles). Wireless electrical stimulation was attempted for several days to maximize the nerve regeneration effect. Histological studies show that there is no mechanical or immunochemical damage by biodegradable conductive conduit. In-vivo demonstration for rodent model shows the successful treatment results.

5:00 PM SB09.04.07
Self-Healing Ionic Skins with Moisture Self-Regulation Characteristics for Ultra-Long Ambient Stability Peisheng He, Yu Long, Chao Fang and Liwei Lin; University of California, Berkeley, United States

Vulnerability to mechanical damages and dehydrations limits the operations of conductive hydrogels in ambient conditions. Inspired by the self-healing and water regulation behavior of jellyfish, we designed hydrogel-based self-healable ionic skins that can self-regulate internal moisture level by exploiting the mutually cohesive interactions among water, ions, and zwitterionic polymer networks. The material can sustain in the ambient for an ultra-long period of over 16 months and exhibit high stretchability (>1650% strain) and conductivity (as high as 23.5 mS/cm). Furthermore, after incidental exposures to harsh environments, including heating at 200 °C, freezing and vacuum drying conditions, the hydrogel can self-replenish water content from the ambient moisture and regain most of its conductivity and stretchability. Meanwhile, reversible ionic and hydrogen bonds allow the material to heal from fully cut-through damages repeatedly recouping conductivity (>90%) at room temperature within one minute. Utilizing the ionic skins as building blocks, flexible transparent piezoelecret sensors have been constructed to monitor physiological signals. Additionally, a facile transfer-printing process has been introduced to fabricate a breathing sensing system with self-healable supercapacitor and humidity sensor printed directly on ionic skins. These demonstrations illustrate broad-ranging possibilities of the ionic skin in areas including energy storage devices, wearable sensors, and human-machine interfaces.

5:00 PM SB09.04.08
Preparation-Free Hydrogel EEG Electrodes for Concurrent EEG-fMRI-TMS Yuhan Wen, Nehal Almamun, Michael Lustig and Ana C. Arias; University of California, Berkeley, United States

Transcranial magnetic stimulation (TMS) techniques provide a non-invasive tool to modulate cortical excitability by inducing charges at targeted brain areas and suppressing or enhancing local neural activity patterns. In neurological studies, it can be combined with other multimodal brain recording tools, such as Magnetic Resonance Imaging (MRI) or Electroencephalography (EEG), to provide important insight into how cells and neural circuits interact on a system level. Currently, only separate EEG-TMS and EEG-MRI systems are commercialized and clinically available. However, a concurrent EEG-fMRI-TMS system will allow EEG and fMRI to provide complementary spatial and temporal information of the transient and dynamic TMS-evoked network response and help advance neurological knowledge. One major challenge of such a system is that MRI and TMS environments are harsh on electronics and impose strong EMI due to the large switching magnetic fields in both RF ranges and EEG-relevant domains. Therefore, careful EEG material selection and electrode design are critical to ensure patients' safety, minimize heating, improve EEG signal quality, and reduce interference on MR images and TMS operation.

In this work, we aim to develop preparation-free hydrogel EEG electrodes compatible with concurrent EEG-fMRI-TMS. Biocompatible physically-crosslinked alginate hydrogel and freeze-thawed PVA hydrogel were prepared with varying polymer concentrations, crosslinking densities, and conductive additives. Different conductive additives including salt, PEDOT:PSS, and CNT were tested to enhance the conductivity of the hydrogel. The hydrogel conductivity was characterized with an LCR meter for EEG relevant range (20Hz-2MHz) and a Vector Network Analyzer at MRI-relevant frequencies that are sources of RF noises and major heating. After integration with stencil-printed Ag/AgCl electrodes, we measured the contact impedance on the subjects' forearms. Alginate/CaCl2/Ag/AgCl and PVA/NaCl/Ag/AgCl showed the most comparable performance to the gold standard wet gel and compatibility with MRI and TMS.

To validate the MRI compatibility of the EEG electrodes, we performed common MRI and fMRI sequences (T2*-weighted GRE scan and GRE EPI fMRI

BOLD scan) with the electrodes on the subject's head. No MR image distortions due to the EEG electrodes were observed, and no heating occurred during the sequences. The EEG data were recorded by a commercial MR-compatible amplifier and power unit. RF noises were removed by in-line filtering and the gradient noise can be canceled by synchronization with the scanner clock and signal processing methods. We also characterized artifacts from polarization during biphasic repetitive TMS pulses to test TMS compatibility. The electrodes were submerged in a physiological saline solution, wired out through a twisted pair, and aligned with the TMS coil in the worst-case scenario. Varying TMS intensity from 10% (14A/us) to 50% (70A/us), the hydrogel electrodes showed a settling time of less than 10us after the TMS pulses, and no significant heating was observed. Our results demonstrate that the proposed hydrogel EEG electrodes are safe and suitable for application in harsh MRI and TMS environments with performance comparable to the traditional wet electrode, and without complex skin preparation and clean-up afterward. This work demonstrates an important step towards a fully integrated multimodal concurrent EEG-fMRI-TMS system.

5:00 PM SB09.04.09
Organic Iono-Electronic Composite Materials Towards High-Performance Bioelectronic Devices Camille E. Cunin, Sanket Samal and Aristide Gumyusenge; Massachusetts Institute of Technology, United States

Organic semi-conducting materials with mixed ionic-electronic transport properties have gained a lot of attention over the past few years due to their ability to operate in close contact with the body and accurately transmit physiological signals. By mimicking the function of biological synapses, such bio-inspired conductors have shown great potential for future applications in bioelectronics and health monitoring. However, despite their better mechanical properties, biocompatibility, ease of integration into miniaturized architectures, low-cost production, low-power consumption, and chemical tunability -compared to their inorganic counterparts, organic semiconductors still suffer from a mechanical mismatch at the body-machine interface, poor charge carrier mobility, and low environmental stability. While polymer backbone and side chains engineering are promising chemistry approaches for addressing these limitations, we demonstrated that engineering organic iono-electronic composites (OIECs) further enables a fine tuning of both microstructural and electrochemical properties of conjugated polymers. OIECs were developed by blending an insulating matrix (poly(methyl methacrylate) (PMMA)) with a novel semiconducting polymer (PDPP3T-20gT), made of polar tetraethylene glycol side chains tethered to a backbone of 80% diketopyrrolopyrrole and 20% thiophene derivatives. The influence of the insulator's tacticity (e.g., atactic, isotactic, syndiotactic) was also investigated. Structural changes across blends were characterized using high-precision atomic force microscopy, grazing-incidence wide angle X-ray scattering, and UV-vis spectroscopy. Mixed conduction properties were assessed using transducing devices (organic field-effect transistors (OFETs) and organic electrochemical transistors (OECTs)). We demonstrated that both the semiconductor/insulator ratio and the insulator's tacticity strongly impact the nanostructure and the electrochemical properties of the semiconducting polymer. We showed that developing OIECs adds an extra layer of flexibility for engineering more mechanically compliant, low-cost, and readily processable channel materials for implementation into transducing devices. In conclusion, while engineering backbone and side chains is an efficient strategy to improve mixed ionic-electronic conduction and level up the performances of current organic bioelectronic devices, designing OIECs paves the way for the development of highly compliant materials towards prosthetics, smart electronics, and on-body computing.

5:00 PM SB09.04.10
Quinoxalineimide-Based Conjugated Polymers: Synthesis, Characterization and Field-Effect Transistor Performance Minoru Ashizawa[1], Katsuki Yaginuma[1], Yoshihiro Hayashi[1], Susumu Kawauchi[1], Hiroyasu Masunaga[2], Noboru Ohta[3], Wen-ya Lee[4] and Hidetoshi Matsumoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Jasri, Japan; [3]SPring8, Japan; [4]National Taipei University of Technology, Taiwan

Quinoxalineimide (QI) building units are versatile electron-accepting components that can create n-channel and/or ambipolar polymer semiconductors in organic field-effect transistors. Herein, we report five QI-based copolymers with thienyldiketopyrrolopyrrole (TDPP) counterparts and systematically examine polymer structure-function correlations in terms of charge carrier transport properties. The introduction of two fluorine atoms into the QI moieties of a polymer backbone lowered both the HOMO and LUMO levels, resulting in n-channel dominant ambipolar FET performance with the highest maximum mobilities of 1.45 $cm^2V^{-1}s^{-1}$ for electrons and 0.71 $cm^2V^{-1}s^{-1}$ for holes, which was attributed to improved crystalline ordering. The electronegative triazole- and thiadiazole-fused QI moieties resulted in drastically decreased LUMO levels in the copolymers, with values close to or below -4.0 eV, as required for stable n-channel operation, whereas the HOMO levels remained unchanged because of the quinoidal resonance contribution. As a result, triazole- and thiadiazole-fused QI-based polymers showed near-infrared (NIR) light absorption across the whole NIR-II window (1000-1700 nm) with an optical energy gap of less than 0.8 eV. Investigation of the charge carrier transport properties indicated that both polymers displayed n-channel-dominant and non-off ambipolar behavior. These results suggest that a series of QI electron-accepting units are excellent building blocks for the development of novel n-channel and/or ambipolar polymer semiconductors with a high NIR light response.

5:00 PM SB09.04.11
A Biodegradable Bioinspired Oil-Coated Adhesive Film for Enhanced Wet Adhesion Yeon Soo Lee, Da Wan Kim, Jinhyung Kim, Seung Hwan Jeon, Gui Won Hwang and Changhyun Pang; Sungkyunkwan University, Korea (the Republic of)

Bioinspired and biodegradable polymer-based adhesive films have attracted attention in the medical field because of their stable adhesion performance and ability to decompose in the body without additional surgical procedures. Among biodegradable materials, poly (glycerol sebacate) (PGS) can be applied to softenss-tuned microarchitecture-based adhesive films, because it has bioresorbable and residue-free characteristics. Herein, we presented a bioinspired oil-coated adhesive film fabricated using PGS, which can maintain adhesion on a wet surface by mimicking the toe pad and mucus of a frog. To implement frog-like adhesive architectures, the particular criteria under which PGS can be patterned were presented using simple models based on the degree of esterification and interfacial energy difference. Wet adhesion of our oil-coated film was achieved by replicating the frog-like hexagonal micro-channel and concave cup structures coated with vicious glycerol oil, resulting in a stable residue-free wet adhesion against diverse non-flat soft organ surfaces.

5:00 PM SB09.04.12
Erythrocyte-Camouflaged Biosensor for α-hemolysin Detection Yonghwan Kim and Hyo Gi Jung; Korea University, Korea (the Republic of)

Without appropriate treatment, Staphylococcus aureus (S. aureus) infection can cause life-threatening diseases. However, a rapid and accurate point-of-care test for the infection remains challenging. The bacterium secretes α-hemolysin (Hla), which spontaneously binds to the cell membrane of erythrocyte, and eventually lyses the cell via pore formation. Taking advantage of this phenomenon, we apply the erythrocyte membrane (EM) extracted from human whole blood as a novel bioreceptor for detecting Hla, fabricating erythrocyte-camouflaged biosensors (ECB) by coating EM onto electrochemical impedance electrodes. We verify the existence of EM on the ECB by using confocal microscopy and atomic force microscopy. We demonstrate that ECBs sensitively detect Hla spiked in phosphate buffer saline and human serum. Also, the sensor shows higher sensitivity to Hla than major blood proteins, such as human serum albumin, fibrinogen, and gamma globulin. Finally, we validate the constant sensing performance of ECB with 99.0 ± 5.6% accuracy for 35 days of storage.

5:00 PM SB09.04.13
Near-Field Electromagnetic 3D Printing for Nanomaterials-Based Electronics Samuel Hales[1], Jared Anklam[1], Yang Xin[2], John S. Ho[2] and Yong Lin

Kong[1]; [1]University of Utah, United States; [2]National University of Singapore, Singapore

The inability to selectively anneal printed materials on a broad range of temperature-sensitive constructs has limited the potential functional complexity and performance of 3D printed electronics. Thermal annealing of 3D printed nanomaterials is a critical process that dictates electronic performance by (1) merging otherwise disconnected nanomaterials, (2) reducing defects and interfaces, (3) removing polymeric additives, and (4) improving contact between printed layers. Prior works primarily rely on heating the entire printed object post-printing in a bulk annealing process, which severely limits the possible multimaterial integration and geometrical configurations. Here, we demonstrate the ability selectively and locally anneal 3D printed nanomaterials *in situ* on a broad range of temperature-sensitive substrates, including plant media and low-melting-temperature polymers, by exploiting metamaterial-inspired electromagnetic structures. The demonstrated near-field electromagnetic 3D printing (NFP) enables exceptional control of printed nanomaterial annealing parameters, creating spatially freeform microstructure where the electronic and mechanical properties can be locally programmed in a multimaterial construct. We envision that NFP significantly broadens the possible class of materials compatible with additive manufacturing processes, enabling the creation of hybrid multi-functional constructs and the integration of functional electronics on temperature-sensitive constructs.

Recording and Manipulation of Cell Signaling with Multifunctional Fibers Polina Anikeeva; Massachusetts Institute of Technology, United States

In this talk, I will highlight the recent developments in multimaterial fiber technology that enable recording and modulation of signaling in neuronal as well as non-neuronal cells. Although electrogenic cells such as neurons can be manipulated via electrical signals, the ability to manipulate or record from genetically identifiable neuronal subtypes demands optical or chemical techniques. Using multimaterial fiber technology, our group has demonstrated how optical and chemical recording and manipulation methods can be combined with traditional electrical approaches. Additionally, given emergence of evidence supporting the critical role of signaling between neurons and tumor cells in the development of brain cancers, our group has developed interfaces to optically probe signaling in non-electrogenic tumor cells. As the studies of neuron-tumor interactions require non-immunogenic functional interfaces with both neuronal and tumor tissues, my talk will highlight the materials advances aimed reducing the impact of the implantable tools on local biological environments. Together, our advances in multifunctional, non-immunogenic fiber-based probes pave the way toward unraveling the roles of communication between neuronal and non-neuronal cells in the context of health and disease.

8:45 AM *SB09.05.02
Soft and Stretchable Implantable Electrodes to Interface with the Human Brain Nicolas Vachicouras; Neurosoft Bioelectronics, Switzerland

Neural implants aim at restoring lost or impaired functions of the nervous system by electrical stimulation or recording of the brain. Current neural implants suffer from a mechanical mismatch compared to the soft host tissue, as they constrain mechanically the physiological motion of the central nervous system. This mismatch causes poor electrode-tissue contact, leading to unspecific stimulation or recording, as well as chronic scarring. At Neurosoft Bioelectronics, we overcome these fundamental limitations by developing soft and stretchable neural electrodes, using more compliant materials, that seamlessly interface with the brain, promoting the long-term bio-integration of the devices and reducing surgical risks.

Our electrodes are made of a thin-film (<100 nm) of gold evaporated on a low modulus (<1 MPa) silicone substrate, allowing for reversible elasticity while maintaining electrical properties. The electrode sites are coated with a rough platinum-silicone composite, which increases the electrochemical surface area and thus allowing for reduced interfacial impedance.

Neurosoft Bioelectronics has been working on the translation of these materials to the clinic by developing a subdural electrode, SOFT ECoG, to record from and electrically stimulate the surface of the brain.

9:15 AM SB09.05.03
Magnetic-Driven 3D Curvilinear Neural Probe for Minimal Invasive Injury Tao Zou[1,2] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, Hong Kong; [2]Advanced Biomedical Instrumentation Centre, Hong Kong Science Park, Hong Kong

Recording and stimulation of neural circuits in-vivo at the cellular level are essential for us to understand the function of brain and establishing a brain-computer interface. Due to the relatively complicated patterning and fabrication steps, the neural probes with multi-function stimulation and large-area coverage are usually based on conventional semiconductors such as silicon. The major drawback of these rigid neural probes is it will inevitably damage parts of the brain and induce immune response lead to lead to glial scars which limits the long-term recording.

In this work, we will present a polymer-based flexible neural probe, based on standard lithography process and 3D printing process. The probe equip with eight closely spaced 30 µm diameter PEDOT:PSS/pHEMA electrode and a soft magnetic polymer fiber shuttle which can be driven by external gradient magnetic field and go into brain with 3D curvilinear path. We designed and fabricated a magnetic actuation platform for controlling the magnetic probe motion and positioning precisely. We also integrated the Fiber Bragg Gratings (FBG) into this neural probe as the feedback of the probe position and shape. In the talk, the operating mechanism and the fabrication process of the magnetic neural probe will also be discussed. This neural probe can minimize the risks of brain damage or glial scaring during neural spike recording and neuron stimulation and have great potential for biomedical applications. As a demonstration, we will also discuss the application of the flexible neural probe in the brain of the rat for the direct neural spike and local field potential sensing.

Design, Characterization and *In Vivo* Application of Multi-Conductive Layer Organic Electrocorticography Probes Remy Cornuejols[1,2], Amelie Albon[2], Suyash Joshi[3], James Alexander Taylor[3], Martin Baca[2], Pascale P. Quilichini[1], Sofia Drakopoulou[2], Tania Rinaldi Barkat[3], Christophe Bernard[1] and Charles Rezaei-Mazinani[2]; [1]Aix-Marseille Université, France; [2]École des Mines de Saint-Étienne, France; [3]Universität Basel, Switzerland

Biocompatible and plastic neural interface devices allow for minimally invasive recording of brain activity. Increasing electrode density on such devices is essential for high resolution neural recordings. Superimposing conductive leads on devices can help multiplying the number of recording sites while keeping probes width small and suitable for implantation. However, because of leads' vertical proximity, this can create capacitive coupling (CC) between overlapping channels, which leads to crosstalk. In our study, we present a thorough investigation of CC phenomenon in multi gold layer thin-film MEAs with a Parylene C (PaC) insulation layer between superimposed leads. We also propose a guideline on the design, fabrication and characterization of such type of neural interface devices for high spatial resolution recording. Our results demonstrate that the capacitance created through CC between superimposed tracks decreases non-linearly then linearly with insulation thickness. Moreover, CC creates a high pass filter between superimposed leads, with maximum gain and cutoff frequency depending not only on device geometry but also on the recording equipment. We identified that there is an optimal PaC insulation thickness that leads to a drastic reduction of CC between superimposed gold channels, while not significantly increasing the overall device thickness. Finally, we show that double gold layer electrocorticography probes with this optimal insulation thickness exhibit similar performances *in vivo* when compared to single layer devices. This confirms that these probes are adequate for high-quality neural recordings.

10:15 AM SB09.05.05
Implantable Bioelectronics with Shape Actuation for Minimally Invasive Electrocorticography Lawrence Coles[1], Ben Woodington[1], Domenico Ventrella[2], Alberto Elmi[2], Maria L. Bacci[2], George G. Malliaras[1], Damiano G. Barone[1] and Christopher Proctor[3]; [1]University of Cambridge, United Kingdom; [2]Università di Bologna, Italy; [3]University of Oxford, United Kingdom

The development of innovative neural interface devices would allow for novel approaches to diagnose, monitor, and treat neurological conditions and impaired neural-mediated motor function. Electrocorticography (ECoG) is an implanted neural interface technique that has been developed to record brain activity using large-area electronic arrays placed on the cortical surface and is used as a diagnostic tool in Epilepsy and Parkinson's monitoring, and brain-computer interfaces for prosthesis control. There has been extensive investigation into flexible ECoG devices, with a variety of substrate materials and electrode designs, however, the implantation of these devices is very invasive due to the size of craniotomy required.

This project aims to design shape-morphing ECoG neural implants that can be implanted with minimally invasive surgical techniques, whilst still retaining the large area mapping and spatial resolution of existing ECoG technologies. We have developed a microfluidics-based soft-robotic ECoG design that allows us to deploy a folded thin-film ECoG with a small burr-hole craniotomy onto the cortical surface, before deploying the full large bioelectronic array onto the cortex using fluidic actuation. The application of soft-robotic technologies in shape-morphing implants is an emerging field, applying the use of soft polymeric materials to form actuators that enable the shape actuation of these devices post-implantation. This approach to shape-morphing bioelectronics using soft, compliant materials also allows the large bioelectronic arrays to match the surrounding soft environment of human tissue mechanically.

The ECoG designs were tested in porcine models, with the integration of x-ray opaque PDMS markers allowing the expansion of the devices to be tracked with real-time fluoroscopy. This demonstrated that soft-robotic technologies would be a feasible approach for delivering larger ECoG designs to the cortical surface with a burr-hole craniotomy. By reducing the invasiveness of flexible ECoG sensors, this innovation allows for the reduction of both surgical risk and cost, increasing the availability of these sensors for clinical applications.

10:30 AM SB09.05.06
Spatially Controlled, Bipolar, Cortical Stimulation with High-Capacitance, Mechanically Flexible Subdural Surface Microelectrode Arrays Ilke Uguz and Ken Shepard; Columbia University, United States

Most neuromodulation approaches rely on extracellular electrical stimulation with penetrating electrodes at the cost of cortical damage. Surface electrodes patterned on thin-film plastic substrates, in contrast, can be subdurally implanted and adhere to the pial surface in chronic settings minimizing the mechanical compliance mismatch between probe and neural tissue. However, surface stimulation strategies are challenged by the lack of proximity to axonal processes, leading to poor resolution. Here, we examine how these constraint can be overcome by using high-density (40-µm pitch), high-capacitance (>1 nF), single neuronal resolution poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) electrodes in a bipolar stimulation configuration to shape the charge injection. We tune the surface electrode array to be optically transparent to allow concurrent calcium imaging for mapping immediate neural response to stimulation pulses at depth. This allows us to generate synaptic activation maps and to determine stimulation mechanisms. In addition, we pattern the flexible arrays using dry etching techniques to shape the functional front. This way we generate devices both in the form of surface arrays and implantable probes which can be inserted inside the brain aided by temporary, rigid carriers to generate a three dimensional neural interface. The resulting stimulation effects are captured with both two-photon imaging and simultaneous recording from depth electrodes. We demonstrate the ability to stimulate at depths up to 300 micrometer with lateral resolutions of better than 100 micrometer. We have also been able to show that single-units recorded form the surface correspond to activity from L2/3 pyramidal neurons. By integrating Polydimethylsiloxane microfluidic channels and release sites on the array, we show that the surface stimulation is not influenced by surface apical dendrites through selected drug release between the stimulation electrodes. These studies highlight the bidirectional interfacing possibilities that exist with high-quality, micron-scale surface electrodes for emerging neuro-technologies that rely on surface electrodes.

10:45 AM *SB09.05.07
Translational Neuroelectronics Dion Khodagholy; Columbia University, United States

Our understanding of the brain relies on discoveries in neuroscience and neurology fueled by sophisticated bioelectronics enabling visualization and manipulation of neural circuits at multiple spatial and temporal resolutions. In parallel, to facilitate clinical translation of advanced materials, devices, and technologies, all components of bioelectronic devices have to be considered. Organic electronics offer a unique approach to device design, due to their mixed ionic/electronic conduction, mechanical flexibility, enhanced biocompatibility, and capability for drug delivery. We design, develop, and characterize conformable, stretchable organic electronic devices based on conducting polymer-based electrodes, particulate electronic composites, high-performance transistors, conformable integrated circuits, and ion-based data communication.

These devices established new experimental paradigms that allowed monitoring of the emergence of neural circuits during development in rodents and elucidated patterns of neural network maturation in the developing brain. Furthermore, the biocompatibility of the devices also allowed intra-operative recording from patients undergoing epilepsy and deep brain stimulation surgeries, highlighting the translational capacity of this class of neural interface devices.

In parallel, we are developing the fully-implantable, conformable implantable integrated circuits based on high-speed internal ionic gated organic electrochemical transistors that can perform the entire chain of signal acquisition, processing, and transmission without the need of hard Si-based devices. This multidisciplinary approach will enable the development of new devices based on organic electronics, with broad applicability to the understanding of physiologic and pathologic network activity, control of brain-machine interfaces, and therapeutic closed-loop devices.

11:15 AM *SB09.05.08
Tissue-Adhesive Hydrogel Biointerfaces for Sutureless Implantable Electronics Mikyung Shin; Sungkyunkwan University, Korea (the Republic of)

Soft and stretchable bioelectronics have been attractive due to mechanical modulus matching to biological tissues. Nevertheless, there still have remained challenges to optimize biotic-abiotic interfaces for long-term and reliable bidirectional electrical stimulation and signal recording. Herein, we propose a hydrogel biointerface with wet-resistant tissue adhesiveness – which is inspired by mussel byssal threads, enabling immediate fixation of implantable electronics on nerve and cardiac tissues without any sutures. Firstly, adhesive and strain-gradient artificial epineurium is presented for efficient nerve-to-nerve connection and regeneration, implementing further stable neural interfacing. Secondly, a strain-adaptive fiber-interlocked bioelectronic patch is introduced for efficient cardiac interfacing even in freely moving animals. Such patch-type devices containing tissue adhesive hydrogel interfaces would be promising for developing sutureless bioelectronics.

11:45 AM SB09.05.09
From 2D to 3D Flexible Intraretinal Implants—Towards a New Generation of Visual Prostheses Viviana Rincón Montes[1], Marie Jung[1,2], Jamal Shihada[1,2], Lina Koschinski[1,2], Tibor Lohmann[2], Frederic K. Balcewicz[2], Sven Ingebrandt[2], Frank Müller[3], Peter Walter[2] and Andreas Offenhaeusser[1,2]; [1]Institute of Biological Information Processing (IBI-3) Bioelectronics, Forschungszentrum Jülich, Germany; [2]RWTH Aachen University, Germany; [3]Forschungszentrum Jülich GmbH, Germany

The development of visual prostheses that stimulate the retina electrically has allowed significant advances toward the restoration of useful vision in the daily life of blind patients with retinal degenerative diseases. Nonetheless, such improvements are still rudimentary and the efficiency of retinal implants did not meet the expectations of patients, to the point that commercially available retinal implants were withdrawn recently from the market [1]. To further develop the field of retinal-based visual prosthetics, it is of vital importance to better understand the physiology of healthy and diseased retinas and to improve the efficiency of retinal implants upon electrical stimulation. To this end, feedback about electrical activity in the retina is desirable. Given the above, our research consortium has proposed the development of a bidirectional communication strategy. The idea is that the implant comes in close contact with vital neurons inside the retina to perform simultaneous electrical stimulation and recording of the retina. It thereby allows optimization and acknowledgment of the efficiency of the electrical stimulation process for the restoration of vision.
To this end, we developed a bidirectional microelectrode array (BiMEA), comprising flexible (parylene-C-based) penetrating multi-shank and multi-site neural probes for retinal applications with iridium oxide or PEDOT: PSS electrodes [2-4]. 2D intraretinal probes were first developed, allowing an *in vitro* proof of concept with explanted rodent retinas that showed the feasibility of an intraretinal bidirectional prosthetic device. Here, we showed the capability of intraretinal recording while capturing distinct neuronal responses upon electrical stimulation on both, healthy and diseased retinas. Excitatory and inhibitory, as well as monotonic, non-monotonic, and saturated neural responses were captured when charges between 0.2 nC – 2.5 nC were applied. Furthermore, our devices showed a small acute insertion footprint in explanted retinas when using miniaturized probes (7 µm-thick, 50 µm-wide, and 140/180 µm-long), thereby reducing the acute insertion trauma area by 2-fold when compared to silicon Michigan-like arrays (20 µm-thick, 60 µm-wide, 312 µm-long). Moving even one step forward, we designed, developed, and tested *in vitro* 3D flexible penetrating retinal implants for the first time. The latter allowed the recording of physiological responses of light-adapted retinas. Paving the way toward *in vivo* applications, intraretinal probes were validated in cadaveric animal models, exposing the feasibility of implanting such probes with an open-sky surgery for a future acute *in vivo* validation of the BiMEA concept.

Development of Semiconducting Polymers for Organic Electrochemical Transistors Iain McCulloch; University of Oxford, United Kingdom

Organic electrochemical transistors (OECTs) have been shown to be promising devices for amplification of electrical signals and selective sensing of ions and biologically important molecules in an aqueous environment, and thus have potential to be utilised in bioelectronic applications. The sensitivity, selectivity and intensity of the response of this device is determined by the organic semiconducting polymer employed as the active layer. This work presents the design of new organic semiconducting materials which demonstrate good OECT performance, through operation in accumulation mode, with high transconductance and low operating voltage.
We discuss here the design, synthesis and performance of novel intrinsic semiconducting polymers for efficient accumulation mode OECT devices. Key aspects such as ion and charge transport in the bulk semiconductor and operational voltage and stability of the devices are addressed in order to elucidate important structure-property relationships. A range of new semiconducting polymers, designed to exhibit facile electrochemical doping of either holes or electrons, facilitate ion penetration and migration, as well as have aqueous compatibility are reported. Optimisation of a series of polymer parameters including electrochemical doping, charge carrier mobility and capacitance are discussed.

2:00 PM SB09.06.02
Characterization of the 3D Neuronal Network Read-Out Platform with an Improved Ratio of Measurable Neurons Using Alginate Patterning on Microelectrode Array for Precise Network Analysis Dongjo Yoon and Yoonkey Nam; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The In vitro biological neuronal network model has been widely used as a tool to improve understanding of neuronal networks by lowering the complexity of the native brain. Among them, the three-dimensional (3D) neuronal network model embedded in the extracellular-based matrix (ECM) is known to be closer to the gene expression and functional activity of the native brain than the flat cultured neuronal network. With these advantages, the 3D neuronal network model has been developed into models with various structures, such as modular structures and layer-by-layer structures. Microelectrode array (MEA) device has the advantage of being able to track the network activity for a long time with high-temporal resolution and has been used to measure the functional activity of a 3D neuronal network. However, signal measurement of the 3D neuronal network models had a limitation in that most of the neurons could not be measured by electrodes because neurons were randomly distributed in 3D space and far from electrodes. 3D MEAs which have electrodes in 3D have been developed, but there are still many neurons that cannot be measured compared to the total neurons in the network.

In this study, we introduce an engineered 3D neuronal network model in which neurons are located only on electrodes. This model can be used as a 3D neuronal network read-out platform to read most of the neurons in the 3D network. In order to develop this 3D network structure, we used the previously reported alginate patterning technique on flat MEA (electrode diameter: 30 μm, interval: 200 μm). Alginate hydrogel was biocompatible and neuron-repulsive so that neurons can be attached to the desired region (diameter: 100 μm) on microelectrode. Then, collagen type 1 (Col1, 1.0 mg/mL) which is ECM-based hydrogel was covered on the cultured cells at 3 days in vitro (DIV). For stable adhesion of Col1, a polydimethylsiloxane (PDMS) sheet (outer diameter: 7 mm, inner diameter: 4 mm, thickness: 200~250 μm) was attached to the bottom of the MEA, and a nylon mesh (Outer diameter: 4 mm, inner diameter: 50 mm) was inserted in the middle.

We investigated the morphological characterization of our model through immunostaining and confocal microscope (LSM880, Zeiss) imaging. It was confirmed that somas were maintained only in the originally placed area even after 3 weeks. Neurites grew more densely in space over 5, 7, and 14 DIV. The neurite density decreased as the height increased, but on the top interface, the neurites were concentrated. There are also dendrites and synapses in 3D space. We verified that our model was formed as a 3D neuronal network through morphological characterization.

In addition, we measured spontaneous activity for 10 to 28 DIV. The 2D neuronal network produced without covering Col1 was compared as a control group. The ratio of the active channel (firing rate > 0.1 Hz) and the amplitude of spikes were similar without significant differences from the 2D network. It was confirmed that the process of covering Col1 had no adverse effect at the electrode-neuron interface. The array-wide firing rate, burst rate, burst duration, percentage of burst spikes, and network synchronization index increased until 19 DIV and were maintained thereafter. As the result of the peristimulus time histogram (PSTH) through electrical stimulation, the 3D network showed a longer reaction during 200-400 msec compared with the 2D network which had 50 msec. It is inferred that more diverse paths are formed by the synapses in 3D space than the 2D network, so the synaptic reverberation is maintained long.

Our platform was able to successfully measure the activity of biological 3D neuronal networks and alginate patterns covered with Col1 maintained the position of all neurons on the electrode for 4 weeks. It can be used as a 3D neuronal network read-out platform to measure the signals from most neurons in the network for precise network analysis.

2:15 PM SB09.06.04

Photobiocatalytic Hydrogen Production from Water Using Conjugated Polymer Nanoparticle-Recombinant *Escherichia coli* Biohybrid Systems
Ying Yang[1], Reiner S. Sprick[2], Lu-Ning Liu[1] and Andrew I. Cooper[1]; [1]University of Liverpool, United Kingdom; [2]University of Strathclyde, United Kingdom

In the pursuit of systems with high solar-to-fuel conversion efficiencies, different strategies have been employed to interface synthetic and biological components. Semi-artificial photosynthesis is aimed to combine the light-absorbing ability of synthetic materials and efficient metabolic pathways in biological systems. As such, it has attracted significant interest over the last 10 years for solar-to-chemical energy conversion. With the development of new photocatalysts, especially organic photocatalysts in the last five years, this presentation will discuss the potential of conjugated polymers, rather than traditional inorganic semiconductors, as photosensitiser materials in biological hybrid systems.

This polymer-microorganism biohybrid system - the first report of polymer/*Escherichia coli* (*E. coli*) system for hydrogen production - not only offers the ability to tune the materials' photophysical properties but also to explore structure-activity relationships, especially for possible electron/energy transfer involved. In this work, nanoparticles of a series of linear polymers with different backbone structures were assembled with recombinant *E. coli* cells. Confocal fluorescence microscopy and scanning electron microscopy confirmed the successful assembly which is driven by hydrophobic and electrostatic interactions. Under simulated solar light irradiation, there a more than 10-times performance improvement for hydrogen production of polymer/*E. coli* biohybrid systems compared with the polymer sample, was observed, while no detectable hydrogen was generated from the bacteria sample. Trends within the series of hybrid systems could be explained by differences in the physical interactions between synthetic materials and microorganisms, energy level alignments, and kinetics. Further insights into the fundamental processes of these biohybrid systems were gained through a range of techniques, including time-correlated single photon counting, transient absorption spectroscopy, and metabolic analysis.

2:30 PM BREAK

3:00 PM SB09.06.05

Molecular Design and Degradation Lifetimes of Semicrystalline to Near-Amorphous Degradable Semiconducting Polymers Jerika A. Chiong and Zhenan Bao; Stanford University, United States

Transient electronics have received widespread interest for their potential applications in reducing electronic waste and improving human health through implantable devices. Synthetic polymers serve as an attractive platform for the development of degradable electronic components due to their ability to be rationally tuned by molecular design for exploration of desired mechanical, electronic, and degradation properties. Although there has been much development on biobased and biodegradable insulating polymers for substrate and dielectric components in recent years, there are only several existing degradable semiconducting materials. As a result, the degradation behavior of semiconducting polymers in relation to molecular design as well as morphological and electronic properties has not been properly studied. Herein, we prepare imine-based semiconducting polymers with tuned polymer architectures, ranging from semicrystalline to near-amorphous morphologies, for the systematic exploration of the impact of several molecular design parameters on the degradation lifetimes of these polymers. To rationalize differences in electronic performance and degradation behavior, we characterize the polymers' optical and morphological properties by ultraviolet-visible (UV-vis) spectroscopy, grazing-incidence X-ray diffraction, and atomic force microscope. By monitoring degradation via UV-vis, gel permeation chromatography, and NMR, we discover that polymer degradation in solution is heavily aggregation and hydrophilicity dependent. Additionally, the aggregation-dependence of these degradable polymers rely heavily on the solvent used, with a fivefold difference in degradation time depending on solvent. We develop a new method for quantifying the degradation of polymers in the thin film and observe that similar considerations used for designing high-performance semiconductors impact the degradation of imine-based polymer semiconductors. This study provides crucial principles for the molecular design of degradable semiconducting polymers, and we anticipate that these findings will expedite progress toward implantable electronics with targeted, controlled lifespans.

3:15 PM SB09.06.06

A Comparative Study of *In Situ* and *Ex Situ* Synthesized Conductive Polymers on Natural Lipid Bilayers Diana Priyadarshini; Linköping University, Sweden

Seamless integration between biological systems and electrical components is essential for enabling a twinned biochemical-electrical recording and therapy approach to understand and combat neurological disorders. Employing bioelectronic systems made up of conjugated polymers, which have an innate ability to transport both electronic and ionic charges, provides the possibility of such integration. In particular, translating enzymatically polymerised conductive wires, recently demonstrated in plants and simple organism systems, into mammalian models, is of particular interest for the development of next generation devices that can monitor and modulate neural signals. As a first step toward achieving this goal, enzyme-mediated polymerisation of two thiophene-based monomers was recently demonstrated on a synthetic lipid bilayer supported on a Au surface. In this paper, a comparative study of in situ vs. ex situ synthesized conductive polymers is conducted on Au supported bilayer substrates made up of natural lipids. Microgravimetric studies of these polymer films provide insights into their interactions with a lipid bilayer model that mimics the cell membrane. Moreover, resulting electrical and viscoelastic properties of these self-organising conducting polymers suggest their potential as materials to form the basis for implantable neural devices targeting novel therapeutic approaches.

3:30 PM *SB09.06.07
Macromolecular Bioelectronics Helen Tran; University of Toronto, Canada

Next-generation electronics will autonomously respond to local stimuli and be seamlessly integrated with the human body, opening the doors for opportunities in environmental monitoring, advanced consumer products, and health diagnostics for personalized therapy. For example, biodegradable electronics promise to accelerate the integration of electronics with health care by obviating the need for costly device-recovery surgeries that increase infection risk. Moreover, the environmentally critical problem of discarded electronic waste would be relieved. The underpinning of such next-generation electronics is the development of new materials with a wide suite of functional properties beyond our current toolkit. Organic polymers are a natural bridge between electronics and soft matter, where the vast chemical design space allows tunability of electronic, mechanical, and transient properties. Our research group leverages the rich palette of polymer chemistry to design new materials encoded with information for self-assembly, degradability, and electronic transport. In this talk, I will share an overview or projects underway in our group.

8:30 AM SB09.07.01
New Semiconducting Polymers for Bioelectronic Applications Christian Nielsen; Queen Mary University, United Kingdom

Semiconducting materials have long played a pivotal role in the development of organic electronic applications such as OLEDs and OFETs. More recently, semiconducting polymers have made their entry into the new field of bioelectronics, where electronic materials are interfaced with a biological milieu. In my talk I will discuss our recent work on new semiconducting materials for organic bioelectronic applications with an emphasis on the development of efficient mixed ionic and electronic conductors for biosensing applications. Our work encompasses both small-molecule and polymeric semiconductors with tailored properties for mixed conduction, while we are also actively developing both p- and n-type mixed conductors with examples of both classes of materials discussed in my talk.

8:45 AM SB09.07.02
Strong and Tough Conductive Organo-Hydrogels via Freeze-Casting Assisted Solution Substitution Wei Zhai, Xinyu Dong, Xiao Guo, Quyang Liu, Yijing Zhao and Haobo Qi; National University of Singapore, Singapore

High strength, toughness, and conductivity are among the most sought-after properties of flexible electronics. However, existing engineering materials find it difficult to achieve both excellent mechanical properties and high conductivity. To address this challenge, this study proposes a facile yet versatile strategy for preparing super-tough conductive organo-hydrogels via freeze-casting assisted solution substitution (FASS). This FASS strategy enables the formation of organo-hydrogels in one step with exquisite hierarchical anisotropic structures coupled with synergistic strengthening and toughening effects across multiple length scales. As an exemplary material, the prepared polyvinyl alcohol (PVA) organo-hydrogel with solvent content up to 87 wt% exhibits a combination of high strength (6.5 MPa), high stretchability (1710% in strain), ultra-high toughness (58.9 MJ m^{-3}), as well as high ionic conductivity up to 6.5 S m^{-1} with excellent strain sensitivity. The exceptional combination of mechanical properties and conductivity makes the PVA organo-hydrogel a promising flexible electronics material. In addition, the FASS strategy can also endow hydrogels with multi-functions, including thermo-healability, freezing tolerance and shape recoverability, and can be applied to various hydrogel materials, such as carboxymethyl cellulose, sodium alginate, and chitosan. Hence, this work provides an all-around solution for preparing advanced strong and tough conductive soft materials for a multitude of applications.

9:00 AM SB09.07.03
Intrinsically Conducting Polymers Self-Adhesive to Dry and Wet Skins as Compliant Dry Electrodes for Long-Term Motion-Robust Epidermal Biopotential Monitoring Jianyong Ouyang; National University of Singapore, Singapore

Epidermal biopotential monitoring such as ECG, EMG and EEG can provide vital health information, and they are popularly used in clinic. However, they cannot be used for long-term healthcare monitoring because of the conventional electrodes. Wearable dry electrodes are needed for long-term biopotential recordings but are limited by their imperfect compliance with the skin, especially during body movements and sweat secretions, resulting in high interfacial impedance and motion artifacts. Here, I will report compliant dry electrodes made of an intrinsically conductive polymer that can have excellent self-adhesiveness to both dry and wet skins, high mechanical stretchability, high conductivity, and good biocompatibility. They can show much lower skin-contact impedance and noise in static and dynamic measurement than the current dry electrodes and standard gel electrodes, enabling to acquire high-quality ECG, EMG and EEG signals in various conditions such as dry and wet skin and during physical movements. Hence, these dry electrodes can be used for long-term healthcare monitoring in complex daily conditions.

9:15 AM *SB09.07.04
Mechanically Transformative Electronics as Bio-Interfaces Jae-Woong Jeong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Conventionally, electronics are constructed with invariant form factors to serve targeted applications. For example, recent soft wearable and implantable electronics are designed to allow dynamic accommodation of applied stress to maximize user comfort and biocompatibility when integrated with the body. In contrast, the traditional consumer electronics are made flat and stiff to offer solid interfaces for easy user handling and interaction. However, the fixed mechanical properties of both types of electronics make them highly target-specific, limiting their broad use in a more compliant manner.
To overcome the fundamental limitation of these current electronics, we developed a new class of device systems, referred to as ‘transformative

electronics', that can reconfigure their shape, flexibility and stretchability for desired purposes. Transformative electronics are realized by integrating flexible, stretchable electronics with a variable-stiffness platform built using a composite of liquid metal gallium and soft elastomer. Utilizing temperature-triggered solid-liquid phase transition of gallium, these electronics can make on-demand conversion between the rigid and the soft modes, thus leveraging advantages of both forms of electronics. We have investigated applicability of this novel technology to promote interfaces between electronics and biological organs. For example, for the skin, we developed a transformative wearable system capable of rapid reversible mechanical switching, which allows the user to utilize it as both a rigid handheld electronic device and a flexible skin-mounted biosensor for improved versatility. For interfaces with internal organs such as the brain and the blood vessel, we employed the property of the gallium-based devices that can tune their stiffness and shape based on body temperature (above 30 °C). Based on this, we established neural probes and intravenous needles that softens upon penetration into tissue, which can significantly reduce inflammatory response in the injected site compared to the rigid devices with similar dimensions. Our proof-of-concept experiments and studies prove the potential of transformative electronics for biological interfaces, which may open new opportunities for diverse applications including wearables, implantables, robotics, and prosthetics.

9:45 AM SB09.12.05
Fabrication of Soft Biobatteries for Powering a Biomedical Sensor Patch Mahya Karamimosammam[1,2], Doris Danninger[1,2], David Schiller[1,2] and Martin Kaltenbrunner[1,2]; [1]Johannes Kepler University Linz, Austria; [2]Linz Institute of Technology, Austria

Many modern medical therapeutic and diagnostic operations are assisted by electronic devices. However, integrating these devices into biomedical systems attached to human organs or skin relies on their flexibility and biocompatibility to adapt to living tissues and deformations. Besides, environmental pollution caused by the rapid increase in tech wastage and improper disposal of them makes degradable electronics indispensable. Addressing these requirements necessitates the development of new materials and methods for fabricating a new generation of soft bioelectronics. Consequently, the fabrication of power sources that withstand the high-power demand of modern bioelectronic devices is of crucial importance. We introduce a new approach for fabricating not only biocompatible but wholly biodegradable batteries as entirely stretchable systems. Here, a concept for merging intrinsically stretchable gels with engineered stretchability through kirigami patterning for the realization of high-power biodegradable batteries with reversible elasticity of up to 35% for uniaxial strain and 20% for biaxial strain is demonstrated. A combination of molybdenum metal foils, a molybdenum trioxide paste, and magnesium metal foils as electrode materials provide a peak power output of 196 μW cm^{-2} and an energy density of 1.72 mWh cm^{-2}. A biomedical sensor patch on the skin for monitoring sodium levels in sweat is powered by biodegradable batteries. An adjustable pathway for high-power biodegradable batteries that enable unbound soft electronics in a sustainable future is offered by this concept.

10:30 AM SB09.07.06
Adhesive-Free Hydrogel Bioelectronics Enabled by a Template-Directed Assembly of Metallic Nanofibrous Network Jooyeun Chong and Jiheong Kang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Over the past decade, conductive hydrogels have received great attention as tissue-interfacing electrodes due to their soft and tissue-like mechanical properties. However, a trade-off between robust tissue-like mechanical properties and good electrical properties has prevented the fabrication of a tough, highly conductive hydrogel and limited its use in bioelectronics.
Here, I present a new synthetic method for the realization of highly conductive and mechanically tough hydrogels with tissue-like modulus. I employed a template-directed assembly method, which enables the arrangement of a disorder-free, metallic nanofibrous conductive network inside a highly stretchable hydrogel network. The resultant hydrogel exhibits exceptionally high conductivity (247 S/cm), high stretchability (>600%), and tissue-like Young's modulus (35 kPa). Furthermore, it can provide tough adhesion (800 J/m2) with diverse dynamic wet tissue after chemical activation. In addition, its biocompatibility in vivo was confirmed, which makes our hydrogel an ideal bio-interfacing electrode for bioelectronics. For the first time, this hydrogel enables suture-free and adhesive-free, high-performance hydrogel bioelectronics. I successfully demonstrated ultra-low voltage neuromodulation and high-quality epicardial electrocardiogram (ECG) signal recording based on in vivo animal models. This template-directed assembly method provides a new platform for hydrogel interfaces for various bioelectronic applications. I will discuss the details of the synthesis of T-ECH and its application for adhesive-free hydrogel bioelectronics.

10:45 AM SB09.07.07
A Highly Stable Electrode with Low Electrode-Skin Impedance for Wearable Brain-Computer Interface Huiliang Wang; The University of Texas at Austin, United States

To date, brain-computer interfaces (BCIs) have proved to play a key role in many medical applications, for exam- ple, the rehabilitation of stroke patients. For post-stroke rehabilitation, the BCIs require the EEG electrodes to precisely translate the brain signals of patients into intended movements of the paralyzed limb for months. How- ever, the gold standard silver/silver-chloride electrodes cannot satisfy the requirements for long-term stability and preparation-free recording capability in wearable EEG devices, thus limiting the versatility of EEG in wear- able BCI applications over time outside the rehabilitation center. Here, we design a long-term stable and low electrode-skin interfacial impedance conductive polymer-hydrogel EEG electrode that maintains a lower imped- ance value than gel-based electrodes for 29 days. With this technology, EEG-based long-term and wearable BCIs could be realized in the near future. To demonstrate this, our designed electrode is applied for a wireless single- channel EEG device that detects changes in alpha rhythms in eye-open/eye-close conditions. In addition, we vali- date that the designed electrodes could capture oscillatory rhythms in motor imagery protocols as well as low- frequency time-locked event-related potentials from healthy subjects, with better performance than gel-based electrodes. Finally, we demonstrate the use of the designed electrode in online BCI-based functional electrical stimulation, which could be used for post-stroke rehabilitation.

11:00 AM SB09.07.08
An Integrated ECoG and Depth Electrodes for Signal Monitoring and Deep Brain Stimulation Treatment of Epilepsy Na Xiao[1,2,3], Tao Zou[1,2], Gary Kwok Ki Chik[1,2], Chung Tin[3] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, China; [2]Advanced Biomedical Instrumentation Centre, Hong Kong; [3]City University of Hong Kong, Hong Kong

Epilepsy is a central nervous system disorder in which brain activity becomes abnormal, causing seizures or periods of unusual behavior, sensations, and sometimes loss of awareness and even sudden death. It affects more than 65 million people worldwide. Deep brain stimulation (DBS) has been approved to be effective means of seizure control for patients with drug-resistant seizures. However, traditional metal neural probes used for monitoring the neural signal and delivering electrical stimulation have significant disadvantages in poor conformability, risk of tissue damage, long-term stability issue and etc. Soft-material based electrode array has emerged as a promising alternative to metal probes for their small size, biocompatibility, and more importantly, their flexibility and conformability.
Here we designed a multifunctional device that has 16-channel ECoG electrodes and 16-channel depth electrodes for both neural signal monitoring and real-time DBS delivery. The electrodes were fabricated with gold as conducting layer and parylene as the supporting layer, coated with PEDOT:PSS to

reduce the impedance and increase the charge injection capacity and pHEMA to enhance the bio-compatibility. Our device allows multiscale electrophysiological recording in vivo. In the experiment, the ECoG electrodes were placed on the surface of the brain cortex for sensing the ECoG signals and the depth electrodes were implanted into the hippocampus region to record the single neuronal spike and local field potential (LFP), as well as deliver electrical stimulation. The results show that we were able to acquire high-quality ECoG, LFP and spikes signals from both acute and chronic epileptic rat models under anesthesia or awake. We also showed that the electrical stimulation delivered to the hippocampus region through our device effectively suppressed the seizures in these animals.

11:15 AM *SB09.07.09
Wound-Integrated Bioelectronic Sensors with Polymeric Electronics John S. Ho; National University of Singapore, Singapore

Monitoring surgical wounds is essential to prevent infection and other complications. However, current clinical monitoring is typically limited to indirect observations or costly diagnostic investigations that often fail to detect complications before they become severe. In this talk, I will describe wound-integrated bioelectronic sensors based on polymeric electronic materials that provide continuous wireless monitoring of both surface wounds and deep surgical sites. First, I will introduce multifilament surgical sutures functionalized with a conductive polymer that can be operated via radiofrequency identification and used to monitor physicochemical states deep in the body. Next, I will discuss a wireless and battery-free sensors that provides smartphone-based detection of wound infection using a bacteria-responsive DNA hydrogel. In vivo experiments in both small and large animal models highlight the ability of these sensors to integrate seamlessly with wounds and enable the early detection of complications. Wound-integrated bioelectronic sensors may facilitate post-surgical monitoring in a wide range of interventions and improve clinical outcomes.

SESSION SB09.08: Wearable Bioelectronics II

1:45 PM SB09.08.01
Stretchable Semiconductor Metallization for Skin-Like Organic Transistors Jin Young Oh, MinWoo Jeong, Jun Su Kim, Tae Uk Nam and Ngoc Thanh Phuong Vo; Kyung Hee University, Korea (the Republic of)

Despite recent remarkable advances in stretchable organic thin-film field-effect transistors (OTFTs), the development of stretchable metallization remains a challenge. In this talk, I present a highly stretchable and robust silver (Ag) metallization on an elastomeric semiconductor film based on metal-polymer intermixing. Ag atoms have a high diffusivity in polymers, which results in the formation of intermixing layer consisted of Ag nanoclusters and polymer chains during thermal evaporation, providing strong adhesion to the metallized Ag film. The Ag metallization maintains a high conductivity ($>10^4$ S/cm) even under 100% strain and successfully preserves its conductivity without delamination even after 10,000 stretching cycles at 100% strain and several adhesive-tape tests. Moreover, a native silver oxide layer formed on the intermixed Ag clusters facilitates efficient hole injection into the elastomeric semiconductor, which transcends previously reported stretchable source and drain electrodes for OTFTs.

2:00 PM SB09.08.02
Conducting Polymers for Neurostimulation Gerwin Dijk, Adam Marks and Alberto Salleo; Stanford University, United States

Microelectrodes for high resolution neurostimulation enable therapies and treatments for a variety of neurological disorders and diseases. To enhance the electrochemical interface and ensure sufficient charge injection capabilities, microelectrodes are commonly coated with organic mixed ionic-electronic conductors (OMIECs) that provide a volumetric interaction with the electrolyte. Despite the accelerated development of a large variety of OMIECs, PEDOT:PSS is almost exclusively used as an electrode coating material and is favored for its commercial availability, electrical conductivity, stability and processability. Other OMIECs with different electronic-ionic transport and coupling properties have been characterized and benchmarked for organic electrochemical transistors by determining the product of the electronic mobility and the volumetric charge storage capacitance (μC^*), however, remain largely unexplored in the context of neurostimulation.

In this work, we investigated various OMIECs for neurostimulation applications. The materials are examined with electrochemical methods and pulse experiments to determine typical performance parameters such as the electrode impedance, charge injection limit and stability. Furthermore, the observed performance parameters are linked to the OMIEC specific transport and electronic-ionic coupling properties. The results reveal which OMIEC properties are crucial for optimal performance of microelectrodes and provide guidelines that aid the development of OMIECs for electrical stimulation applications.

2:15 PM SB09.08.03
Long-Term Comfortable Skin Electrodes Based on Conductive Microfiber Mesh and Ion Gel Composites Jongwon Lee and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

With the development of Internet of Things and artificial intelligence technologies, various machines have become an inseparable part of human life. Accordingly, while the importance of interaction via information transfer between machines and humans has increased, the development of suitable skin electrodes have received considerable attention. However, most of commercial skin electrodes exhibit uncomfortable fit and unfavorable look for long-term usage. Herein, we report on a novel gas-permeable highly-transparent skin electrode based on the composite made of grid-type PEDOT:PSS microfiber mesh and PVA-PAA nanofiber ion gel which were prepared by self-fusion and electrospinning, respectively. The fabricated composite skin electrodes showed thin nominal thickness, good optical transparency, and high gas permeability which afforded users comfortable fits. Furthermore, they showed low electrochemical impedance, thus, excellent performance in terms of electromyography recording comparable to those of commercial Ag/AgCl electrodes. We expect that the present gas-permeable highly-transparent skin electrode based on grid-type PEDOT:PSS microfibers will spur the development of many different types of user-friendly human machine interfaces which require both electrochemical performance and aesthetic aspects, particularly, for skin/face attachment.

3:30 PM SB09.08.05
Connecting Nanoscale Heterogeneity and Bulk Performance in Organic Mixed Conductors for Bioelectronics Seth Jackson, Garrett W. Collins,

Arnel Besic and Connor G. Bischak; The University of Utah, United States

Developing the next generation of bioelectronics interfaces requires understanding the underlying structure-function relationships in polymeric materials that dictate device performance. Organic mixed ionic-electronic conductors (OMIECs) have emerged as promising materials for bioelectronics and biosensors. The performance of these materials depends on a complicated relationship between ion motion, electron transport, and structural dynamics. Here, we interrogate coupled ionic-electronic-structural dynamics in OMIECs using a suite of spectroscopic and electrochemical methods. We show that structural changes in OMIECs are often complex, resulting in disorder-to-order transformations upon repeated electrochemical cycling. We also demonstrate that heterogeneity at the nanoscale impacts OMIEC performance and map the distribution of ions in OMIECs using nanoscale infrared imaging with photoinduced force microscopy. Our results demonstrate the need to understand structural heterogeneity and dynamic processes at the nanoscale in OMIECs to develop design principles for next-generation materials.

3:45 PM SB09.08.06
Stretchable, Skin-Adherent Piezoelectric Patch with Hierarchically Bio-Inspired Architectures for Energy Amplification Seung Hwan Jeon[1], Hyunseng Kim[2], Da Wan Kim[1], Chang Kyu Jeong[2] and Changhyun Pang[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of)

Recently, the piezoelectric energy harvester with advantages including high-power density, simple design, and high scalability under low strain changes has emerged as an alternative to supply electrical energy to intelligent technologies such as wearable healthcare electronics, robots, and biomedical devices. However, the low adhesion between the wearable energy harvesting device and the biological skin interface has limited its ability to generate electrical energy from physical movements of the body. Here, we report a Stretchable skin-adherent piezoelectric patch with a hierarchically designed octopus-beetle inspired array (HOBA). HOBA is composed of adhesion layer, stretchable electrode, and piezoelectric energy composite. Each layer is based on a polymer material, which helps HOBA to be monolithic and has excellent mechanical stability between layers. The adhesion layer has high normal adhesion and shear adhesions in rough skin. Stretchable electrodes with a wrinkle structure show stable electrical conductivity even in omnidirectional stretching and bending. The energy composite layer is based on a lead-free material that can be used on the human body and has a constant power density of 1.52 W/cm^3 in repeated bending (150°). Finally, our energy patch shows potential for use as a self-powered sensor for monitoring muscle movement and finger movement for medical applications.

5:00 PM SB09.09.01
Enhancing Ion Injection Kinetics in Organic Mixed Ionic-Electronic Conductors by Balancing Crystalline and Amorphous Regions Seth Jackson and Connor G. Bischak; The University of Utah, United States

Organic mixed ionic-electronic conductors (OMIECs) have emerged as promising materials for an array of next-generation devices, including bioelectronics interfaces, neuromorphic computing platforms, and energy storage modules. To advance these technologies, we need to uncover the structure-function relationships in OMIECs that underlie device performance. Here, we study poly(3-hexylthiophene) (P3HT), a common conjugated polymer, and how its crystallinity affects ion injection kinetics by blending a regioregular (RR) P3HT and a regiorandom (RRa) P3HT. Using steady-state and time-resolved spectroelectrochemistry, we show that a 75:25 RR:RRa blend of P3HT has faster ion injection kinetics than that of pure RR P3HT and pure RRa P3HT, indicating a potential "Goldilocks ratio" between crystalline and amorphous polymer content that maximizes ion injection kinetics. We also find using steady-state spectroelectrochemistry that positively charged holes initially dope crystalline regions of the polymer before doping the amorphous regions. Using grazing incidence wide-angle x-ray scattering (GIWAXS), we see the negatively charged ions enter the polymer film at the same potential the positively charged holes form. Taking a closer look at the time-resolved spectroelectrochemistry results, we notice a hysteresis effect in doping and dedoping P3HT, signifying that doping and dedoping are occurring through different pathways. We image the distribution of ions in the P3HT films using nanoscale infrared imaging with photo-induced force microscopy (PiFM) of an infrared-active ion. From these images, we see an increase in ion heterogeneity in the blended P3HT films as we increase the crystalline content. Overall, these results highlight the importance of balancing crystalline and amorphous regions in organic mixed conductors to enhance ion injection kinetics and the importance of connecting bulk performance with nanoscale heterogeneity.

5:00 PM SB09.09.02
Ultrasoft Stretchable Electronics for Stable and Imperceptible Integration with Soft, Dynamic Bio-Tissues Yang Li, Nan Li, Yahao Dai and Sihong Wang; The University of Chicago, United States

Interfacing electronics with the human body as wearable or implantable devices provides a large collection of functions in health monitoring, disease treatment, and even basic biological studies. To achieve seamless and compatible interfacing, it is imperative to minimize the mechanical mismatch between electronic devices and human skin/tissue. Hydrogels and ultrasoft silicones have been utilized due to their extraordinary performance in stretchability and softness. However, building complex electronics on top of such ultrasoft materials remains challenging because of the mismatched mechanical properties with highly rigid, electrically functional materials, which further introduces problems to the interface, as well as the fabrication process. To achieve stretchable electronic devices with ultralow Young's modulus, here, we present a generalizable soft interlayer design that can effectively solve the challenge of using existing electrically functional materials with high modulus to build the tissue-level-modulus devices (e.g., transistors, active matrix, sensors) with high stretchability. When the soft interlayer is inserted in between the high-modulus functional layers and ultrasoft substrate, interfaces within the device are improved by decreasing the modulus mismatch and enhancing interfacial toughness. We successfully demonstrated stretchable conductive interconnections with high stretchability and ultralow modulus based on conventional high modulus materials (CNTs, AgNWs and PEDOT: PSS composite). Also, a transistor device with Young's modulus of 6.7 kPa is fabricated, which can be stretched up to 100% strain. Furthermore, a 5x5 transistor array device on patterned soft interlayer and hydrogel substrate can even achieve a lower modulus of 3.6 kPa, which is 3 orders of magnitude softer than previously reported stretchable transistor arrays on SEBS substrate. Benefiting from the tissue-level softness, our electronic devices demonstrate highly stable and imperceptible integration with soft bio-tissues with nonzero Gaussian surfaces. Besides, combined with the high stretchability, the ultrasoft electronic devices further promote concurrent deformation on bio-tissues, causing less immune response when implanted.

5:00 PM SB09.09.03
Probing the Initial Steps in Electrochemical Doping of Organic Mixed Conductors with Photoluminescence Quenching Garrett W. Collins and Connor G. Bischak; University of Utah, United States

Organic mixed ionic-electronic conductors (OMIECs) are conjugated polymers that conduct electrons and ions. Due to their mixed conductivity, OMIECs are promising materials for many applications, including bioelectronics, electrochemical energy storage, neuromorphic computing, and supercapacitors. OMIECs function through electrochemical doping, in which an electrical charge is injected into the polymer matrix, and a complementary ion from an adjacent liquid electrolyte enters the polymer matrix to compensate for the electronic change. As OMIECs become more prevalent, new characterization techniques are needed to understand their structure-function relationships. Photoluminescence measurements as a function of voltage are much more sensitive to small concentrations of dopants, as well as changes in the polymer morphology associated with ion intercalation and hydration, compared to other characterization methods. We performed *in situ* photoluminescence measurements on two different polythiophenes with ethylene glycol-based side chains, poly(3-{2-[2-(2-methoxyethoxy)ethoxy]ethyl}thiophene-2,5-diyl) (P3MEEET) and poly(3-{[2-(2-methoxyethoxy)ethoxy]methyl}thiophene-2,5-diyl) (P3MEEMT). Potassium salts of bromide (KBr), chloride (KCl), perchlorate ($KClO_4$), bis-(trifluoromethanesulfonyl)imide (KTFSI), and hexafluorophosphate (KPF_6) were the electrolytes of choice, as they span the Hofmeister series. It was found that as the voltage increases, the photoluminescence of the OMIEC is quenched due to the presence of polaron-ion pairs in the material. Results indicate that the voltage at which quenching first occurs depends on the identity of the ion and the polymer side chains. These changes in photoluminescence are compared to other processes that occur during electrochemical doping, such as absorption spectroelectrochemistry, electrochemical quartz crystal microbalance (EQCM), and *in situ* grazing incidence wide-angle X-ray scattering (GIWAXS), to determine how photoluminescence quenching correlates to other dynamic processes in OMIECs.

5:00 PM SB09.09.04
Direct Electrical Biointerfacing with Adhesive and Stretchable Polymer Semiconductors Nan Li and Sihong Wang; University of Chicago, United States

Polymer semiconductors have shown distinct promise for merging human-machine interface, owing to their solution processability and soft mechanical nature. Organic electrochemical transistors (OECTs) as an advanced type of sensing devices, are highly desired for direct electrical biointerfacing due to their low operation voltage, high sensitivity and signal-to-noise ratio. To interface with wet and dynamically moving tissues, for example, heart, brain, or sciatic nerve, conventional suturing causes tissue/device damage and cannot achieve good conformability; having the adhesive property will ease the attachment process and help achieve a conformable contact and high spatial sensing resolution. So far, however, to the best of our knowledge, none of the existing high-performance polymer semiconductors are adhesive owing to a number of challenges, which prevent OECTs from achieving direct and conformable electrical interfacing with wet and dynamically moving biotissues.

Here, we develop an intrinsically adhesive and stretchable semiconducting polymer by creating a rationally designed polymer network with interpenetrating semiconducting polymers and adhesive brush polymers to realize both high normalized maximum transconductance (~100 siemens per centimeter) and good adhesion on wet biotissues (interfacial toughness ~35 joules per square centimeter). Benefiting from the brush polymer design, the semiconducting polymer network possesses soft and viscoelastic mechanical properties (Young's modulus ~10 kilopascal) comparable to biotissues, moderate water absorption (30 %), controllable swelling (<10 %), and abundant tissue-reactive groups (-COOH and -NHS), which synergically contribute to the adhesion on wet tissue surfaces. In addition, the semiconducting material shows abrasion-resistance and high stretchability above 100 % strain, which lead to the robust electrical performance. Also, the material presents good biocompatibility owing to low mechanical strain. Furthermore, enabled by the compatibility of the adhesive polymer with solution processing, we fabricated an intrinsically adhesive and stretchable OECT with the adhesive semiconducting polymer as both the active channel and gate and further demonstrated its use for monitoring electrophysiological signals consistently and reliably on wet heart surfaces even under perturbation scenarios.

5:00 PM SB09.09.05
Conductive Hydrogel Nerve Guidance Conduits with NGF-Gradient for Peripheral Nerve Repair in Diabetics Yuting Cai and Zhengtang Luo; The Hong Kong University of Science and, Hong Kong

Owing to hyperglycemia and microvascular complications, diabetics suffer from segmental axon demyelination and slow repair of injured nerves and result in motor function loss, muscle paralysis, and even life-long disability. Besides, autologous nerve transplantation which is the gold choice for repair is bothered by the poor size match between the donor and the acceptor and limited source of the donor. Therefore, multifunctional nerve guidance conduits for diabetics are proposed as an alternative. This study demonstrates a graphene-based nerve guidance conduit by integrating natural double network hydrogel and a neurotrophic concentration gradient. Wet-adhesive design of conduit can not only wrap and adhere to the injured nerve rather than suture, but also provide protection for the injured nerve and accelerate regeneration. The novel design of GelMA/silk fibroin double network hydrogel plays quadruple role for rapid setting/curing, strong mechanical-supporting, superior biocompatibility, and sustainable growth factor delivery. Additionally, encapsulated graphene mesh not only can enhance the mechanical strength of tube but also promote the regeneration of peripheral nerve and muscle fibers. Importantly, silk tapes achieve long-term and tough adhesion with wet surface via constructing the mechanical interlocking followed by covalent bonds. The histological staining reveals that conduits with gradient concentration of netrin-1 have better performance than uniform concentration for axon extension, remyelination, and angiogenesis which may cause by chemotaxis phenomenon. All in all, the new guidance conduit with gradient netrin-1 and adhesive design can enormously promote repair of peripheral nerve and prevent the atrophy of muscles for diabetics.

5:00 PM SB09.09.06
Ultra-tough, Highly Conductive and Electrochemically Stable Solid Electrolytes for Accurate Detection of Mechanical Motion Minsu Kim, Jeong-hui Kim, Kyung Gook Cho and Keun Hyung Lee; Inha University, Korea (the Republic of)

As a promising candidate of next-generation solid-state electrolytes for electrochemical devices, polymer gel electrolytes face two important challenges: insufficient mechanical toughness and low ionic conductivity compared to liquid electrolytes. To overcome these limitations, various methods of solidifying ionic liquids and fabricating the tough ionogel electrolytes have been suggested. Herein, we report the fabrication of physically crosslinked ionogels by utilizing phase separation of a semicrystalline homopolymer swollen in ionic liquids. The crystalline domains that serve as the network junction points were formed by solvent exchange and dissipates enormous energy upon application of external stress. The ionogels exhibited excellent mechanical properties including very high toughness (~ 46.24 MJ m^{-3}), and stretchability (~ 2135 %). Simultaneously, the ionogels possessed outstanding electrochemical performance, including high ionic conductivity (as high as 20 mS cm^{-1}) and wide electrochemical windows (~ 3 V). By using the ultra-tough ionogels as a piezoelectric sensing element, stretchable strain sensors were successfully fabricated to accurately detect mechanical movements of automobile parts. Overall, these results provide a new direction to fabricate tough ionogels for widespread electrochemical/electronic device applications.

5:00 PM SB09.09.07
Hydrogel Based Anisotropic Conductive Film (H-ACF) for Versatile Electrical Interfacing in Soft Electronics Yurim Lee, Yejin Jo and Jungmok

Seo; Yonsei University, Korea (the Republic of)

Electronic packaging, which attaches electronic elements to the substrate and connects the circuits, has developed from soldering to anisotropic conductive film (ACF). ACF is a mixture of conductive particles and an adhesive for making electrical connections only in the vertical direction. Thus, it prevents short-circuiting with neighboring circuits and can form a more concentrated electrical connection to circuits compared to the previous packaging technology. However, the conventional ACF has a limitation in that it is inappropriate for interconnecting elastic material, which has become more problematic as soft electronics have received attention as an interface to connect electronic devices to the human body. Because the electrical connection between integrated circuits (ICs) embodied on the flexible printed circuit boards (FPCBs) and soft electronics is necessary to perform the advanced function. Therefore, more investigations have been demanded to develop advanced ACF that is capable of electrically connecting various materials like stretchable polymer and moist hydrogel to electronics.
In this study, a hydrogel-based anisotropic conductive film (H-ACF) is designed for material-independent interconnection between electronic parts. H-ACF is composed of stacked poly (vinyl alcohol) (PVA) with conductive particles and tannic acid (TA) layers. PVA is non-toxic and one of the well-used hydrogel adhesives. So, it serves as the primary adhesive containing conductive particles. TA enhances hydrogel mechanical properties by acting as a crosslinker of PVA. Also, TA makes the film to adhere to the substrate regardless of the surface properties due to its abundant hydroxyl groups.
Based on these features of the components, H-ACF enables rapid (>1 min) and strong bonding (<1.5 MPa), which is essential for consistent connection even in harsh conditions with mechanical. Also, H-ACF can allow bonding between bumps on rigid PCBs and soft stretchable materials including polydimethylsiloxane (PDMS) and hydrogels. Particularly, the hydrogel can be adhered to the H-ACF by entangling the chains with the linkers of the film, which enables a heat-free bonding process. We confirmed that H-ACF has comparable electrical performance with conventional ACF, which is explained by low connection resistance and excellent insulation value.

5:00 PM SB09.09.08
Ionically Conductive, Soft Neural Interface for Non-Faradaic Neurostimulation Bokyung Kim[1], Joo Sung Kim[1], Junho Kim[2], Jun Woo Lim[3], Dong Jun Kim[1], Jihong Kim[1], Jae Hyun Jeong[3], Sung-Min Park[2,2] and Do Hwan Kim[1,1]; [1]Hanyang University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of); [3]Soongsil University, Korea (the Republic of)

Despite extensive clinical and biomedical research, optimal treatment of prominent neurological disorders is not fully established. Deaths per neurological disorder have perpetually increased, becoming a global burden today. Implantable neural prostheses with enormous potentials, such as spinal-cord stimulators, deep-brain stimulators, and vagus nerve stimulators are used for the effective therapeutic approaches in this field. Most stimulating metal electrodes in direct contact with the neural system use platinum or iridium oxide, which have low bulk resistance and high charge injection capability. However, conventional metal electrodes are prone to the mechanical mismatch of the neural interface between hard solid metal and soft tissue. Research on implantable neurostimulators using soft conductors based on conducting polymers and hydrogels is surging to overcome this limitation. However, both the faradaic charge injection in the conducting polymers, which results in the gas evolution, and ion diffusion in hydrogels, which leads to loss of biomolecule, cause neurological disorders.
In this talk, we propose a soft ionic neural interface design for highly stable neuromodulation using a non-faradaic charge injection mechanism. The ionic neural interface serves as a bioadhesive, based on biocompatible multi-crosslinked membrane–ionogel assembly (McMiA) soft electrodes. Importantly, we incorporated a crosslinked graphene oxide (X-GO) membrane and a crosslinked biopolymeric ionogel (X-BI) conductor onto metal electrode-coated flexible substrates. Contrary to conventional bioelectronics neural interfaces, the ionic neural interface allows neurostimulators to provide a non-faradaic charge injection because of the wide electrochemical potential window without undesirable electrochemical reactions even under high voltage conditions. In addition, the distorted ion-diffusion pathway of the GO membrane prevents ion exchange at the neural interface in physiological-relevant conditions. Our results corroborate the biological signaling processes starting from the sciatic nerve using Myoblast fusion in cultured muscle cells. Eventually, we developed a peripheral neurostimulator based on the ionic neural interface to control overactive bladder syndrome and performed proof-of-concept tests using a rat model. We believe that our bioadhesive ionic neural interface can provide a direct connection between the fields of electronics and biology for the design of next-generation implantable devices.

5:00 PM SB09.09.09
Electrically Induced Bursting of Aqueous Capsules Made from Biopolymers— 'Switching On' the Release of Payloads Wenhao Xu, Ankit Gargava and Srinivasa R. Raghavan; University of Maryland, College Park, United States

The use of electric fields to stimulate the delivery of drugs or other active ingredients is of great interest for wearable electronics and other applications. Most attempts at electrically induced delivery with soft materials in water have focused on electronically conducting polymers (e.g., polypyrroles) or conductive nanocomposites (e.g., polymers with carbon nanotubes). Here, electrical responses are induced even in structures made from nonconducting biopolymers that are widely available, biocompatible, and biodegradable. The materials studied here are spherical capsules created from the anionic polysaccharide alginate by cross-linking with cations like Ca^{2+} or Cu^{2+}. When these capsules are placed in an aqueous solution and subjected to an electric field (direct current) of ≈8 V/cm, they deform within a couple of minutes and then burst and disintegrate into pieces within ≈5 min. Capsules across a range of length scales (200 μm to 2 cm) respond in the above manner, and the electroresponse persists even if the capsules are embedded in a nonionic gel matrix. This electroresponse is due to electrophoretic migration of charged species (ions and/or polyelectrolyte chain-segments) within (or out of) the capsules. In an alginate capsule, the cations are induced to migrate away from the positive electrode, which creates a weakly cross-linked region of the capsule that swells appreciably. This anisotropic swelling continues until the capsule eventually bursts. Applications for electroresponsive capsules that highlight the spatial and temporal accuracy possible with an electrical stimulus are discussed. The bursting of capsules can be used to release solutes loaded inside these structures. Also, even the deformation of intact capsules can be used to create electrically actuatable valves, where a liquid flows out through the valve only when a capsule plug is dislodged.

5:00 PM SB09.09.10
The Effect of Polyethylene (glycol)diacrylate Post-fabrication Rest Time on Compressive Properties Ozlem Yasar and Najvan Kased; City University of New York, United States

Tissue Engineering has been studied to develop an alternative way to organ transplantation. Choosing the right type of biomaterials, cell sources, growth factors, and engineered scaffolds determine the success rate of Tissue Engineering. In this research, poly(ethylene glycol) diacrylate (PEGDA) is used to fabricate the scaffolds as it is a biocompatible and biodegradable material, and its porous microstructure help cells to breathe.

In this research, we studied how the mechanical properties of different concentrations of PEGDA change with the post-fabrication ageing time. Cylindrical PEGDA samples were prepared at 20%, 40%, 60%, 80%, and 100% concentrations and cured under UV light. After the solidification process, the weight of each sample was monitored every 0, 2, 4, 6, and 24 hours post-fabrication ageing time until the mechanical testing. Compressive elastic modulus and strength were calculated and statistically analyzed. Our results indicated that the water content of each PEGDA group constantly decreased over time, however, this loss significantly affected the elastic modulus and strength only after 6 hours in some PEGDA concentrations.

In recent years, tissue engineering has been utilized as an alternative approach for the organ transplantation. The success rate of tissue regeneration is influenced by the type of biomaterials, cell sources, growth factors and scaffold fabrication techniques used. The poly(ethylene glycol) diacrylate (PEGDA) is one of commonly used biomaterials because of its biocompatibility, ease of use, and porous microstructure. The mechanical properties of PEGDA have been studied to some extent by several research groups. However, the stability of the mechanical properties with time has not been investigated.
In this research, we studied how the mechanical properties of different concentrations of PEGDA change with the post-fabrication ageing time. Cylindrical PEGDA samples were prepared 20%, 40%, 60%, 80%, and 100% concentrations and cured under the UV light. After the solidification process, weight of each sample was monitored in every 0, 2, 4, 6, and 24 hours post-fabrication ageing time until the mechanical testing. Compressive elastic modulus and strength were calculated and statistically analyzed. Our results indicated that the water content of each PEGDA group constantly decreased by time, however, this loss significantly affected the elastic modulus and strength only after 6 hours in some PEGDA concentration.

5:00 PM SB09.09.11
Amphiphilicity-Driven Polymer Assembly Enables Performance Enhancement in n-Type Organic Electrochemical Transistors Dahyun Jeong[1], Il-Young Jo[2], Seungjin Lee[1], Ji Hwan Kim[2], Youngseok Kim[2], Donguk Kim[1], John R. Reynolds[3], Myung-Han Yoon[2] and Bumjoon Kim[1]; [1]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [2]Gwangju Institute of Science and Technology (GIST), Korea (the Republic of); [3]Georgia Institute of Technology, United States

A series of naphthalene diimide-based polymers incorporated with branched oligo(ethylene glycol) (OEG) side chains are developed to enable eco-friendly-processed, high-performance n-type OECTs. The OEG side chains afford processability in ethanol/water solvents. Importantly, taking advantage of the amphiphilicity of OEG-based polymers, ethanol/water solvents selectively solvate hydrophilic OEG side chains, while producing tight π–π stacks of hydrophobic backbones. This enables highly edge-on-oriented polymer packing, and thus excellent lateral charge transport. In particular, the fine-tuned OEG side chains of P(NDIMTEG-T) provide compact backbone packing, effective polaron generation, and superior electrochemical stability. The resultant OECT shows the best electrical/electrochemical performance, represented by a figure-of-merit (μC^*) of 0.56 F V^{-1} cm^{-1} s^{-1}. This study demonstrates the aqueous processing in OECTs and the design rule of n-type organic mixed ionic-electronic conductors.

5:00 PM SB09.09.12
Cellulose/Chitosan Composite Aerogel Based Triboelectric Nano-Generator for Harvesting Mechanical Energy Shadman Sakib; UTRGV, United States

Triboelectric nanogenerators have garnered much attention over recent years as the world continues advancing toward it's goals of green renewable energy and a more cohesive relationship with our environment. Every day small amounts of energy are lost in the form of mechanical energy as we move throughout our daily lives, triboelectric nanogenerators seek to use some of this otherwise lost mechanical energy for the purpose of powering small devices which would otherwise have to be powered using more costly and unsustainable sources of energy. Ideally these nanogenerators would be made of readily available, inexpensive, and safe natural materials which possess high mechanical and triboelectric properties. The goal of this research is to fabricate an aerogel made of cellulose and chitosan and reinforced with natural nanofiber materials for an increased level of mechanical strength and durability. While also generating enough electricity to power a small device or sensor. Currently it has been difficult to generate sufficient power via biiopolymer-based trio electric nano generators. Challenges in our research have been producing an aerogel which can produce a significant electrical charge through the triboelectric effect to harness mechanical energy as well as have the aerogel be durable and flexible enough to endure the daily wear and tear it must face as part of a person's clothing to make effective and practical nanogenerators which will power small embedded biosensors.
In our triboelectric layers high charge density is desired. This can be achieved with a combination of high surfac area(provided by porous nano fiber mats) and dopants with high electropositive and high electronegative charge affinities. We envision the sliding contact to be the main method for charge generation in this context. The high structural strength and flexibility will be provided by a porous, flexible aerogel/xerogel complex matrix structure. Medical applications for these (TENGs) are the goal of this research, the fruits of this research will go into producing TENGs for small medical devices which would otherwise have to be charged or be powered by external batteries which currently makes them expensive and impractical. Expecting mothers with high risk pregnancies have a very big concern when it comes to their fetuses and every minute counts especially when it comes to them. For these special cases a way to constantly monitor vital signs for their fetuses is crucial especially if something happens and there is a need for corrective action or a physician intervention. Our device would be flexible, safe and accurate to be embedded in everyday garments and used as a self powered tool to monitor their fetus's health in real time and be able to alert the mother when things are starting to get serious and their is an urgent need for medical attention.

Hole-Limited Electrochemical Doping in Conjugated Polymers Scott T. Keene[1], Joonatan Laulainen[1], Raj Pandya[1], Maximilian Moser[2], Christoph Schnederman[1], Paul Midgley[1], Iain McCulloch[2], Akshay Rao[1] and George G. Malliaras[1]; [1]University of Cambridge, United Kingdom; [2]University of Oxford, United Kingdom

Organic mixed ionic electronic conductors (OMIECs) have recently risen as a promising material choice for bioelectronic devices due to their low impedance, soft mechanical properties, and ability to transduce ionic signals to electronic currents. These materials properties have enabled the development of high-performance devices for electrophysiological recordings, chemical sensing, cell monitoring, energy storage, and neuromorphic devices. The unique behaviour of OMIECs arises from ion intercalation through the bulk of the material which can modify the oxidation state, and therefore charge carrier concentration, of the conjugated polymer backbone.

While the mixed conductors enabling these technologies are widely used, the dynamic relationship between ionic and electronic motion is generally poorly understood, hindering the rational design of new materials. In most semiconducting electrodes, mixed transport is assumed to be limited by motion of ions due to their large effective mass compared to electrons/holes. Here, we show that this basic assumption does not hold for conjugated polymer electrodes. Using *operando* optical microscopy to differentiate between ionic and electronic transport, we reveal that electrochemical doping in a state-of-the-art polythiophene is limited by hole transport. This hole transport-limited regime leads to substantially slower switching speeds than expected for electrochemical devices using otherwise high-performing materials. Structural characterisation reveals that the timescale of hole-limited doping can be controlled by the degree of heterogeneous disorder in the polymer microstructure. The hole-limited doping revealed in this work enables a deeper understanding of mixed conduction and informs the design of new mixed conducting polymers.

Capillary Force-Assisted CNT Microstructuring for Biomedically Applicable Flexible Microelectrode Array Kwangjun Kim[1], Minwook Kim[1], Hyunmin Baek[1], Hyeonhee Roh[2], Maesoon Im[2] and Jong G. Ok[1]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]Brain Science Institute, Korea Institute of Science and Technology (KIST), Korea (the Republic of)

Interconnecting technologies for sensing neural signals are investigated with microscale needle or rod-shaped electrode array foams. In this regard, the first point is to design an electrode whose shape can be easily integrated with biological organs. Flexibility and electrical conductivity are the second and third requirements, respectively, to facilitate structural and electrical connections between the device and the biological organs. In many previous studies, the devices are made by using the top-down process for feasible fabrication, array formation, and device packaging, but in this case, high mechanical stiffness of materials (Si, SiC) is involved. Alternatively, a microelectrode array could be fabricated by developing specific novel approaches, in which case the inferior reproducibility is pointed out as a bottleneck. Addressing these issues, we have developed carbon nanotube (CNT) microstructures for flexible microelectrode arrays that can be readily fabricated by chemical vapor deposition (CVD) and densification process; the CMS (CNT microstructure) once reliably grown by CVD can be shaped into mechanically robust and electrically conducting microelectrodes through the capillary force-assisted densification postprocess. Essentially, CMS growth technology on micropatterned catalyst layer was optimized; a stable CMS growth with appropriate CNT density on a micropatterned catalyst layer was realized by the control of catalyst thickness and CVD parameters. Next, a densification process is conducted for the needle-like shaping of CMS, which could make feasible biological integration (e.g., tissue implantation). With an exposure of CMS to acetone vapor under specific conditions, intrinsic nanopores inside the CMS can be considerably reduced to densify the structure with slenderized shape. Here the acetone vapor flow was controlled by adjusting temperature, while the CMS deformation characteristics were qualitatively investigated. Furthermore, in order to improve the mechanical properties and the electrical properties of densified CMS, additional structural and electrical reinforcement by using reductive Ag ion ink was conducted. The Ag ink consists of silver cations and their compounds. With direct contact with the densified CMS, Ag ink is absorbed into the intrinsic nanopores some of which are still present inside. Subsequently, with simple thermal annealing at a mild temperature, a silver particle is formed on and inside the CMS. The Ag particles bind the adjacent CNT pillars, which further improves the mechanical stiffness and the electrical conductivity of the CMS. Finally, the PDMS-hexane mixture was permeated into each structure: as-grown, densified, and Ag-reinforced CMS structure, to convert the entire structure into a flexible platform. The polymer mixture is gradually filled up from the side of the CMS array structure. Right upon contact to the CMS array, the polymer mixture was permeated into individual CMS pillars by the capillary force. Thereafter, the CMS array is completed as a flexible microelectrode array by curing at 80°C for a sufficient time and separating it from the substrate. Since then, microelectrode arrays based on as-grown/densified/Ag-reinforced CMS have been quantitatively investigated in terms of their strength and elastic properties through compression tests. As a result, sufficient mechanical stiffness and elastics for stable biological integration were confirmed. These structures can be used for sensing biological signals through implantation, attachment, and other connecting methods.

Advanced silicon processing has enabled neural sensing or modulation at an unprecedentedly large scale and a spatial resolution matching that of the neuron density. However, most planar and rigid silicon electronics have limited access to regions within neural tissue, and it still remains challenging to scalably obtain high-density neural activities in 3D. There has been progress in bridging the geometrical gap between silicon electronics and neural tissues, but the demonstrated penetrating electrodes have low spatial density and their fabrication processes can damage sensitive silicon electronics.
Here, we leveraged the state-of-the-art 2-photon polymerization technology to directly build high-density penetrating microelectrode arrays onto silicon electronics. We demonstrate with an array consisting of 6,600 electrodes pitched at 35 microns and with varying heights. The customizability of the process allows tailoring of array shape and spatial density to target different tissue shape or neuron density. As a proof-of-principle demonstration, we recorded retinal ganglion cell activities *ex vivo*, and were able to distinguish the neural activities with single-cell and single-cell-type resolution. We believe this technology will be crucial for next-generation neural interfaces that enable communication with neural circuits using their natural neural codes.

Engineering of Conjugated Polymers for Sensing Applications in Organic Electronics Raymundo Marcial Hernandez[1], William G. Neal[1], Sofia Giacalone[1], Peter Gilhooly-Finn[1], Dilara Meli[2], Ruiheng Wu[2], Jonathan Rivnay[2], Matteo Palma[1] and Christian Nielsen[1]; [1]Queen Mary University of London, United Kingdom; [2]Northwestern University, United States

Organic semiconductors have gained attention due to their versatility in various organic electronic applications. Polythiophenes like Poly(3-hexylthiophene) (P3HT) are polymers that have been extensively investigated as reference materials due to their attractive properties such as flexibility, biocompatibility, lightweight, stretchability, solvent processing and charge-carrier mobilities in organic field-effect transistors (OFETs). Despite the promising results obtained in OFETs, the implementation of conjugated polymers in other applications such as organic electrochemical transistors (OECTs) has been limited due to the hydrophobic nature of the material. In this talk, we will discuss the development of new synthetic paths and methodologies to increase the interaction between the semiconductor layer and the aqueous electrolyte solution used in many sensing applications. Along with new synthetic routes the effects of side chain engineering over the polymer backbones have also been investigated. In particular, we have extensively studied the exchange of the conventional alkyl side chains for polar chains in various ratios to understand its effects on chemical and electrochemical doping processes, conjugated polymer nanoparticle formation, and mixed ionic and electronic conduction properties relevant for bioelectronic applications.

8:45 AM SB09.10.02

Sensitive Immuno-Biosensors Based on Different Bioreceptor Layers and Organic Electrochemical Transistor (OECT) Configurations Yunjia Song; Johns Hopkins University, United States

Electronic biosensors based on conjugated polymers have been developed in recent decades because of the ease of attaching receptor functional groups and modulating electronic properties [1]. Organic electrochemical transistors (OECTs) have been recognized as an emerging platform technology for biosensing because of their architecture, flexibility, and amplification capability [2]. A typical OECT structure consists of two metal electrodes (source and drain) and one gate electrode immersed in an electrolyte. The gate electrode is electrically coupled to the organic semiconducting layer (usually conjugated polymer layer), which covers the channel region between the source and drain, through the electrolyte.
In this presentation, we will first discuss the properties of different polymers as bioreceptor layers. Poly 3-(3-carboxypropyl) thiophene-2,5-diyl (PT-COOH) and hydroxylated polythiophene (PT-OH) can be both bioreceptor layer as well as channel region material, which show different sensing properties as well as stability. PT-COOH can be a good biomolecule receptor layer on the channel of organic electrochemical transistor (OECT) devices; it shows the ability to immobilize multiple types of biomolecules and transduce the interaction between biomolecules into electrical signals. Myelin basic protein, SARS-CoV-2 spike glycoprotein S1, and their antibodies were alternately used in the attached molecule form as receptors and analytes. The sensitivity was indicated by the change of currents as well as threshold voltages.
Besides the typical OECT configuration, we also developed a dual gate functionalization organic electrochemical transistor (D-OECT) configuration. D-OECT connects two OECT devices in series, while the biomolecule interaction happens on the gate electrode. The gate electrodes were connected in series through buffer solutions, so the solution-electrode interfaces had opposite polarities. We proved that the D-OECT configuration has the ability to increase the accuracy of antibody-antigen interaction detection, and further decrease or eliminate the effect of ions in the buffer solution.

Near-Amorphous Semiconducting Polymers with Non-Covalent Interactions Xiaozhou Ji, Hao-Wen Cheng and Zhenan Bao; Stanford University, United States

High-performance semiconducting polymers with high charge carrier mobility and stretchability are desired for skin-like organic electronics. For conventional semi-crystalline semiconducting polymers, crystalline regions with π-π interactions are critical for interchain charge transport to endow good mobility, while it decreases mechanical stretchability. Near-amorphous polymers with high mobility, such as poly(indacenodithiophene benzothiadiazole) (IDTBT), brings in a new strategy of high-performance stretchable polymer semiconductors. The good charge carrier mobility is attributed to its rigid and coplanar backbone structure. Previously, various structural modifications on IDTBT have been studied, while most led to decreased mobility. In this work, non-covalent interactions, including S-F, S-O, and S-N, are introduced in IDTBT to further modify the backbone conformation and improve mobility performance. IDTBT derivatives are synthesized with optimized polymerization. The energy-favored backbone conformations are evaluated by computational simulation. The non-covalent interactions also influence energy levels, aggregation behaviors, and thin film morphology of IDTBT derivatives, which are related to their charge transport properties. High hole-mobility is obtained in top-gate bottom-contact field-effect transistors (FETs) for IDTBT with non-covalent interactions, which is further investigated with the low activation energy and disorder level. Stretchable FET devices are fabricated with the high-mobility IDTBT derivative and demonstrate good performance under strains.

Topological Supramolecular Network Enabled High Conductivity, Stretchable Organic Bioelectronics Yuanwen Jiang; University of Pennsylvania, United States

Intrinsically stretchable bioelectronic devices based on soft and conducting organic materials have been regarded as the ideal interface for seamless and biocompatible integration with the human body. First, compared to rigid inorganic materials, soft organic electronic materials do not suffer from the inherent trade-off between overall system stretchability and device density. Therefore, high-resolution mapping/intervention can be realized with conformal biointerfaces. Second, the high volumetric capacitance of conducting polymers (CPs) can reduce the electrode-tissue interfacial impedance, especially at physiologically relevant frequency ranges (<10 kHz), which allows high recording fidelity and efficient stimulation charge injection. However, the electrical conductivities of existing stretchable CPs are too low once they are micro-fabricated into bioelectronic devices. As a result, rigid metal interconnects are still required, which greatly diminished the advantages of soft CPs.

We describe here a rationally designed topological supramolecular network to simultaneously enable three significant advancements in bioelectronics. These are (i) biocompatible and stretchable CPs with high conductivity, (ii) direct photo-patternability down to cellular level feature sizes, and (iii) high stretchability maintained after micro-fabrication with no crack formation under 100% strain, which are all essential for low-impedance and seamless biointegration. The unprecedented performances of the conducting polymer with 2 orders of magnitude improvement in the conductivity under strain allow us to realize previously inaccessible applications including (i) high resolution recording of muscle signals from both human palm and highly malleable and soft-bodied octopus, and (ii) localized neuromodulation through delicate brainstem for precise controls of individual muscle activities down to single nucleus level.

Hyperconnective 3D Polymeric Nanofiber Networks for Tissue-Mimetic Soft Electronics Lizhi Xu; The University of Hong Kong, Hong Kong

Microfibrillar networks are essential structures in natural biological tissues, which exhibit a combination of mechanical flexibility, fracture resistance, and mass permeability to enable many important physiological functions. Inspired by natural soft tissues, we exploit biomimetic nanofiber composites as building blocks for the construction of a variety of bio-integrated soft devices. In this presentation, I will introduce our recent works on nanofiber-enabled polymer soft bioelectronics including the following examples: (1) Electroconductive hydrogels and devices involving framework-assisted assembly of conducting polymers; (2) Rugged and breathable kirigami electronics from hyperconnective nanofiber aerogels; and (3) Theoretical understanding and microstructural engineering of biomimetic 3D nanofiber networks. These works address the fundamental microstructural mismatches between electronic devices and biological soft tissues, paving the way for the development of advanced wearable human-machine interfaces, implantable electronics, tissue engineering platforms, and other biomedical systems.

Ion Selective-OECTs for Blood Testing and *In Vivo* Sensing Xiang Meng[1] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, China; [2]Advanced Biomedical Instrumentation Centre, China

Organic electrochemical transistors (OECTs) have received extensive attention owing to their ability to translate and amplify ion signals to electron signals recently. Compared to other types of transistors, in the operation of OECT, the ions from the electrolyte permeate into the channel and form a mixed of ionic-electronic conducting materials while a gate voltage (V_g) is applied. This phenomenon causes a volumetric change of the channel doping state, with significant modulations of source-drain current (I_{ds}) at low V_g (below 1V) and very high signal amplification (transconductance values can reach tens of mS). Furthermore, the promising biocompatibility allows the OECTs to be one of the most attractive candidates in biophysical and biochemical sensors for a large variety of targets. These sensors usually have high sensitivity and on-site amplification.

To date, there is a significant need for miniaturized ion sensors for monitoring of ion concentrations in health care applications. Portable and disposable ion sensors could monitor electrolyte levels in human blood or cerebral fluid, which can reflect the health conditions of the patients or neuron activities. In this talk, we will report an ion selective membrane-functionalized OECTs for specific ion detection. Compared to the OECT state-of-the-art, our sensor exhibits high performance, sensitivity of 126 μA/dec, response time of 1.9 s, dynamic range of 10^{-4} to 1 M, excellent stability, reversibility and accuracy. Furthermore, calibrations for Na^+ within the physiological range (110 mM – 160 mM) with blood serum show highly sensitivity of 498 μA/dec. While this investigation focused on Na+ as the target analyte, this platform can be adapted to sense variety of ionic species by simply tuning the ISM composition with the appropriate ionophore molecule. The advances in device architecture can further miniaturize devices and enable device placement in an implantable neural probe, while maintaining the ion sensing capability, i.e., a change of I_{ds} from 20 μA to 5 μA is observed when ion concentration changes from 1 mM to 100 mM. We expect the IS-OECT integrated neural probe to pave the way toward the design and fabrication of a new generation of multifunctional bioelectronics devices.

Plant Bioelectronics for High Resolution Monitoring and Electronic Control of Plant Processes Eleni Stavrinidou; Linkoping University, Sweden

The climate change and growing population calls for plants with increased tolerance to biotic and abiotic stress and plants with higher productivity. In my group we are developing organic bioelectronic technologies for sensing and actuation in plants that overcome limitations of conventional methods used in plant science but also enable new possibilities for plant interface. In my talk I will present our recent advancements of interfacing bioelectronic tools with plant model systems. With miniaturized OECTs and polymeric electrodes we monitor with high resolution sugar dynamics in trees and stress induced responses in Arabidopsis plants. Furthermore, we developed a flexible organic electronic ion pump for controlled delivery of phytohormones in the vasculature enabling activation of long distance responses related to stress tolerance. Finally, I will present a novel bioelectronic platform for stimulation of plant growth. Our results highlight the potential of bioelectronics in elucidating and enhancing plant processes but also for their application in agriculture.

2:30 PM BREAK

3:00 PM SB09.11.04
AC Amplification Gain in Organic Electrochemical Transistors (OECTs) for Impedance-Based Single Cell Sensors Filippo Bonafè, Francesco Decataldo, Isabella Zironi, Daniel Remondini, Tobias Cramer and Beatrice Fraboni; University of Bologna, Italy

Research on electrolyte-gated and organic electrochemical transistor (OECT) architectures is motivated by the prospect of a highly biocompatible interface capable of amplifying bioelectronic signals at the site of detection. Despite many demonstrations in these directions, a quantitative model for OECTs as impedance biosensors is still lacking. We overcome this issue by introducing a model experiment where we simulate the detection of a single cell by the impedance sensing of a dielectric microparticle. The highly reproducible experiment allows us to study the impact of transistor geometry and operation conditions on device sensitivity. With the data we rationalize a mathematical model that provides clear guidelines for the optimization of OECTs as single cell sensors, and we verify the quantitative predictions in an in-vitro experiment. In the optimized geometry, the OECT-based impedance sensor allows to record single cell adhesion and detachment transients, showing a maximum gain of 20.2±0.9 dB with respect to a single electrode-based impedance sensor.

3:15 PM SB09.11.05
Phase Separation in Organic Mixed Ionic-Electronic Conductors and Their Interface with Bioelectronics—A Multiphysics Approach Xiaokang Wang and Kejie Zhao; Purdue University, United States

Organic mixed ionic-electronic conductors (OMIECs) are ideal material candidates for bioelectronics owning to their unique capability of mixed conduction and biocompatibility. When integrated to organic electrochemical transistors (OECTs), they enable interaction between electrochemical devices and living matter, such as transmitting and accepting neuron signals and monitoring sweat as a skin sensor. Of all types, two-phase OMIECs exhibit exceptional performance due to their high stretchability and balanced ionic-electronic conduction. However, the electron-conducting phase may segregate from the ion-conducting phase in a two-phase OMIEC, changing the conducting path and eventually leading to degraded performance and dysfunction of the devices. In this work, we study the mechanics and electrochemistry of a two-phase OMIEC channel undergoing phase separation in an OECT model. The computational model captures the concurrent transport of charge carriers, mechanical swelling, and phase separation in the OMIEC and replicates the transfer curves of an OECT which agree well with the experiments. More specifically, we reveal the origin of the volumetric capacitance as the accumulation of charge carriers at the two-phase interfaces. We examine the parametric space to elucidate experimental observations such as the molecular size-dependent conductivity and substrate-dependent phase separation. The swelling behavior and the transfer curves of OECTs under stretched, free, and constrained states are compared, demonstrating the effects of deformation on the phase dynamics and the electron-conducting behavior. This work provides a theoretical basis for the mechanics and electrochemistry of two-phase OMIECs for biological interfaces and sheds light on synthetic and processing principles.

3:30 PM SB09.11.06
Strain-Insensitive Intrinsically Stretchable Transistors and Circuits Weichen Wang; Stanford University, United States

Intrinsically stretchable electronics can form intimate interfaces with the human body, creating devices that could be used to monitor physiological signals without constraining movement. However, mechanical strain invariably leads to the degradation of the electronic properties of the devices. Here we show that strain-insensitive intrinsically stretchable transistor arrays can be created using an all-elastomer strain engineering approach, in which the patterned elastomer layers with tunable stiffnesses are incorporated into the transistor structure. By varying the cross-linking density of the elastomers, areas of increased local stiffness are introduced, reducing strain on the active regions of the devices. This approach can be readily incorporated into existing fabrication processes, and a strain insensitivity of less than 5% performance variation when stretched to 100% strain. We also show that it can be used to fabricate strain-insensitive circuit elements, including NOR gates, ring oscillators and high-gain amplifiers for the stable monitoring of electrophysiological signals.

3:45 PM SB09.11.08
Complementary Internal Ion-Gated Organic Electrochemical Transistors (C-IGT) Duncan Wisniewski and Dion Khodagholy; Columbia University, United States

To understand and modulate neural network processes, bioelectronic devices capable of forming physiologically safe circuits to capture, amplify, process, and stimulate neural activity are required. Because signals of communication between neurons can be read out from minute changes in the ionic flux within brain tissue, organic mixed-conducting-based transistors that transduce ions to electrons can most effectively convert physiological signals to those suitable for input to electronics. These transistors can be fabricated to form conformable systems using scalable microfabrication processes to enable complex computational functions. Because most integrated circuits are currently designed based on complementary transistors (N and P-type), development of the combination of equal performance N and P-type IGTs would permit seamless integration with pre-existing designs. Here we demonstrate a method to create transistors with N-type function, transistor action in the first quadrant and resistor like in the third quadrant, from P-type materials which usually express the opposite behavior, modulating in the third quadrant and acting as a resistor in the first quadrant. These opposing behaviors enabled a complementary logic device with an output voltage range similar to the input voltage dynamics. Additionally, similar channel material and geometry resulted in equal impedances between the two transistors yielding a higher power efficiency. To accomplish this, we created geometrically asymmetric transistor design for optimal complementary performance. An array of devices with different source, gate, and drain sizes were analyzed to determine design rules N and P type performance. Channel material additives were evaluated to find the best formula for creation of both types of transistor for use in complementary devices. Transistors were characterized in terms of asymmetry, voltage required for complementary operation, speed, and gain. Using designs informed by the characterization of channel asymmetry we then fabricated all logic gates to demonstrate digital operations. These complementary IGT designs which can be fabricated with both N and P type single channel materials have a broad range of applications in bioelectronics including wearable electronics, neural interfacing, and therapeutic implants.

SESSION SB09.12: Virtual Session I

SB09-virtual

8:00 AM SB09.12.01
Nanostructures of PEDOT Derivatives Decorated on the Channel Layer of Organic Electrochemical Transistor Influences the Sensitive Detection of Sweat Cortisol. [a] Jayakrishnan Aerathupalathu Janardhanan[1], Ying-Lin Chen[2], Chun-Ting Liu[3], Hsueh-Sheng Tseng[2], Po-I Wu[2], Jia-Wei She[1], Yu-Sheng Hsiao[2] and Hsiao-hua Yu[1]; [1]Academia Sinica, Taiwan; [2]National Taiwan University of Science and Technology (NTUST), Taiwan; [3]National Taiwan University, Taiwan

Nanostructures of conducting polymers are versatile candidate for the development of biosensors. Electrochemical polymerization is a simple and efficient technique to engineer such conducting polymer nanostructures as bioelectronics interface (BEI) platform. This study highlights the influence of functionalized poly (3,4-ethylenedioxythiophene) (PEDOT) nanostructures decorated on the channel layer of an organic electrochemical transistor (OECT) for the detection of sweat cortisol-an adrenocorticosteroid stress hormone. Our design of novel OECT cortisol immunosensor highlight an active channel area decorated by poly(EDOT-COOH-co-EDOT-EG3) nanotube embedded upper layer engineered from two monomers such as EDOT-COOH and EDOT-EG3 by template free electrochemical polymerization and PEDOT: polystyrenesulfonate (PSS) under layer for the sensitive detection of sweat cortisol. The molecular design provides an easy access of antibody conjugation by 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide/N-hydroxysulfosuccinimide (EDC/Sulfo-NHS) coupling chemistry through carboxylic acid side chain and EDOT-EG3 is best known to reduce non-specific binding of biomolecules. The electropolymerization parameters were optimized for channel morphology of the OECT device together with the output characteristics and electrical properties of the device, pH of the electrolyte solution and monomers feed ratios prior to the immobilization of anti-cortisol antibody. Cortisol antibody was covalently attached inside the channel layer by EDC/Sulfo-NHS coupling chemistry. OECT device having channel area without any nanostructures were also engineered to get insight into the influence of nano topology of the channel area for enhanced analyte detection. Cortisol antibody immobilization on the channel layer was confirmed by different spectroscopic techniques such as Fourier transform infrared spectroscopy (FT-IR), X-ray photoelectron spectroscopy (XPS) and Quartz Crystal Microbalance (QCM) technique. QCM experiments revealed that the polymer nanotube embedded active channel area of the device displayed enhanced immobilization of cortisol antibody compared to the active channel area without any nanostructures. The real time detection of cortisol ranging from 1fg /mL to 1 μg/mL were investigated by the newly engineered OECT device. The OECT cortisol immunosensor embedded with nanotubes on the channel area showed enhanced detection limit of 0.0088 fg/mL with good linearity (R^2 =0.9566). In addition, the device displayed excellent selectivity to cortisol with the other structurally similar interfering compounds such as cholesterol, corticosterone, prednisolone and cortisone. Predominant selectivity to cortisol was observed for OECT device with nanotube channel layer compared with the OECT device having channel layer without any nanostructures. Moreover, the newly designed OECT cortisol immunosensor showed rapid response towards 100 ng/ mL cortisol spiked artificial sweat, highlighted the clinical practicality of the novel OECT device towards wearable sensors for future healthcare applications.

Thermal-Drawn Fiber-Based Multiplexed Electrochemical Sensor for Sweat Sensing Applications Jingxuan Wu[1], Yuichi Sato[2] and Yuanyuan Guo[2,3,4]; [1]Graduate School of Engineering, Tohoku University, Japan; [2]Frontier Research Institute for Interdisciplinary Sciences (FRIS), Tohoku University, Japan; [3]Graduate School of Biomedical Engineering, Tohoku University, Japan; [4]Graduate School of Medicine, Tohoku University, Japan

The sweat, representing the most easily accessible body fluids, contains important biomarkers, including electrolytes and metabolites that are directly associated with our health status. Recently, a significant amount of research effort has been devoted to developing sweat sensors for wearable applications. However, photolithography or printing techniques are often the mainstream of the fabrication process, resulting in sweat sensors based on 2D planar structures with limited surface area for body contact. The strict definition for wearable sensors is the ones that we wear daily, which are clothes. In this study, we developed a flexible fiber with all-in-one multiplexed sensing capabilities, which has a footprint of 750 µm × 370 µm to 1100 µm × 550 µm and can be weaved into textile for on-body sweat sensing. Such fibers were fabricated by the scalable and versatile thermal drawing process that has been conventionally used in the telecommunication industries to produce optical fibers. Here it has been adopted to fabricate multiplexed electrochemical sensing fibers. The fiber is composed of two polymer electrodes based on carbon black loaded polyethylene (CPE) and stainless-steel wires right beneath them, an internal microfluidic channel between the electrodes, which then were further encapsulated within the polycarbonate (PC) cladding. To realize the longitudinal functions, we used laser machining techniques to expose the CPE within the PC cladding at the designated positions along the length of the fiber. The exposed electrodes were further modified with sensing materials, such as gold nanoparticles (AuNP)s as well as ion-sensitive membranes (ISM) for either direct monitoring of uric acid oxidation or sensing Na+ concentration. In addition, the pseudo reference electrode (p-RE) based on Ag/AgCl was also incorporated into the fiber by integrating Ag/AgCl ink, NaCl-containing hydrogel buffer zone and membrane passive layers, to realize all-in-one electrochemical sensing. We carefully characterized the electrochemical functions of each component. First, the electrode modified with AuNPs exhibits a high sensitivity of 0.82 ± 0.08 nA/µM towards UA in the physiological ranges of 0 to 500 µM. Secondly, Na+ ion-sensitive electrodes (ISE) achieved via the ISM showed sensitivity to Na+ of up to 55.2 ± 0.8 mV/decade, close to the theoretical Nernstian value of 59.2 mV/decade. In addition, p-RE had excellent stability, which had no response in NaCl solution with varying concentrations (- 4.0 ± 0.5 mV/decade). Lastly, we integrated all the functions within a single fiber as an all-in-one sensor and characterized its performance in the artificial sweat. It exhibited UA sensitivity of 0.62 ± 0.1 nA/µM and Na+ sensitivity of 43.1 ± 3.5 mV/decade, the performance of which can meet requirements for on-body applications. Additionally, we also showed the proof-of-concept of the fluid delivery capability of its internal microfluidic channels, for washing and resetting the sensor surfaces. In summary, the thermally drawn fibers and textiles-based multiplexed electrochemical sensing system shows great promise in its future deployment as wearable clothes for monitoring important physiological signals in sweat and beyond.

Flexible Microneedle Patch for Wound Oxygenation and Biofilm Eradication Akshay Krishnakumar, Sina Nejati and Rahim Rahimi; Purdue University, United States

In the United States alone, chronic non-healing wounds impact more than 6 million people each year and constitute a major social issue. These wounds are further colonized by bacteria developing intricate biofilms which builds up barriers against antibiotics, impede tissue oxygenation (hypoxia) and wound healing. Clinical experts frequently utilize wound debridement and forceful mechanical abrasion procedures to manage and remove biofilms from wound surfaces which are extremely nonselective and painful. Local tissue oxygenation and delivery of antimicrobial species into the wound bed would effectively discriminate the biofilm growth and enhance the host wound healing simultaneously. Henceforth, we have developed a flexible polymer composite microneedle array that can overcome the physicochemical barriers (i.e., bacterial biofilm) present in chronic nonhealing wounds and co-deliver oxygen and bactericidal agents. The polymeric microneedles were developed *via* a facile UV polymerization process using polyvinylpyrrolidone and calcium peroxide onto a flexible fiber mat substrate for conformable attachment onto different locations of the human body surface. Dry heat autoclave parameters were experimented to sterilize the microneedles effectively without compromising its performance characteristics. The bactericidal properties of these microneedles were studies using gram negative *Pseudomonas* Aeruginosa as they are commonly observed to form biofilms. Additionally, microneedles exposed to human dermal fibroblast cells exhibited high levels of cytocompatibility and less than 10% apoptosis. Skin irritation and compatibility of the microneedle structures will be experimented on *in-vivo* animal models. Finally, the efficacy polymeric microneedles to collapse the biofilm formation and wound healing would be investigated in *in-vivo* rat models after inducing a biofilm on the wound model.

SESSION SF01.01: Overview of High Entropy Alloys
Session Chairs: Peter Liaw and Eun Soo Park
Tuesday Morning, April 11, 2023
Marriott Marquis, B2 Level, Golden Gate C2

10:30 AM *SF01.01.02
Fracture and Damage-Tolerance in *fcc* and *bcc* High-Entropy Alloys Robert O. Ritchie[1,2], Andrew M. Minor[1,2], Mark Asta[1,2], Mingwei Zhang[2], Punit Kumar[2], Flynn Walsh[1,2], Madelyn I. Payne[1,2], Wenqing Wang[1,2] and David Cook[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Face-centered cubic (*fcc*) medium- and high-entropy alloys (M/HEAs) can display exceptional combinations of strength, tensile ductility and fracture toughness, properties that can be further enhanced at cryogenic temperatures. Body-centered cubic (*bcc*) refractory HEAs, conversely, can display exceptional strength and compressive ductility at elevated temperatures, but are often compromised by poor lower-temperature behavior. We examine here the damage-tolerance of these two classes of multiple principal-element alloys, and show that whereas some of the *fcc* HEAs exhibit among highest fracture toughness values on record, the *bcc* HEAs can display extremely low toughness (and ductility) when subject to tensile loading. The *fcc* M/HEAs are also examined under extreme conditions of ultrahigh strain rates and liquid helium temperatures. We further examine the role of short-range order (SRO) in these two alloy classes, theoretically using DFT-based Monte-Carlo and Molecular Dynamics simulations and experimentally using energy-filtered TEM and 4D-STEM techniques. Whereas atomistic simulations predict the existence of SRO in *fcc* and *bcc* HEAs, together with its influence on plastic deformation behavior, *e.g*., slip behavior, dislocation mobility, *etc*., direct experimental evidence is difficult. We discuss some of the complicated aspects of defining the nature of the local order and its potential role on mechanical properties of *fcc* HEAs; however, studies for the *bcc* systems show an influence of SRO on dislocation motion but this is diminished at the high temperatures where these alloys are expected to perform. Our overall emphasis is on defining the origins of damage-tolerance in both *fcc* and *bcc* medium- and high-entropy alloys and how SRO can affect the mechanistic sequence of processes that underly their strength, ductility, and toughness.

Prospects for BCC Refractory High-Entropy Alloys Given Their Phase Stability and Mechanical Properties Easo P. George[1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Ruhr University Bochum, Germany

Refractory high-entropy alloys (RHEAs) are high-entropy alloys in which the constituent elements are refractory elements. Their high melting points make them attractive as next-generation high-temperature materials because of their potential for applications beyond state-of-the-art Ni-base superalloys. However, before that potential is realized, a few critical aspects of RHEAs need to be clarified, including the following: (1) are their tensile creep properties in fact superior to those of leading superalloys, (2) do they possess a minimal level of tensile ductility at room temperature to withstand normal handling and accidental drops, and (3) do they undergo phase transformations (microstructural instabilities) and the associated degradation of mechanical properties under expected service conditions. In this talk I will address these points by presenting our experimental and thermodynamic simulation results on model RHEAs of the VNbMoTaW and TiZrHfNbTa systems and their lower-order subsystems (quaternary, ternaries, etc.). Our results show that, the latter alloys, although relatively ductile at room temperature, have a long way to go before they can be creep-competitive with Ni-base superalloys at elevated temperatures. The former alloys are brittle at room temperature, and there is insufficient tensile creep data to judge whether they will be creep-competitive with Ni-base superalloys. Additionally, many of these RHEAs undergo phase decompositions when subjected to the expected thermal cycles of engine components such as turbine blades, which would further deteriorate the already marginal ductility and toughness of these alloys. By systemic investigation of pseudo-binary subsystems of these model quinary alloys, we attempt to understand the key factors responsible for the observed phenomena and provide suggestions for improvement of their physical and mechanical properties.

SESSION SF01.02: Structural/Mechanical Properties I
Session Chairs: Haruyuki Inui and Robert Ritchie
Tuesday Afternoon, April 11, 2023
Marriott Marquis, B2 Level, Golden Gate C2

1:00 PM *SF01.02.01
Short Range Order and the Evolution of Deformation Mechanisms in the CrCoNi Medium Entropy Alloy Mingwei Zhang[1,2], Flynn Walsh[2,1], Yang Yang[3], Madelyn I. Payne[1,2], Punit Kumar[2], Mark Asta[1,2], Robert O. Ritchie[1,2] and Andrew M. Minor[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]The Pennsylvania State University, United States

This talk will describe our recent results utilizing energy filtered diffraction, 4D-STEM and in situ TEM nanomechanical testing and ex situ nanoindentation that provide insight into multiscale deformation phenomena in the CrCoNi medium entropy alloy. Using energy-filtered TEM and HRSTEM techniques it is possible to directly image, and therefore quantitatively assess, SRO and its effect on mechanical properties. In order to understand the effect of SRO in terms of the evolution of plasticity at different stages, the technique of 4D-STEM was used during in situ deformation and fracture experiments. 4D-STEM can provide both real-space imaging and diffraction analysis during *in situ* testing, making it possible to perform strain mapping via diffraction pattern analysis during in-situ deformation in a TEM. The diffraction patterns are used to identify defects and map relative strain, while the images formed by using virtual apertures provide microstructural context for the analysis. Our results from electron microscopy are then correlated with mechanical testing including nanoindentation to examine how SRO evolves with different processing conditions. Lastly, we will consider the role of both SRO and planar defects in the both the mechanical response as well as structural determination via electron diffraction as a function of heat treatment in the CrCoNi MEA.

1:30 PM *SF01.02.02
Dislocation Pathways in Refractory Multi-Principal Element Alloys Daniel S. Gianola; University of California, Santa Barbara, United States

Emerging classes of structural materials proposed to meet the demands of aggressive applications share a common theme: complexity across a large range of length scales. A common denominator is the intentional design of disorder in these new materials. In load-bearing materials, this disorder can manifest as topological disorder as found in glassy materials, or chemical disorder as found in compositionally-concentrated alloys. Of particular interest from the latter class, refractory multi-principal element alloys (MPEAs) are promising candidates for structural applications demanding mechanical robustness at temperatures exceeding the capacity of state-of-the-art superalloys. While excellent high temperature strength has been demonstrated in many refractory MPEAs, a fundamental understanding of (i) the nature of dislocation pathways in the BCC versions of these chemically complex alloys, (ii) their ability to enable macroscopic ductility, and (iii) the role of interstitial species such as oxygen is still in its infancy. This talk will detail a study of a ternary MPEA, MoNbTi, and its binary derivative, NbTi, through a combination of *in situ* dislocation observations, microstructural investigations, and atomistic calculations. Our results highlight multi-planar, multi-character dislocation slip in MoNbTi at low homologous temperature, *encouraged by the substantial dispersion in the glide resistance for dislocation due to the atomic-scale chemical fluctuations*. The ability of dislocations to choose the easy gliding direction and plane enables an excellent combination of strength and homogeneous plasticity in this alloy. We further compare the mechanical response of MoNbTi to its binary counterpart NbTi, to which we also incorporate oxygen to study the influence of interstitials on phase evolution and concomitant changes in dislocation slip behavior. The presence of oxygen mediates spinodal decomposition, leading to compositional fluctuations comprising length scales and interfacial regions that alter the pathways for dislocation glide.

2:00 PM SF01.02.03
Investigating the Origin of Diffuse Scattering and Extra Reflections in Electron Microscopy Studies of FCC High/Medium Entropy Alloys Mingwei Zhang[1,2], Flynn Walsh[2], Madelyn I. Payne[2], Punit Kumar[1,2], Robert O. Ritchie[1,2], Mark Asta[1,2] and Andrew M. Minor[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The observation of diffuse superlattice intensities in many FCC high/medium entropy alloys by transmission electron microscopy has been attributed to the presence of chemical short-range order (CSRO). Namely, streaking, 1/3<422>, and 1/2<311> peaks were observed under electron diffraction along [110], [111], and [112] zone axes, respectively. However, displacive planar defects in FCC crystals (i.e., stacking faults or nanotwins) can produce the exact set of those peaks, making the interpretation ambiguous. In addition, our theoretical predictions of ordering reveal discrepancies between predicted superlattice peaks and observed ones. In this presentation, we discuss the origin of extra electron reflections in FCC concentrated solid solutions using the insights from our recent experiments and simulations as well as the implications on the mechanical properties. We will compare our TEM analysis of diffuse scattering and superlattice peaks with both diffraction contrast and high resolution electron microscopy imaging of defect structures.

2:15 PM SF01.02.04
Defect Interactions in High Entropy Alloys and Development of *In Situ* Atomic Scale Defect Spectroscopy Farida Selim[1], Maciej Oskar Liedke[2], Maik Butterling[2], Andreas Wagner[2], Djamel Kaoumi[3], Geoffrey Beausoleil[4], Khalid Hattar[5], Adric Jones[1], Matthew Chancey[6], Peter Hosemann[7], Blas P. Uberuaga[6] and Yongqiang Wang[6]; [1]Bowling Green State Univ, United States; [2]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [3]North Carolina State University, United States; [4]Idaho National Laboratory, United States; [5]Sandia National Laboratories, United States; [6]Los Alamos National Laboratory, United States; [7]University of California, Berkeley, United States

Defects in materials form, interact, and evolve at the atomic level. The measurements and analysis of their atomic level generation and evolution can reveal the mechanisms of defect interactions which dictate the macroscopic material properties and strength. This work investigates atomic scale defects in high entropy alloys (HEAs) using positron annihilation spectroscopy (PAS). I will present several examples that reveal how ion irradiation induced defects interact with the original microstructure and intrinsic defects in HEAs and the strong impact of the nature of chemical disorder on atomic scale defect interactions and evolution during the growth process and under irradiation. Then I will describe the recent development of the first in-situ PAS (iPAS) with high energy irradiation in the world at the ion beam materials laboratory at the Los Alamos National Laboratory and discuss how it can advance our understanding of the physics of defects in HEAs. Further, Early tests of the in-situ system will be presented to demonstrate its unique capabilities.
This work was funded as part of FUTURE (Fundamental Understanding of Transport Under Reactor Extremes), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences. It was also supported by the National Science Foundation (NSF) under grant number DMR-2005064.

2:30 PM SF01.02.05
Processing Pathways for Chemical Short-Range Order in Equiatomic CoCrNi Alloy Sakshi Bajpai, Calvin H. Belcher, Benjamin E. MacDonald, Timothy Rupert, Enrique Lavernia and Diran Apelian; University of California, Irvine, United States

Historically, the defining feature of complex concentrated alloys (CCAs) has been a primary phase with random atomic distribution of multiple principal elements in the lattice. Our understanding of this distribution has evolved in recent years with modeling and experimental observation of certain CCAs exhibiting preferential arrangement of atoms within a very short distance (~5-10 nm) in the crystal lattice. This phenomenon is known as chemical short-range ordering (CSRO). To date, it is not apparent how CSRO influences the bulk mechanical properties of CCAs, which may have important implications on the industrial application of CCAs. Can CSRO be manipulated via processing, for example, remains an unanswered question. In this work, the effect of processing pathways on the formation of CSRO in the equiatomic CoCrNi alloy is investigated. Heat treatments with variable temperatures, time, and cooling rates are conducted to systematically probe for the onset of CSRO formation. The variation in the microstructure, such as twin density and grain size, with different heat treatments is taken into consideration to isolate the impact of CSRO on the bulk and nano-level mechanical properties of the CoCrNi alloy. Nano-indentation, Vickers micro-hardness, and tensile testing are used for this purpose. Furthermore, the characterization of CSRO in various heat-treated CoCrNi alloys is done. Trends in behavior are discussed in the context of CSRO as well as the impact on processability to consider future steps toward commercially viable CCAs.

2:45 PM SF01.02.06
***In Situ* TEM Observation of High Entropy Alloy Silicadation and Diffusion Behavior** Chih-Lin Chiu, An-Yuan Hou and Wen Wei Wu; NationalYang Ming Chiao Tung University, Taiwan

High entropy alloy (HEA) has been widely used in the engineering applications due to its high hardness and outstanding corrosion resistance. Previous study reported how the metal elements affected the electrochemical performance and mechanical property of HEA. However, the research of HEA in the field of semiconductor Si is rarely discussed. In this study, $Al_{0.5}CoCrFeNi_2$ was deposited on silicon substrate by sputter. The dynamic synthesis process of high entropy silicide (HES) has been observed by *in-situ* transmission electron microscopy (TEM). During the heating process, Fe, Co and Ni atoms diffused into silicon substrate at 500 degree celsius, Cr would then react with FeCoNi silicide at 700 degree celsius. In addition, the participation of Al in the reaction was observed. Furthermore, HES was found to possess low resistivity, implying a potential candidate for the contact material of complementary metal oxide semiconductor(CMOS). This study demonstrates the formation mechanism of HES, providing a new material for future semiconductor industry.

SESSION SF01.03: Structural/Mechanical Properties II

Effects of Short-Range Ordering on Mechanical Properties of Single Crystals of the Equiatomic CrCoNi Medium-Entropy Alloy Haruyuki Inui, Le Li, Zhenghao Chen and Kyosuke Kishida; Kyoto University, Japan

The plastic deformation behavior of single crystals of the FCC equatomic CrCoNi medium-entropy alloy has been investigated in a temperature range of 10-1273 K, paying special attention to possible variations in mechanical properties with heat-treatment that may cause short-range ordering of the constituent elements. Deformation occurs via slip of the {111}<110> system exclusively in the whole temperature range regardless of different heat treatments. The CRSS values increase with decreasing temperature, especially below room temperature, so that the concept of 'stress equivalence' is obeyed. This is a clear indication that the strength of these alloys should be described by a mechanism based on solid-solution hardening. Dislocations are smoothly curved in the slip plane without any preferred line orientation, indicating no significant anisotropy in the mobility of edge and screw segments. Planar ½<110>{111} dislocations dissociate widely into Shockley partials for all alloys investigated, indicating the low stacking fault energy of 13 ± 3 mJ/m^2 for CrMnFeCoNi and CrCoNi, respectively. The CRSS values extrapolated to 0 K for polycrystals of equiatomic quinary, quaternary and ternary alloys are reported to be well scaled with the mean-square atomic displacement from the regular FCC lattice points (calculated based on density-functional theory). This seems also the case for the CRSS values at 10 K for single crystals of CrCoNi and its related quaternary (CrFeCoNi) and quinary (CrMnFeCoNi) alloys. Deformation twinning occurs on the conjugate system in the form of the Lüders type deformation in the later stage of deformation at low temperatures in all of the three alloys. No significant variation of the CRSS values, twinning stress and the stacking-fault energy was noted upon the formation of short-range order by heat-treatment.

3:45 PM *SF01.03.02
Effects of Nitrogen on the Plasticity of Co-Rich Complex Concentrated Alloys Hyunseok Oh; Massachusetts Institute of Technology, United States

Introducing interstitial elements in complex concentrated alloys (CCAs) has received considerable attention due to its effectiveness in changing plasticity mechanisms, resulting in superior mechanical properties. However, fundamental investigation of the effects of interstitial elements is challenging because of the complex chemical interactions among interstitial elements, substitutional elements, and defects. Here, we present the effects of dilute nitrogen on defect evolution in Co-rich complex concentrated alloys with low (negative) stacking fault energies. We will systematically discuss the possible effects of nitrogen: solute pinning, short-range ordering or clustering, stacking fault energies, and segregation.

4:15 PM SF01.03.03
Investigation of Hydrogen Behavior and Hydrogen Embrittlement Mechanisms of FCC-BCC Dual-phase High-Entropy Alloys with Controlled Phase Fraction and Stability Sang Yoon Song[1], Dae Cheol Yang[1], Han-Jin Kim[2], Sang-In Lee[2], Hyeon-Seok Do[3], Alireza Zargaran[3], Byeong-Joo Lee[3] and Seok Su Sohn[1]; [1]Korea University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Pohang University of Science and Technology, Korea (the Republic of)

Hydrogen embrittlement (HE) has been considered a serious issue as it deteriorates the strength and ductility of metallic materials. Among various kinds of alloys, the face-centered cubic (FCC) + body-centered cubic (BCC) dual-phase alloys are known to be susceptible to hydrogen environments due to the inherent characteristic of the BCC structure stemming from a high diffusivity of hydrogen. Thus, it is reasonable to believe that reducing the fraction of BCC would improve the resistance to HE in the FCC-BCC dual-phase alloys. However, most of these alloys accompany the transformation-induced plasticity (TRIP), indicating that the FCC phase also contributes to the HE susceptibility through undergoing martensitic transformation. This suggests that it is hard to readily estimate the HE susceptibility of the FCC-BCC dual-phase alloys as both the phase fraction and stability have critical roles on the HE susceptibility. Therefore, it is necessary to reveal each effect of FCC and BCC phases on HE phenomenon and to conduct a systematic study by controlling phase fraction and stability. In this study, four model VCrFeCoNi high-entropy alloys are designed to form FCC-BCC martensite whose phase fraction and stability are largely controlled. Among them, two alloys possess a single FCC phase, while the others consist of FCC and as-quenched BCC martensite. As the Ni content decreases, the thermal and mechanical stabilities of FCC reduce, resulting in the increased BCC fraction and sensitivity to deformation-induced martensitic transformation. For the four model alloys, the HE susceptibility is evaluated by slow strain rate tests (SSRTs) for the specimens H pre-charged via electrochemical cathodic methods. These four alloys showing different HE susceptibility are subjected to detailed analysis of hydrogen diffusion, trap behavior, hydrogen-affected brittle zone, and hydrogen-induced cracking. The initial as-quenched martensite provides diffusion paths for hydrogen, while the deformation-induced martensite possesses an inherently high concentration of hydrogen, leading to dominant roles in crack propagation behaviors. This work suggests the guidance for microstructural designs to enhance the resistance to HE for the metastable FCC-BCC dual-phase alloys.

4:30 PM SF01.03.04
Compositive Role of Refractory Element Mo in Improving Strength and Ductility of Face-Centered-Cubic Complex Concentrated Alloys Tae Jin Jang[1], You Na Lee[1], Yuji Ikeda[2], Fritz Körmann[3], Ju-Hyun Baek[4], Hyeon-Seok Do[5], Yeon Taek Choi[5], Hojun Gwon[5], Jin-Yoo Suh[4], Hyoung Seop Kim[5], Byeong-Joo Lee[5], Alireza Zargaran[5] and Seok Su Sohn[1]; [1]Korea University, Korea (the Republic of); [2]University of Stuttgart, Germany; [3]Max-Planck-Institut für Eisenforschung GmbHdisabled, Germany; [4]Korea Institute of Science and Technology, Korea (the Republic of); [5]Pohang University of Science and Technology, Korea (the Republic of)

Complex concentrated alloys (CCAs) containing multiprincipal elements have been investigated extensively for the last two decades due to the potential for extended mechanical properties from their wide range of compositional space. Particularly, CCAs having a face-centered-cubic (FCC) structured solid-solution containing various 3d-transition metal elements exhibit improved mechanical properties attributed to their enhanced solid solution strengthening, grain boundary strengthening, and strain hardening capability. Due to their distinctive mechanical properties, great efforts have been conducted to demonstrate the origin of improved mechanical properties. Most of these investigations, however, have been focused on the FCC CCAs composed of 3d-transition metal elements. The addition of other elements with a larger atomic size compared to 3d-transition metal elements usually forms secondary phases. Especially, even a small addition of Mo in FCC CCAs generally causes the formation of topologically close-packed phases such as m and s phases, inducing embrittlement of the alloys. Therefore, it is a lack of systematic study on the effect of refractory element Mo on the mechanical response in single-phase FCC CCAs. In this study, three alloys with different Mo content of the CoNiMo system were fabricated, which is predicted to maintain a single FCC with a wide range of Mo content. Interestingly, solid-solution strengthening and grain-boundary strengthening improve simultaneously with increasing Mo content. In particular, the highest Mo alloy exhibits a high yield strength of ~1 GPa attributed to their significant solid-solution strengthening of 229 MPa and Hall–Petch coefficient of 1028 MPa×mm$^{1/2}$. The effect of Mo element on solid-solution strengthening is demonstrated via increasing lattice distortion with increasing Mo content computed by *ab initio* calculation. The improved grain-boundary strengthening is also correlated to lattice distortion, and grain-boundary segregation of Mo leads to a further increase of the Hall–Petch coefficient. In addition to the strengthening contributions, the addition of Mo contributes to improving the strain hardening capacity, which is crucial for sustaining plastic deformation. The transition of dislocation and deformation twin substructures depending on the decrease of stacking fault energy on increasing Mo content makes the dislocation glide more difficult and leads to a higher strain hardening capability of the alloys.

SESSION SF01.04: Structural/Mechanical Properties III
Session Chairs: Hyunjoo Choi and Simon Schweidler
Wednesday Morning, April 12, 2023
Marriott Marquis, B2 Level, Golden Gate C2

8:30 AM *SF01.04.01
High-Throughput Methods Combined with AI for the Development of High-Entropy Materials Simon Schweidler[1], Leonardo Velasco[2], Pascal Friedrich[1], Anurag D. Khandelwal[1], Ben Breitung[1], Jasmin Aghassi-Hagmann[1] and Horst Hahn[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Direccion Academica Universidad Nacional de Colombia Sede de La Paz, Colombia

High-entropy materials offer a huge research area for new material compositions and potential applications, e.g. in the field of rechargeable batteries, electrochemical catalysis, hydrogen storage or supercapacitors.[1] In particular, the combinatorial complexity of several elements in a single-phase structure, can lead to unexpected and unpredictable material properties, which may affect potential application areas. Exploring the vast compositional space of high-entropy materials in a conventional approach, i.e., one experiment at a time is prohibitive in terms of cost and time. Consequently, the development of high-throughput experimental methods supported by machine learning and theoretical predictions will facilitate the search for multicomponent materials in their compositional diversity.
Therefore, this talk will focus on the establishment of automated high-throughput methodologies in the field of synthesis and characterization of metallic and non-metallic (ceramic) high-entropy materials, enabling the creation of material libraries.[2,3] This facilitates the analysis of material properties in terms of composition or morphological and structural differences. Machine learning-based data analysis and theoretical approaches also provide opportunities for the virtual development of novel materials for both functional and structural applications.

9:00 AM SF01.04.03
Old Materials, New Life—Using diffusion-Controlled Synthesis for Discovery of Novel Alloy Systems Annica Wetzel, Ozlem Ozcan, Yasemin Yesilcicek and Julia Witt; Federal Institute for Materials Research and Testing (BAM), Germany

Multi principal element alloy (MPEAs) concept allows us to rethink how we develop application-tailored, sustainable materials. The vast composition space leads to nearly indefinite material combinations and will facilitate finding Pareto optimal materials with lower CO_2 footprint and avoidance of critical minerals as design criteria. To probe this large compositional space efficiently, the use high-throughput screening methods is inevitable. Diffusion-controlled synthesis of gradient materials is the optimal technique for screening complex compositional materials that would otherwise require comprehensive modelling or experimental efforts.

In this study, we have used a series of diffusion couples of pure metals and alloys with the aim to create a materials library with correlated data on composition and microstructure. With future recycling prospects in mind, and possible applications of Cu containing alloys in electrocatalytic carbon dioxide reduction and antimicrobial alloys we have generated diffusion couples of brass ($Cu_{63}Zn_{37}$) and bronze ($Cu_{89}Sn_{11}$) with either pure metals (Fe, Ni, etc.) or with binary or ternary alloys (FeNi, FeNiCr etc.). For different diffusion times and temperatures, we calculated diffusion constants for the material combinations. Following a detailed characterisation of the gradient materials, we have investigated general and local corrosion properties, electrocatalytic activity for oxygen evolution reaction (OER) and carbon dioxide reduction reaction (CRR) as well as mechanical properties (hardness, elastic modulus) on single-phase alloys synthesized in bulk by means of vacuum arc-melting based on the selected local compositions.

In most cases, due to the short diffusion times, the contact between the diffusion couples lead to two separate diffusion zones and thus, different alloy families on both sides. Especially with ternary alloys, interesting selective diffusion processes and unexpected repulsion effects were observed. The presentation will provide an overview of the gradient materials with a focus on the functional properties of single-phase alloy families derived from them.

9:15 AM SF01.04.04
A Map of Single-Phase High-Entropy Alloys Wei Chen[1], Antoine Hilhorst[1], Stéphane Gorsse[2], Pascal J. Jacques[1] and Geoffroy Hautier[3,1]; [1]Université

Catholique de Louvain, Belgium; [2]CNRS, University of Bordeaux, France; [3]Dartmouth College, United States

High-entropy alloys (HEAs) with five or more elements mixed at equal or near-equal compositions in a single crystalline phase have been the focus of much research as they exhibit unusual functional and mechanical properties. Yet, only a limited number of single-phase HEAs have been identified experimentally, highlighting the difficulty of experimental screening and, more fundamentally, the effects beyond the high-entropy criterion for the stabilization of HEAs. Here, through an ab initio driven thermodynamic model, we navigate the vast chemical space of equimolar quinary alloys from the combination of 40 metallic elements. In particular, the enthalpic contribution to the HEAs is described by a simple regular solution model for which the interactions are limited to binary terms and are obtained with density-functional theory. Within this model, the Gibbs free energy of any random solid solutions can be evaluated efficiently as a series of precomputed binary interactions in addition to the ideal configurational entropy. The thermodynamic stability of HEAs is then determined through the convex hull construction which directly compares the free energy of the system in the solid-solution phase versus any linear combination of its subsystems including intermetallic phases. Applying our model to the 658,008 possible equimolar quinary alloys, we find that 35,506 alloys can be stabilized in a single-phase solid solution at near-melting temperature, significantly expanding the scope of chemistry known to the HEA community. In line with the prevalence of BCC HEAs in the literature, the majority (75%) of our predicted HEAs are BCC HEAs, the stabilization of which originates from a combined effect of the high melting point of the constituent BCC elements, which are typically refractory, and a favorable mixing of elements on a BCC lattice. We show that the high melting point is in fact the main driving mechanism for the formation of single-phase HEAs. We further demonstrate the power of our method by predicting the existence of two new HEAs, i.e., the BCC AlCoMnNiV and the FCC CoFeMnNiZn, which have been synthesized and confirmed experimentally. The series of the Al- and Zn-containing HEAs show that non-refractory and cost-effective HEAs with a relatively low melting point can be stabilized by the subtle enthalpic competition between intermetallics and solid solutions. The discovery of a new BCC alloy and a FCC alloy analogous to the Cantor alloy but with an unusual element (Zn) is a compelling demonstration of how our approach can suggest unexpected chemistries and new avenues to the development of HEAs.

9:30 AM SF01.04.05
Investigation on Gradient Fe-Ni-Cr-Mn Alloy Using Diffusion Multiples Yasemin Yesilcicek, Annica Wetzel, Julia Witt, Christiane Stephan-Scherb and Ozlem Ozcan; Bundesanstalt für Materialforschung und Prüfung, Germany

The high-throughput synthesis and characterization of potential material combinations plays an important role in accelerating the development of new materials. Diffusion controlled synthesis of gradient alloys is widely used to create phase diagrams, and it is also one of the most effective combinatorial approaches for rapid realization of potential material combinations.
This study focuses on the synthesis and investigation of the quaternary multi-principal-element alloy (MPEA) FeNiCrMn by means of diffusion multiples, the correlation of their microstructural and chemical characterization data with their application relevant properties like local mechanical and corrosion properties. A diffusion system was set up by combining an equimolar ternary alloy (FeNiCr) with a single diffusing metallic component (Mn) with the highest interdiffusion coefficient. Scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX) were used to collect microstructural and compositional information which were correlated to local mechanical properties studied with nanoindentation. Local corrosion properties were investigated by means of Atomic Force Microscopy (AFM) and Scanning Electrochemical Microscopy (SECM). We have observed that a >50 µm deep homogeneous diffusion zone was formed the thickness of which scales with the duration of the thermal treatment. Beyond the Mn-concentration gradient in the FeNiCr matrix, a distinct Cr-rich secondary phase, characterized by high hardness and elastic modulus values appeared. We synthesized MPEAs with selected compositions from the diffusion zone as well as the Cr-rich phase as bulk alloys for electrochemical corrosion studies under different environmental conditions. The presentation will summarize the results of our correlative study on the mechanical properties and corrosion resistance of the quaternary multi-principal-element alloy (MPEA) FeNiCrMn family.

SESSION SF01.05: Physical, Chemical and Functional Properties

Marriott Marquis, B2 Level, Golden Gate C2

10:30 AM *SF01.05.01
Thermal Stability and Mechanical Properties of Nanostructured High-Entropy Alloys Yu Zou; University of Toronto, Canada

In my presentation, I will talk about a few strategies for the fabrication of nanostructured HEAs – magnetron co-sputtering and electrodeposition. Such nanostructured HEAs exhibit high yield strengths and thermal stability compared to conventional binary alloys. I also demonstrate that such nanostructured HEA films show substantially enhanced stability for long-duration conditions. Nanostructured HEAs combining these properties represent a new class of materials in small-dimension devices potentially for high-stress and high-temperature applications.

11:00 AM *SF01.05.02
Strengthening of Al Matrix Composites by High Entropy Phases Hyunjoo Choi; Kookmin University, Korea (the Republic of)

Aluminum matrix composites (AMCs) have been extensively studied in future mobility industries because of their excellent mechanical properties and elastic modulus. Although carbon-based or ceramic materials have been used as reinforcement for AMCs, their poor wettability with aluminum should be overcome to develop high-strength lightweight composites.
This study employs high entropy alloys (HEAs) as reinforcement AMCs. HEAs have superior stiffness and strength as well as good wetting ability with aluminum. Two different types of composites are suggested in this study. First, sub-micron sized HEA particles, produced by thermal plasma treatment, were dispersed in aluminum powder. The composite powder was consolidated using hot rolling. Second, gas-atomized HEA powder and Al powder were simultaneously additive manufacturing using a multi-nozzle direct energy deposition (DED) printer. The effect of HEA phases on the strengthening of the Al matrix will be discussed.

11:30 AM SF01.05.03
Laser Annealing-Induced Generation and Phase Transformation of High Entropy Metal Alloy and Ceramic Nanostructures Amber Y. Li and Kwan W. Tan; Nanyang Technological University, Singapore

Metal-based inorganic nanomaterials made up of dissimilar elements have large functional potentials in various fields and applications such as catalysis, sensors and bioengineering. The control of crystal phase and composition of multicomponent nanoparticles is a powerful and effective strategy to introduce new unique physicochemical properties, functionalities and applications. Here we describe a millisecond laser annealing approach that provides control of crystal phases, compositions and functional properties of five-elemental multicomponent nanoparticles of metal alloys, oxides, and nitrides. Laser irradiation of an identical five-metal salt precursor mixture for different laser heating times (from 0.25 to 250 milliseconds) allows control of supercooling kinetics and reaction pathways toward multicomponent alloy nanoparticles have single and multiphasic solid solution characteristics, compositions and new physiochemical properties. In addition, laser annealing of a five-component nitride-former precursor mixture at different laser power levels provides selectivity in the formation of multicomponent tetragonal rutile oxide nanoparticles and phase transformation into cubic rock salt nitride nanoparticles. The method is highly generalizable and further provides access to multidimensional mesoporous metal nitride nanostructures. The resultant high entropy alloy nanoparticles enable various applications, including growth of high-quality carbon nanotubes, stable and efficient hydrogen evolution reaction as well as antimicrobial properties against E. Coli species.

11:45 AM SF01.05.04
Complex Roles and Structures of Short-Range Order in Si-Ge-Sn Medium-Entropy Alloy Xiaochen Jin, Shunda Chen, Christopher Lemkan and Tianshu Li; George Washington University, United States

Short-range order (SRO) has been recently demonstrated to play a crucial role in modulating a wide range of physical properties in medium-entropy alloys (MEAs) and high-entropy alloys (HEAs). However, there is a lack of general understanding of SROs in both their structural diversity and impact of properties in complex concentrated alloys. In this regard, our recent theoretical study[1] already demonstrated two distinct types of SROs, which carry different energies, distinct degrees of local ordering, and dissimilar electronic structures, can coexist across a wide range of compositions in Si-Ge-Sn MEAs. In further examining the structures and properties of these alloys, we combine first-principle calculations with Monte Carlo sampling, and further develop a highly-accurate, machine-learning interatomic potential. Our study shows electronic, optical, and thermal transport of Si-Ge-Sn alloys can be significantly modulated and engineered through tuning SROs. We further propose an extended descriptor of SRO, by taking into account both its distribution and higher-order effect.

This work is supported by Department of Energy through DE-SC0023412.

SESSION SF01.06: Refractory High Entropy Alloys
Session Chairs: Satish Rao and Cem Tasan
Wednesday Afternoon, April 12, 2023
Marriott Marquis, B2 Level, Golden Gate C2

1:00 PM *SF01.06.01
High-Throughput Design of Refractory Multi-Principal Element Alloys Katharine Flores; Washington University in St. Louis, United States

The design of high entropy alloys often focuses on identifying near-equiatomic solid solution alloys; expanding these to include multiphase microstructures offers the opportunity to further enhance and control properties. Designing such multiphase, multi-principal element alloys (MPEAs) requires the ability to efficiently survey compositional space for phases and microstructures of interest using integrated experimental and computational methods. Here, we build on prior studies of the Nb-V-Zr system, which forms a BCC solid solution phase and two Laves phases. Applying a convex hull analysis, we predict the effect of Ti, Ta, and Mo additions on the stability of the BCC phase as a function of temperature and composition. The predicted structures are compared with the microstructures observed in compositional libraries prepared using a high-throughput, laser deposition-based synthesis method. This work provides guidelines for predicting compositional effects on microstructure and properties, which will accelerate the design of MPEAs for high-temperature applications.

1:30 PM *SF01.06.02
A Machine Learning-Driven Framework for Predicting Strength and High Temperature Oxidation Properties in Refractory Complex, Concentrated Alloys Michael Titus; Purdue University, United States

Refractory complex, concentrated alloys (RCCAs) offer new avenues for designing high strength and oxidation resistant materials at elevated temperature. However, RCCAs often exhibit multiple oxidation mechanisms including oxide volatilization, internal oxidation, external scale formation, and pesting. In this talk, we will present a new machine learning for accelerated materials discovery (ML-AMD) framework that utilizes multi-fidelity and multi-cost experiments with physics-based modeling. New semi-high-throughput methods for characterizing hardness and oxidation resistance will be presented, and methods for implementing high-throughput simulations into the ML-AMD framework will be expounded. Our recent efforts utilizing this framework have resulted in the discovery of ultra-high hardness single phase body-centered cubic RCCAs with up to 35at.% Al content. We have additionally created an open-source, automated framework housed in NanoHub for experimental data ingestion and storage of high temperature oxidation experimental data. Predictions of mass gain behavior of RCCAs utilizing machine learning with physics-based descriptors will be presented, and recent efforts to design new RCCAs with superior oxidation resistance will be shown.

2:00 PM SF01.06.03
Accurate Determination of Two-Dimensional Energy Landscape of Dislocation Motion in bcc High-Entropy Alloy Yifan Wang[1], Nicolas Bertin[2], Vasily Bulatov[2] and Wei Cai[1]; [1]Stanford University, United States; [2]Lawrence Livermore National Laboratory, United States

The unusual low-temperature plasticity behaviors of bcc metals and alloys are known to be attributed to the complex core structure of screw dislocations, whose motion is governed by thermally activated kink-pair nucleation mechanisms on the two-dimensional Peierls potential. However, this 2D energy surface is usually estimated by simplified elasticity theory in pure bcc metals, with limited applicability to complex bcc systems such as bcc high-entropy alloys (HEA). Here we present an efficient minimum energy mesh (MEM) method foraccurately determining the 2D Peierls potential surface defined by the three ‘easy core’ configurations, to provide a complete picture of the smooth energy landscape of the core structure. The method proceeds by evolving triangulated meshes, i.e., the smooth surfaces with intrinsic parametrization whose dynamicsautomatically converges to the minimum energy surface in the configurational space. This MEM method accurately determines arbitrary 2D energy landscape, enabling the stress, composition, and short-range order dependence of thermally activated dislocation motion in bcc HEA.

2:15 PM SF01.06.06
On the Molten State Processing of Refractory Complex Concentrated Alloys Calvin H. Belcher, Sakshi Bajpai, Benjamin E. MacDonald, Diran Apelian and Enrique Lavernia; University of California, Irvine, United States

The field has witnessed significant growth in the experimental exploration and understanding of RCCAs. Molten state processing of RCCAs through vacuum arc melting has been the main processing path to produce components. However, there are still challenges in controlling impurity elements in RCCAs. Moreover, the behavior of the impurity elements in the RCCAs is not well understood. In this work, the chemistry of the chamber environment during arc melting was studied using a mass spectrometer. Process methodologies were studied to control impurity gas elements such as oxygen and nitrogen in arc melted RCCAs. Furthermore, by arc melting NbMoTaW and TiNbZr RCCAs in various environments, relationships between RCCA constituents and impurity element absorption were explored. Through mechanical testing, X-Ray diffraction, and electron microscopy, the behavior of impurity elements in various RCCA compositions will be reviewed and discussed.

SESSION SF01.07: Theoretical Modeling and Computational Simulations
Session Chairs: Hyunseok Oh and Michael Titus
Wednesday Afternoon, April 12, 2023
Marriott Marquis, B2 Level, Golden Gate C2

3:30 PM *SF01.07.01
Simulations and Modelling of the High Temperature Yield Behavior of Compositionally Complex Concentrated BCC Alloys Satish Rao[1,2], B. Akdim[1,3], O. Senkov[1,2], Glenn Balbus[1] and E. Payton[1]; [1]Wright Patterson Air Force Laboratories, United States; [2]MRL Materials Resources LLC, United States; [3]UES Inc., United States

Atomistic simulations, using Johnson-Zhou and/or Snap potentials, of the core structure and mobility of ½[111] screw, edge and mixed dislocations in complex concentrated BCC alloys are presented. The core structure and its variations obtained for screw dislocations in NbTiZr using atomistic simulations are compared with first-principles calculation results and good agreement is found. Molecular Dynamics results show that a moving screw dislocation leaves behind interstitial and vacancy dipoles in these alloys. Average solute-dislocation core interaction energies are used to determine the critical stress for the motion of screw dislocations as a function of temperature using Rao- Suzuki model of kink migration / kink-kink collisions controlled mobility, developed for concentrated BCC random alloys. In addition, diffusional effects at very high temperatures on the predicted yield behavior are modelled. Simple expressions for yield stress based on the Rao-Suzuki model is presented. Edge dislocation mobilities in these alloys are modelled using the Maresca-Curtin model. The model results on yield behavior are shown to be in good agreement with experimental data in selected BCC complex concentrated alloys.

4:00 PM SF01.07.02
A Phenomenological Discrete Lattice Model for Simulating the Response of High-Entropy Alloys Vinod K. Tewary and Edward J. Garboczi; National Institute of Standards and Technology, United States

High-entropy alloys (HEAs) are a class of materials with revolutionary applications as structural and functional materials. They are very strong and have high melting points. Moreover, they can retain their strength at high temperatures, even fairly close to melting points. This makes them particularly suitable for use in extreme environments such as in turbines and power stations.
HEAs are essentially random alloys, typically containing five or more elements in approximately equal concentrations. The formulation of predictive theories for the strength of random alloys has been a topic of active research that has resulted into useful theories such as the effective medium theory. However, these theories are, in general, limited to low concentrations of the solutes and are not applicable to HEAs, in which the relative concentration of solutes is high.
We propose a new, phenomenological discrete lattice model for the analysis and representation of measurements of HEA characteristics. Our model is essentially an atomistic version of the theory given by Varvenne, Luque, and Curtin [Acta Materialia **118** (2016) 164]. Instead of the usual continuum approximation, we assume a discrete Born von Karman model for the underlying lattice of the alloy. We define an effective monoatomic lattice, which has the same Bravais lattice structure and bulk elastic and thermal characteristics as the original alloy. In our model, each lattice site is assumed to be occupied by a hypothetical, effective atom, which is an 'average' of all the constituent solutes. Thus, instead of averaging over the field, we average over the solute atoms and replace each real solute by an effective atom.
The next step is to locally replace one single effective atom by a real solute atom. This atom now becomes a defect, which distorts the host lattice. We calculate the lattice distortion by using the multiscale Green's function (GF) method, developed in our group for general solids. The key point of the model (Varvenne et. al.), is that the dislocations in the solid interact with the local distortion field of each defect. This interaction is responsible for the characteristic hardness of the alloy.
As an example, we apply our theory to a Ni-Co-Fe-Cr-Mn alloy. This alloy has been a popular choice in the literature and has an fcc Bravais lattice. The mass of each effective atom is the weighted average of all the solutes. For the interatomic interaction, we choose a two-exponential, four-parameter function, which extends up to second neighbors of each atom. The four parameters are determined using the literature values of the three elastic constants of the alloy, and its average binding energy, which also gives the effective lattice constant. Using this potential, we calculate the interatomic force constants, the phonon dispersion, and the phonon density of states by the method of the phonon GF. The interaction between the local distortion and dislocations is calculated by using the multiscale GF.
The primary advantages of our GF method, compared to the previous methods, are the following:
1. High computational efficiency. It can simulate a large crystallite (million atoms or more) in a few seconds even on an ordinary desktop. The computational expense of ordinary molecular dynamics generally limits the number of atoms that can be included in the model.
2. Multiscale. It is valid at close range as well as at asymptotic distances from the defect. The GF accounts for the discrete lattice effects and nonlinear contributions in the near field. The GF reduces seamlessly to the macroscopic continuum values in the far field limit. This is crucial for modeling the interaction between the dislocations and the defects, which is absolutely essential for HEAs.
3. Flexible model: It can be extended to include more distant neighbors, and more general potentials.
4. The phonon GF can be used to calculate the relevant thermodynamic functions, such as the specific heat and the vibrational entropy.

4:15 PM SF01.07.03
Short-Range Ordering in Unaged High-Entropy Materials Flynn Walsh[1,2], Mingwei Zhang[1,2], Wenqing Wang[1,2], Andrew M. Minor[1,2], Robert O. Ritchie[1,2] and Mark Asta[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The prospect of local chemical ordering in high-entropy materials has received significant attention, but there remains little consensus on the issue. Fundamental questions, such as the role of compositional complexity and the quantitative degree of order expected in quenched or slow-cooled samples, appear largely unanswered. These topics are addressed from a theoretical perspective while drawing on a range of experimental studies. Transferable thermodynamic principles are extracted from lattice models for several types of systems with an emphasis on face-centered cubic alloys. In particular, phenomenological Landau theory is used to determine the forms of order that can arise above a critical temperature in many-component systems; these structures may differ from those obtained from long-term annealing below the critical temperature. The ability of various experimental techniques, such as electron microscopy and resistivity measurements, to directly or indirectly detect this form of order is also discussed.

SESSION SF01.08: Poster Session
Session Chair: Eun Soo Park
Wednesday Afternoon, April 12, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM SF01.08.01
Transmission Electron Microscopy of Temperature Dependent Deformation Mechanisms in High-Entropy Alloys Madelyn I. Payne[1,2], Mingwei Zhang[1], Punit Kumar[1], Mark Asta[1,2], Robert O. Ritchie[1,2] and Andrew M. Minor[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

High-entropy alloys (HEAs) have attracted attention from the metallurgy community due to their exceptional properties, often at both high and low temperatures. Transmission electron microscopy (TEM) provides a means to investigate various deformation mechanisms producing exceptional properties in both face-centered cubic (fcc) and body-centered cubic (bcc) HEA systems. High-resolution TEM and four-dimensional scanning electron microscopy (4D-STEM) analysis reveal an extended sequence of deformation mechanisms that produce exceptional fracture toughness. Spatially-resolved structural information from 4D-STEM datasets uncover how stacking faults, hcp laths, and nanotwins operate synergistically to prolong strain-hardening. Furthermore, TEM imaging of in-situ tensile straining of HEAs demonstrates dislocation mobility mechanisms at both room temperature and elevated temperatures, providing insight to differences of deformation properties at various temperatures. Here we report both ex situ and in situ TEM observations of deformation mechanisms in both fcc HEA and bcc refractory HEAs across a wide range of temperatures.

5:00 PM SF01.08.02
Formability optimization of complex concentrated alloys by utilization of elemental information Jeongwon Yeh[1], Chanyang Kim[2], Myoung-Gyu Lee[1] and Eun Soo Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Materials Science, Korea (the Republic of)

CCAs have been widely considered to be promising structural materials for extreme environment due to their unique mechanical properties at room temperature as well as cryogenic condition and elevated temperatures. Because the selected alloying elements and their composition decide the reactive phase formation and the resulting mechanical properties, many researchers in metallic material fields have focused on the effect of composition on the evolution of microstructures and mechanical behaviors of CCAs. In order to commercialize the CCAs, the formability should be researched in advance. However, there is very little attention up to date to evaluate formability in these materials.
Therefore, in this study aims to propose a compositional range with excellent formability depending on deformation mechanism in the Cr-Mn-Fe-Co-Ni CCA system. Firstly, we tried to equilibriate the $\Delta\chi$, which is known to be proportional to yield strength (σy), to eliminate the effect of strength difference. Afterward, to confirm the effect of deformation mechanism on the formability of CCAs. we evaluate the formability of CCAs by both numerical simulations (Fracture Forming Limit Diagram: FFLD) and experiments (Limit Dome Height test: LDH). To understand numerical and experimental results, microstructures were compared at the same equivalent strain values under plane strain condition and uniaxial strain condition, representing the forming strain condition and tensile strain condition respectively. Through these results, it was possible to proposed a deformation mechanism with excellent formability in Cr-Mn-Fe-Co-Ni CCAs system.

5:00 PM SF01.08.03
Enhancement of low-T impact resistance by activation of multi-deformation mechanisms in HEA with manipulated SFE Kooknoh Yoon[1], Hyunseok Oh[2], Je In Lee[3] and Eun Soo Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States; [3]Pusan national university, Korea (the Republic of)

Low-temperature structural materials have been used in various fields, including LNG pipes, tanks, etc. FCC alloys, such as austenitic stainless steel, invar, etc., are used for applications. Although the FCC alloys do not exhibit DBTT at low temperatures, the capability for elongation is still restricted under dynamic stress conditions due to the high tendency of dislocation entanglement at low temperatures. Therefore, it is necessary to consider the (impact) toughness as well as the mechanical properties for targetting low-temperature applications. Meanwhile, it has been reported that the FCC HEAs exhibit excellent toughness at low temperatures since they can have a large number of nano-twins during deformation at low temperatures. From this idea, we tried to suggest a design methodology to manipulate the deformation behavior at low temperatures of the CrMnFeCoNi alloy by controlling the SFE, as well as to increase the strength by alloying Al to this alloy simultaneously. Finally, the developed the HEA-2 ($Cr_{20}Mn_6Fe_{34}Co_{34}Ni_6$ + Al 2.5at%) shows 20% increased impact toughness than the Cantor alloy at -100ºC since the HEA-2 has a relatively large elongation due to the activation of multi-deformation mechanisms, despite it has 2-times larger yield strength. The results will provide a solid guideline for developing a novel HEA for low-temperature applications.

5:00 PM SF01.08.06
nergy Landscape for Screw Dislocation in Body-Centered Cubic Binary and Ternary Subsystems of MoNbTaW Wenqing Wang[1], Flynn Walsh[1], Mark Asta[1] and Robert O. Ritchie[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Refractory high-entropy alloys (RHEA) exhibit high strength and compressive ductility at elevated temperatures. However, their engineering application is limited by their brittle failure modes under tension. The plastic deformation behavior of RHEAs may be closely linked to the energetics of screw dislocation cores, which depend on local chemical environments. Recent work has shown that, in contrast to pure metals, chemically disordered MoNbTaW exhibits a rough landscape of screw dislocation core energies, but the energy fluctuations are decreased by the formation of local chemical order. It is unclear, however, the extent to which these effects are related to the "high-entropy" nature of the system. We thus compare the dislocation core energetics of MoNbTaW and its binary and ternary subsystems. Using a machine learning interatomic potential, we calculate the dislocation energy landscapes in random and equivalently short-range ordered alloys. Results suggest that the specifics of the ordering phase transition are more important than the number of components.

5:00 PM SF01.08.07
Corrosion Behavior of AZ31 Magnesium Alloy with Different Grain Sizes Wenli Zhao and Qizhen Li; Washington State University, United States

AZ31 magnesium alloy is attractive as a candidate for biodegradable implanting devices. Depending on the actual applications, it is often necessary to modify the microstructure of materials to achieve different properties. It is critical to understand the relationship between microstructure and corrosion property of AZ31 magnesium alloy. This work focused on the effect of grain size on corrosion behavior of AZ31 magnesium alloy. Heat treatment was employed to obtain the samples with different grain sizes. Bio-corrosion test was conducted for the samples through being immersed in simulated body fluid for various time intervals. Scanning electron microscope was employed for observing morphology changes due to corrosion testing. The results show that the corrosion rates increased with the immersion duration for the samples, the samples with larger grain size exhibited better corrosion resistance, and the corrosion mechanisms for the sample was uniformly pitting corrosion.

5:00 PM SF01.08.08
A Study on the Characteristics of Ideal Glass State via Denary High Entropy Metallic Glasses Ji Young Kim[1], Geun Hee Yoo[1], Jung Soo Lee[1,2], Hyejung Chang[3], Jinwoo Hwang[4] and Eun Soo Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Inha University, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of); [4]The Ohio State University, United States

In the field of metallic glasses, the ideal glass state has attracted special attention because it is expected to have exceptional characteristics of high mechanical strength based on its unique atomic structure. The unique structure is characterized by high diversity in local structure, which means that it is not dominated by particular motifs. Even though it is suggested that mixing a large number of elements with different atomic sizes is a way to fabricate ideal metallic glass, there is a lack of research on proving the ideal glass state experimentally. In this study, we designed high entropy metallic glasses (HE-MGs) with 10 different elements to make the atomic structure close to the ideal glass state. Using these HE-MGs, we studied the various characteristics of ideal glasses, such as medium range ordering (MRO) structure, mechanical and thermal response, and crystallization behavior. We expect that the results enhance the insight into the ideal glass state in terms of atomic structural characteristics, unique mechanical properties, and abnormal crystallization behaviors.

5:00 PM SF01.08.09
Porous High Entropy Alloy as Efficient Electrocatalysts for Water Splitting Taehyun Kwon, Suyeon Kim, Minsol Kwon and Dongju Lee; Chungbuk National University, Korea (the Republic of)

High Entropy Alloy (HEA) has attracted attention for its excellent corrosion resistance and adjustable properties due to four core effects. When a non-noble-metal such as Fe, Co, and Ni is used to form the HEA composition, better catalyst properties are exhibited than using each element. In addition, HEAs have good corrosion resistance and stability due to the lattice distortion effect and the slow diffusion effect. Therefore, HEAs are expected to be a key to solving the high price of catalysts for hydrogen production.
In this study, The HEA composition was designed by predicting the composition of the single phase through the CALPHAD program by referring to the Volcano plot. HEA powders were fabricated via a powder metallurgy process. The prepared porous HEAs exhibited remarkable performance in the oxygen evolution reaction and the hydrogen evolution reaction due to the adequate adsorption energy of hydrogen or oxygen atoms being adjusted by the cocktail effect. Based on these results, it is expected that HEAs electrocatalysts are possible to use large-scale alkaline water electrolysis electrode.

5:00 PM SF01.08.10
Characteristic Change of High Entropy Garnet Structure $(Y_{0.2}Yb_{0.2}Lu_{0.2}Eu_{0.2}Er_{0.2})_3Al_5O_{12}$ by Fe^{3+} Substitution Hyeryang Choi, Janghyeok Pyeon, Bong-Gu Kim, Junseong Kim, Dong Gyeong Kim, Haeun Seo, Jung-Hun Son, Byungil Yang, Yeon-Gil Jung and SeungCheol Yang; Changwon National University, Korea (the Republic of)

YSZ (Yttria-Stabilized Zirconia) have been widely used as thermal barrier coating (TBC) materials for gas turbine. However, use of YSZ was limited at high temperature of over 1200 celsius due to phase transformation of YSZ accompanied with volume expansion and its low sintering resistance. In present work, we synthesized Fe-doped HEYAG (High Entropy Yttrium Aluminum Garnet) powder via a solid-state reaction. And then pellet, made with the powder, was sintered at 1450 celsius. The sintered Fe-doped HEYAG samples were characterized by using X-ray diffraction, scanning electron microscopy, Vickers hardness, thermal conductivity and thermal expansion coefficient. The Fe-doped HEYAG samples showed higher uniform element distribution compared to HEYAG samples. As Fe was more doped, XRD peaks of HEYAG shift to lower angle due to increment of average bonding length. Thermal conductivity of Fe-doped HEYAG is lower as Fe was more doped. When compared with YSZ, Fe-doped HEYAG with optimized Fe content shows lower thermal conductivity.

5:00 PM SF01.08.13
Effects of Mixing on High Entropy Spinel Oxides for Oxygen Evolution Reaction Jihyun Baek[1], Delowar Hossain[1,2], Michal Bajdich[2] and Xiaolin Zheng[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

High entropy oxides (HEOs) consist of five or more metal cations, offering ample opportunities to tune their catalytic properties toward high oxygen evolution reaction (OER) efficiency. We combine theoretical and experimental studies to scrutinize the OER activity and stability for spinel-type HEOs. First, we employ density functional theory (DFT) calculations to predict mixing enthalpies and OER activity descriptors for various metal active sites using a spinel-type HEO impurity model under the equimolar mixing conditions. Our DFT results show that the randomly mixed metal sites exhibit negative Gibbs free energy of mixing and are hence thermodynamically stable. Later, we utilize the rapid sol-flame method to synthesize various spinel oxides with up to five metal cations (Co, Fe, Ni, Cr, and Mn). The HEO shows the highest OER activity compared to the lower entropy oxides under alkaline conditions and excellent durability with the slight formation of surface oxyhydroxide with Fe and Ni. Finally, the calculated HEO activity predicts the lowest overpotential for Co active site compared to other active sites and lower entropy oxides, which is in good agreement with experimental activity trends for different spinel oxides. Interestingly, the OER activity of HEOs with the same composition exhibits a distribution of overpotential varies due to the broadening of intermediates adsorption energies, which originates from the equatorial strain (contraction/expansion) of the active metal-oxygen bonding configurations, leading to weaker/stronger surface thermodynamics.

SESSION SF01.09: Functional Properties and Innovative Applications I
Session Chairs: Cecilia Cao and Mitra Taheri

8:30 AM *SF01.09.01
Tailoring High Entropy Alloys—From Nearest Neighbor to Bulk Processing Mitra L. Taheri; Johns Hopkins University, United States

High entropy alloys are promising for candidates for a wide variety of applications, from aerospace to medicine. One tuning knob that HEAs possess is the short range order. Designing alloys for short range order can be done but measuring order is time consuming and difficult. Here we describe a data-driven, high throughput approach to alloy synthesis, characterization, and scale up with short range order as a design element. We reveal that order can be tracked in hundreds of alloys in real time, on the fly, using ML tools for semi-autonomous experimentation. Notably, the presence of short range has been connected to metastable phase evolution and non-equilibrium structures. These findings provide a pathway for tailoring high entropy alloys through these novel microstructural evolution pathways. To that end, highlights from scaling these alloys via bulk processing will be discussed.

High-Entropy Materials for Energy Applications Ben Breitung[1], Simon Schweidler[1], Anurag D. Khandelwal[1], Yanjiao Ma[1], Qingsong Wang[2], Abhishek Sarkar[1] and Jasmin Aghassi-Hagmann[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Universität Bayreuth, Germany

Recently, the concept of high entropy has found its way into many different application areas. One example is applications whose operation is based on the properties of crystalline materials, which is a promising field for this type of materials.
High-entropy materials are materials that contain many different elements in a single-phase crystal structure and therefore exhibit high configurational entropy. Due to the complex interactions between the contained elements and other structural features such as lattice distortion by ions of different sizes, high-entropy materials can exhibit diverse and unexpected properties compared to binary materials. High entropy ceramics have only been known since 2015[1], so this field of research is still relatively unexplored, leaving room for further work.
In this talk, the advantages of different high entropy ceramics in the field of energy and electrical applications will be highlighted.[2] In particular, various high entropy ceramics for energy storage and materials for electronic applications will be discussed. It has been shown that certain high entropy ceramics can stabilize Li- and Na-battery cycling, increase capacity, or suppress structural changes that might otherwise lead to structural degradation of the active material.[3–5] In addition, their implications for some electronic applications are discussed, e.g., for catalytic applications or as functional materials for printed electronics.

Tuning Morphology and Cation Selection for OER and ORR Bifunctional Catalytic Activity in Nano (nA1/n)Co2O4 Xin Wang[1], Harish Singh[2], Manashi Nath[2] and Katharine Page[1]; [1]The University of Tennessee, Knoxville, United States; [2]Missouri University of Science and Technology, United States

Reducing carbon emissions to meet the carbon neutrality goal while providing global energy demand on the terawatt level promotes the pursuit of clean energy technologies such as photovoltaics, wind turbines, and the production of hydrogen from water in a sustainable manner. Water splitting to produce hydrogen via the electrolysis pathway is considered a promising direction toward carbon-free energy production, especially considering the potential utilization of renewable (wind, solar, geothermal) and nuclear energy for the electricity source. A key research challenge lies in improving the energy efficiency for converting electricity to hydrogen over various operating conditions. With this regard, designing and developing economically feasible, earth-abundant, inexpensive, efficient electrocatalysts for the oxygen evolution reaction (OER) is a critical research factor. Even further, searching for electrocatalysts that can boost both the OER and the oxygen reduction reaction (ORR) simultaneously is crucial for deploying hydrogen production in a usable form, e.g., fuel cells. Conventional research focuses on noble metal (Pt, Ir, Ru, etc.) based electrocatalysts, which cannot meet the future goal of large-scale deployment due to their low abundance and high cost. Therefore, there have been intense efforts in exploring low-cost transition metal-based electrocatalysts, among which cobalt oxides are promising for both OER and ORR. Early this year, A. H. Li, et al. reported in Nat. Catal. a significant enhancement of the stability of Co3O4 spinel oxide by inserting Mn into the lattice. According to their report, the catalyst lifetime in solid acid (pH=1) environment was extended by two orders of magnitude. In fact, the exploration space can be enormously expanded by introducing compositional complexity in the cobalt spinel oxide system. In such scenarios, the rich variety of local geometry and coordination environment as induced by the compositional complexity enriches the type and/or strength of orbital hybridization. Consequently, the electronic structure could be tuned to control the reactivity of those active elements. Understanding how various local environments (geometry, distortion, coordination) are linked to electrocatalytic performance is therefore crucial, which then further necessitates a clear picture of the nature and tunability of the family's structure across length scales.

Understanding the Mixing and Properties of High Entropy Perovskites Ali Nasrallah[1], Colin L. Freeman[1], Ge Wang[2] and Derek Sinclair[1]; [1]University of Sheffield, United Kingdom; [2]The University of Manchester, United Kingdom

High-Entropy Oxides (HEOs) have gathered a lot of attention over the past few years particularly around their formation and properties[1–4]. The perovskite lattice (ABO_3) is a particularly exciting opportunity as mixing can be carried out on both the A or B site presenting a wealth of enthalpic and entropic possibilities to achieve a single-phase solid solution with a favourable Gibbs free energy[4].
Using a combination of computational modelling and experimental studies, we have examined several 3-, 4-, and 5-B element oxides with combinations of (Ga, Y, In), Nb, (Ti, Zr, Sn). We have studied the influence of a range of factors including the ionic size of the sites, the tolerance factor and the ionic size variation which we can then link to the formation of single-phase materials.

Our experiments on Ba-based perovskites demonstrate that single phases can be formed in a range of 4 and 5-B element perovskites with mixed valence charges (e.g. 3+, 4+ and 5+) but mixing was far more challenging with only 3-B element systems. By adjusting the A-site using Sr and Ca we were able to reduce the ionic size penalties and form further 3-B site single phase systems indicating that the size of the A cation also has an effect on the mixing process.

We have coupled the experimental work with a mixture of classical and ab initio simulation work examining the enthalpy of mixing and comparing to the phase formation from experiment. Our DFT simulations have identified the different mixing and hybridisation characteristics of the ions which affects their ability to mix and can run counter to expected ion size behaviour. Our classical simulations have optimised and examined hundreds of different structures which allows us to comment on the ideality of the solid solutions formed and the competition between entropy and enthalpy in the stability of a phase. We are also able to examine different secondary structures and how their enthalpic stability compares. Moreover, using computational and experimental Raman spectroscopy we are able to comment on the polymorphs obtained experimentally for the various perovskites.

From our results, we offer thoughts on the differing rules governing the mixing processes in these perovskite phases.

10:00 AM BREAK

10:30 AM SF01.09.07

Nanoscale High-Entropy Oxides (HEO) from Spray-Flame Synthesis for Oxygen Evolution Reaction (OER) in Water Splitting and Catalytic Cyclohexene Oxidation Steven Angel[1], Vimanshu Chanda[1], Ignacio Sanjuán Moltó[1], Julia Büker[2], Corina Andronescu[1,1], Martin Muhler[2], Christof Schulz[1,1] and Hartmut Wiggers[1,1]; [1]University of Duisburg-Essen, Germany; [2]Ruhr-University Bochum, Germany

Alternative solutions for energy conversion and storage are continuously developed and envisioned to become ubiquitous and ever more efficient, affordable, and sustainable. This challenging endeavor is enabled by the sustained development and discovery of new functional materials. In this regard, high-entropy oxides (HEO) have recently gained much attention as novel, e.g., anode/cathode materials for Li-ion batteries or fuel cells, and catalysts for low-temperature CO oxidation [1, 2]. HEOs are compounds counting with a configurational entropy higher than 1.609 R (R: gas constant) – requiring to have at least five different cations with similar atomic concentration – which are stabilized above a critical temperature (e.g., >850 °C) [3]. Thus, the synthesis techniques of these compounds typically require high temperatures, which can be achieved using a calcination step after, e.g., a co-precipitation step of the required precursors as in conventional methods [4]. Alternatively, the spray-flame synthesis method – in which temperatures higher than 1300 °C are typically obtained [5, 6] – offers the option to continuously synthesize HEOs in a single step.

In this work, the spray-flame synthesis of three HEOs, HEO1: $(Co_{0.2}Cu_{0.2}Mg_{0.2}Ni_{0.2}Zn_{0.2})O$, HEO2: $(Mn_{0.2}Fe_{0.2}Co_{0.2}Ni_{0.2}Cu_{0.2})_3O_4$, and HEO3: $(Mn_{0.2}Fe_{0.2}Co_{0.2}Ni_{0.1}Mg_{0.05}Al_{0.05}Cu_{0.2})_3O_4$ – is explored. While the spray-flame synthesized HEO1 – according to XRD and SAED measurements – crystallizes as a single phase in the rock-salt (NaCl type) structure, the HEO2 and HEO3 samples were stabilized in the single-phase spinel Fd-3m structure. Based on TEM/EDX measurements, particles from the HEO1 were found to have a predominantly cubic morphology (d_p = 7–10 nm) and a homogeneous element distribution on the atomic scale with local fluctuations of Mg and Zn. In contrast, the HEO2 and HEO3 samples presented particles with polyhedral (e.g., rhombicuboctahedron) morphologies and spherical particles (d_p = 5–12 nm) with uniform elemental distributions. The samples were further characterized by temperature-dependent XRD/TEM, TGA/DSC, FTIR, and XPS.

All spray-flame-synthesized HEOs were tested as oxygen evolution reaction (OER) catalysts in the electrochemical water splitting. HEO1 presented a promising activity, reaching a current density of ~70 mA/cm^2 at a potential of ~1.65 V vs. RHE. Additionally, the HEO1 was also tested as a catalyst for cyclohexene oxidation, showing an unexpected selectivity towards 7-Oxabicyclo[4.1.0]heptan-2-one, which has not yet been found for other catalysts in this form.

Corrosion Properties of Medium Entropy Alloys under Oxygen Evolution Reaction Conditions in Aqueous Electrolytes Annica Wetzel, Ozlem Ozcan, Julia Witt and Daniel Morell; Bundesanstalt für Materialforschung, Germany

Due to their favorable mechanical and anti-corrosion properties, medium entropy alloys (MEA) are of high academic and industrial interest as novel materials for engineering and catalytic applications. Previous studies indicate high transpassive currents without indication of pitting for MEAs, which makes them promising materials for oxygen evolution catalysts [1].

To understand the stability of MEAs CrCoNi and FeCrNi at high anodic potentials, we have investigated the mechanisms of transpassive dissolution and the oxygen evolution reaction (OER). Scanning electrochemical microscopy (SECM) was applied in the interrogative mode for the detection of evolving metal species and oxygen during controlled polarization. SECM operated with oxygen reduction at the probe precisely determined the onset of the OER. Inductively coupled plasma – mass spectroscopy (ICP-MS) analysis was performed to quantify dissolved metal species. Potentiodynamic, potentiostatic and chronoamperometric techniques as well as different electrolytes were used to induce precisely controlled corrosion loads during the SECM experiments and for the ICP-MS analysis. Macroscopic corrosion properties of the alloys, electrical and chemical properties of the passive films were studied by means of potentiodynamic polarization, electrochemical impedance spectroscopy (EIS) and X-Ray Photoelectron Spectroscopy (XPS), respectively.

Finally, the analysis of the corrosion morphology and the potential of the surface before, during and after passivity breakdown was carried out by means of in-situ atomic force microscopy (AFM) and scanning Kelvin probe force microscopy (SKPFM). Our results indicate that even though the OER accounts for the majority of the observed transpassive currents, for alloys showing excellent passivation behavior like CrCoNi, the localization of the corrosion at grain boundaries may still present a challenge for material durability. The presentation will summarize the detailed electrochemical characterization of the corrosion processes of the studied MEAs with a specific focus on the transpassive behavior under OER conditions.

Modeling High-Entropy Intercalation Cathodes with Sparse Lattice Models Peichen Zhong[1,2], Fengyu Xie[1,2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Disordered rocksalt materials are the most promising earth-abundant cathode materials for Li-ion batteries, and as such can enable scaling of Li-ion energy storage to many TWh/year production. Such modern battery materials can contain a large number of elements with substantial site disorder, and their state of short-range ordering has been shown to be critical for their performance. Ab-initio modeling of the configurational degrees of freedom increases exponentially with the number of species included. The problems to apply cluster expansion techniques include: (1) how to generate lattice models without over-fitting; (2) how to properly sample the configurational space in ionic systems with charge-neutrality.

To address these, we will demonstrate two novel methods to approach the multi-component space of DRX: (1) applying L0L2-norm regularized regression with structural hierarchy to construct a robust cluster expansion Hamiltonian. (2) implementing grand-canonical Monte Carlo to sample charge-balanced ionic configurations. We apply these approaches to compute the voltage profile of $Li_{1.3-x}Mn_{0.4}Nb_{0.3}O_{1.6}F_{0.4}$, and demonstrate how Mn and oxygen contributes to the redox potential as Li is intercalated.

SESSION SF01.10: Functional Properties and Innovative Applications II

Crystallography of High Entropy Metal Carbides—A New Class of Ultrahigh Temperature and Irradiation Resistant Ceramics Olivia A. Graeve, Ved Vakharia and Luyao Zhang; University of California, San Diego, United States

We will describe the unique crystallography and microstructure of high-entropy Mo-Nb-Ta-V-W carbides prepared using a novel solvothermal synthesis process. The compounds were produced by mixing metal chlorides and carbon powder in the presence of molten lithium. Solvothermal synthesis occurs at a high temperature (upwards of 2000°C), which allows the carbides to undergo reaction-driven alloying and form single-phase solid solutions of nanopowders without the need for further thermal treatment. We have produced binary, ternary, quaternary, quinary, and senary metal carbides through systematic manipulation of elemental composition, particularly counteracting the tendency of WC and MoC to form. Solid solutions have been confirmed by a combination of X-ray diffraction and energy dispersive spectroscopy. Subsequently, spark plasma sintering (SPS) was used to obtain dense specimens. Carbon was added to the carbide powders to facilitate densification of the targeted compositions at a low sintering temperature (1600°C), compared to typical temperatures required for carbides. Low temperature sintering avoids heat-driven grain growth and allows for a finer grain size distribution.

1:30 PM SF01.10.02
Ablation Threshold and Temperature Dependent Thermal Conductivity of High Entropy Carbide Thin Films Milena Milich[1], Kathleen F. Quiambao-Tomko[1], John Tomko[1], Jon-Paul Maria[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]The Pennsylvania State University, United States

High entropy carbides (HECs) are a promising new class of ultra-high temperature ceramics that could provide novel material solutions for leading edges of hypersonic vehicles, which can reach temperatures > 3,500 °C and experience extreme thermal gradients. Although the mechanical and thermal properties of HECs have been studied extensively at room temperature, few works have examined HEC properties at high temperatures or considered these materials' responses to thermal shock. In this work, we measure the thermal conductivity of a variety of five-cation HECs up to 1200 °C. We find that thermal conductivity increases with temperature, consistent with trends demonstrated in single-metal carbides. We also measure thermal conductivity of an HEC deposited with varying CH_4 flow rate, and find that although thermal conductivity is reduced when carbon content surpasses stoichiometric concentrations, the films all exhibited the same temperature dependent trends regardless of carbon content. To compare the thermal shock resistance of HECs with a refractory carbide, we conduct pulsed laser ablation measurements to determine the fluence threshold the HECs can withstand before damaging. We find that this metric for the average bond strength trends with the theoretical hardness of the HECs as expected.

1:45 PM SF01.10.03
Friction Behavior and Terminal Group Effect of High Entropy MXene at Nanoscale Jiaoli Li[1], Yuwei Zhang[1], Yanxiao Li[2], Yuxiang Gan[1], Risheng Wang[1] and Chenglin Wu[1]; [1]MST, United States; [2]NYU, United States

High entropy MXene (HE MXene) is a new frontier MXene that has great potential for solid lubricants due to its diverse composition, volatile physical and chemical features. Here we experimentally investigated the friction of two HE MXene ($TiVNbMoC_3T_x$ and $TiVCrMoC_3T_x$) and compared their friction properties with $Ti_3C_2T_x$ MXene, Ti_2CT_x MXene, graphene, and $MoSe_2$ at the nanoscale via atomic force microscopy (AFM). Different scan distances (15nm and 1μm) and layers (1, 2, 3, 4, 5, 6, and more than 6 layers) were applied to obtain the corresponding friction properties of each of these 2D materials. Moreover, effect of the terminal groups on the friction behaviors at the nanoscale was also investigated by removing the -OH functional groups on HE, $Ti_3C_2T_x$ and Ti_2CT_x MXene surfaces using annealing treatment. Our preliminary result has shown that the friction properties of HE MXene are similar to $Ti_3C_2T_x$ and Ti_2CT_x MXene, and superior to graphene and $MoSe_2$. Furthermore, decreasing the number of -OH groups could greatly improve the friction performance of all types of MXene. This study provides experimental basis for the application of modified MXene into solid lubrication.

2:00 PM SF01.10.04
Nanoscale Friction of High Entropy Alloy Sulfide Thin Films in Comparison with Molybdenum Disulfide Gokay Adabasi[1], Aditya Deshpande[2], Koichi Tanaka[2], Joshua Ancheta[1], Emmanuel Maldonado[1], Mehmet Ozdogan[1], Mehmet Baykara[1] and Suneel Kodambaka[2,3]; [1]University of California, Merced, United States; [2]University of California, Los Angeles, United States; [3]Virginia Tech, United States

Recent years saw accelerating interest from the scientific community in high entropy alloys (HEA), mainly due to their favorable mechanical properties and resistance to environmental stressors. In principle, their outstanding wear and corrosion resistance make them great candidates for coatings in mechanical systems. On the other hand, the question of whether HEA thin films will also act as solid lubricants, i.e. reduce friction at the interface of mechanical components in relative motion, remains open.

In order to find answers to this critical question, we performed nanoscale friction measurements on sputter-deposited HEA-sulfide ($(VNbTaMoW)S_2$) thin films via atomic force microscopy (AFM). Results reveal (i) the influence of deposition time on film morphology and (ii) the presence of isolated areas of low friction on film surfaces. Taking one step further, we compared the nanoscale friction results obtained on the HEA-sulfide thin films with those on sputter-deposited molybdenum disulfide (MoS_2), a widely-used material for solid lubrication. Friction values obtained on both types of films are on the same order. Finally, variable temperature X-ray diffraction (XRD), performed up to 800 °C, reveals that $(VNbTaMoW)S_2$ films exhibit improved oxidation resistance when compared with MoS_2 films. Combined, the results presented here demonstrate that HEA-sulfide thin films exhibit remarkable potential as environmentally-resistant solid lubricant coatings.

3:15 PM SF01.10.06
Mechanical and Magnetic Properties of an Additively Manufactured Soft-Magnetic High-Entropy $Al_{0.5}$CrFeCoNi Alloy Xipeng Tan; National University of Singapore, Singapore

The demand for new classes of high-performance soft magnetic materials (SMMs) has been rapidly rising in the context of sustainable and electrified world. However, there exists a dilemma between low hysteresis loss and high mechanical performance, thereby motivating the further exploration of advanced materials and manufacturing for the magnetically soft yet mechanically tough electrical machine components. Additive manufacturing (AM), popularly known as a layer-by-layer three-dimensional (3D) printing technology, offers new opportunities of processing SMMs in near-net-shape with superior soft magnetic and mechanical properties. Here, a promising soft-magnetic $Al_{0.5}$CrFeCoNi high-entropy alloy is additively manufactured by laser powder-bed fusion method. The mechanical properties and hysteresis loop of the 3D-printed soft-magnetic high-entropy alloy are examined and compared with state-of-the-art SMMs. Moreover, its as-cast counterpart is fabricated to better understand effects of AM processing on both mechanical and soft magnetic properties.

2:30 PM BREAK

3:30 PM SF01.10.07
Examining High Entropy Alloy Nanoparticles of Small Size and Tunable Composition Prepared via Colloidal Syntheses Evan Gardner and Matteo Cargnello; Stanford University, United States

High entropy alloy nanoparticles (HEA-NPs) – those containing at least five, homogeneously alloyed metals – have rapidly emerged as versatile nanomaterials suited for both thermo- and electrocatalysis. Their unique “high entropy mixing” lends to significantly hybridized electronic structures, which confers noble metal reactivity to base metals and provides improved thermal stability. Base metal containing HEA-NP catalysts provide the opportunity to dilute or eliminate precious metals in legacy catalysts. A preponderance of specialized, high temperature, thermal syntheses of HEA-NPs, however, limits respective catalyst design to carbon supports. Therefore, we have pioneered tunable and scalable colloidal syntheses of HEA-NPs, which are tailored to exploit a variety of active support materials such as alumina, ceria, and titania. Characterization via TEM and STEM-EDS mapping in conjunction with single area electron diffraction methods reveal spherical, 6-7 nm NPs with uniform alloy structures. These HEA-NPs also demonstrate intriguing thermocatalytic behavior and excite future studies designed to systematically probe the impact on HEA-NP composition on reactivity and structural evolution under reaction conditions.

3:45 PM SF01.10.08
Facile Synthesis of High-Entropy Alloy Nanoparticle Decorated Germanane Chuyi Ni and Jonathan Veinot; University of Alberta, Canada

High-entropy alloy nanoparticles have attracted substantial research interest because of their multi-elemental compositions, intriguing solid-solution structure, as well as applications (e.g., multifunctional catalysis). Various methods for the synthesis of these materials have been reported. Even so, the vast compositional space and complex structure result in great challenges related to comprehensive investigations and fundamental understanding. Herein, we will outline a new method for preparing high-entropy alloy nanoparticles comprising Au, Ag, Cu, Pd, Pt that are supported on germanane via comparatively mild solution reduction and in-situ growth. The resulting materials were characterized using X-ray diffraction, X-ray photoelectron spectroscopy, and transmission electron microscopy.

4:00 PM SF01.10.09
Retrosynthetic Design of Core@Shell Nanoparticles for Their Thermal Conversion to High Entropy Alloy Nanoparticles Nabojit Kar, Maximilian McCoy, Joshua Wolfe and Sara Skrabalak; Indiana University Bloomington, United States

In recent years, high-entropy alloy (HEA) nanoparticles (NPs) have attracted a lot of attention as a new class of nanomaterials in the field of catalysis and energy applications due to their tunable compositions, high hardness and strength, high-temperature resistance, and remarkable ductility. The synthesis of HEAs as monodisperse NPs is of high interest to understand how their structure and composition contribute to their function. However, downsizing HEAs to the nanoscale has been synthetically challenging as most colloidal routes to metal NPs rely on the reduction of metal salts, which will occur at different rates depending on the metal precursor. Past work has shown that colloidally prepared monodisperse core@shell NPs can be converted to monodisperse HEA NPs by annealing them at high temperatures. This approach requires fewer metal precursors in each step compared to direct coreduction, facilitating the formation of monodisperse samples with much more control. The initial system considered core@shell PdCu@PtNiM NPs as precursor NPs to HEA NPs, where M = Co, Ir, Rh, Ru, or Fe. These core@shell NPs were prepared by seed-mediated co-reduction (SMCR), and while quite versatile, some metals (e.g., Au and Sn) could not be used in the SMCR process with PdCu seeds. The conversion chemistry not only bounded to PdCu but other bimetallic seeds (e.g. AuCu, PdAg, Pd_3Sn) can also be used. However, consideration must be taken as to which metals go in the core and which metals go in the shell. Herein we propose that the metal precursors for the core and shell of the core@shell NPs synthesis should be judicially chosen according to their relative redox potentials with all the participating metals or metal precursors. We also show that metal precursors with a fast reduction rate that can generate homogenous nucleation in the SMCR step should go in the core of the core@shell NPs. Retrosynthesis is the technique of employing chemical reactions to "deconstruct" a target molecule into easily accessible starting ingredients. Similarly, considering different variables, we may design a retrosynthetic reaction pathway that results in HEA NPs with the targeted metal compositions. More generally, obtaining control over monodisperse HEA NP composition can pave the way for long-lasting catalysts for a variety of processes.

SESSION SF01.11: High Entropy Oxides I
Session Chairs: Cecilia Cao and Katharine Page
Friday Morning, April 14, 2023
Marriott Marquis, B2 Level, Golden Gate C2

10:00 AM *SF01.11.01
Compositionally Complex Oxides—Synthesis, Characterization, Challenges and Opportunities Veerle Keppens; University of Tennessee, United States

High entropy oxides (HEOs), also referred to as multicomponent oxides or compositionally complex oxides (CCOs), have attracted attention due to the tunability of multiple cations on a single site. Since the introduction in 2015 of HEOs stabilized in the rocksalt phase, the high entropy oxide concept has been expanded to various structures, offering a path for the discovery of innovative compounds with unique structure-property relations. However, the intrinsic disorder and highly localized chemical environments of HEOs bring along new challenges. In order to shed light on the complexities associated with multi-cation oxides, we have initiated a systematic study of polycrystalline and single crystalline HEO samples across multiple crystal systems. This work expands the multi-component concept to new compositions and crystal systems and investigates properties of materials across multiple crystal systems, including spinel, perovskite, and Ruddlesden-Popper multi-component materials.

10:30 AM SF01.11.02
Real Space Observation of Reaction Pathway in the Formation of Entropy-Stabilized Oxide John Heron and Avery-Ryan E. Ansbro; University of Michigan, United States

Configurational entropy has enabled a new synthesis pathway to previously unrealized, multi-component, single-phase oxides [1]. Such high entropy and entropy-stabilized oxides are a novel class of materials that offer a wide range of utility as well as an opportunity to understand the role of entropy in the solubility, phase behavior, and stability for the design of disordered materials [2][3]. There has been a large disparity between high entropy compounds that have been predicted to exist as single-phase materials and those that have been generated experimentally, with some high entropy oxides (HEOs) only being realized through high kinetic energy processing such as pulsed laser deposition rather than solid state processing [4]. This suggests that complex reaction pathways may be hindering the ability to discover stable HEOs [5]. Here we show that varying precursor choices can affect the ability to dissolve metal cations into a high entropy structure and in some cases can result in differing phase states at identical conditions. Dissolution of spinel Fe3O4 and corundum Fe2O3 into known entropy stabilized oxide, (Mg0.22Ni0.2Cu0.2Co0.2Zn0.2)O, individually is found to produce different products: Single phase and spinel rocksalt mixture respectively. This can be done reversibly. Using Co3O4 instead of CoO in the synthesis of (Mg0.22Ni0.2Cu0.2Co0.2Zn0.2)O hinders the formation of a single-phase material with spinel as a secondary. Notably, the dissolution of Co3O4 as a sixth component to (Mg0.22Ni0.2Cu0.2Co0.2Zn0.2)O precursor leads to a single phase. Our results demonstrate that precursor choice affects reaction intermediates and final structure under a fixed set of conditions. Further, synthesis from pre-formed (Mg0.22Ni0.2Cu0.2Co0.2Zn0.2)O instead of binary constituents also appears to affect the ability to dissolve metals into a high entropy complex. Examining the synthetic pathways and thermodynamic processes that result in these variances is crucial to understanding solubility and the rational design of disordered systems.

10:45 AM SF01.11.03
Entropy Engineering in the Spinel High Entropy Oxide Mario Ulises Gonzalez Rivas[1,1], Graham Johnstone[1,1], Mohamed Oudah[1,1], George A. Sawatzky[1,1], Robert Green[2,1], Keith Taddei[3], Ronny Sutarto[4] and Alannah Hallas[1,1]; [1]The University of British Columbia, Canada; [2]University of Saskatchewan, Canada; [3]Oak Ridge National Laboratory, United States; [4]Canadian Light Source, Canada

The discovery and development of high entropy oxides (HEOs) has garnered significant attention, in no small part due to the enhancement of functional properties that they often present. As an atomistic explanation of HEOs is beyond current theoretical techniques, auxiliary “descriptors” that characterize them are invaluable. Configurational entropy, being a measure of disorder, is considered a key descriptor when addressing the properties of HEOs. Notably, it has been demonstrated that in systems with inequivalent sublattices, crystal field effects can overwhelm and suppress configurational entropy, introducing a degree of site selectivity in the cationic distribution [1,2]. However, most studies on the subject treat configurational entropy as a fixed, static quantity.

Here, we address this matter within the framework of the 3d transition metal-based AB_2O_4 spinel-type HEO $(Cr,Mn,Fe,Co,Ni)_{3-x}Ga_xO_4$ system, an ideal setting that provides octahedral and tetrahedral sublattices with strong crystal field effects. We harness x-ray absorption and magnetic circular dichroism to elucidate the spinel HEO’s site selectivity and quantify its configurational entropy. Our analysis shows that Ga substitution provides an avenue to seamlessly tune the octahedral sublattice from the medium entropy to the high entropy regime, with the tetrahedral sublattice going from low entropy to medium entropy. These results imply that through careful cation selection, the two sublattices of the spinel HEO can be precisely tuned across different entropy regimes, demonstrating the principle of entropy engineering in HEOs [2].

We then briefly explore the prospect of another avenue through entropy engineering in HEOs. It is well established that changes to the processing conditions involved in the growth of binary spinel oxides can have striking effects on their degree of inversion and the materials’ final properties [3,4]. This tunability hints at the possibility of extending the principles of entropy engineering to other. Our study then turns to the fully 3d $(Cr,Mn,Fe,Co,Ni)_3O_4$ spinel HEO, where several synthesis routes and their effect on the final materials’ site selectivity are discussed, hinting at the richness of the energy landscape in the spinel HEO.

Controllable Phase Heterogeneity in High Entropy Oxides Alexander D. Dupuy and Julie Schoenung; University of California, Irvine, United States

High entropy oxides (HEOs) consist of five or more oxide components which form a single-phase solid-solution structure after processing. Despite their recent discovery, HEOs already show promise in a variety of applications, particularly in electronics and battery components. A unique characteristic of HEOs is their reversible entropy-driven phase transformation between the single-phase and multiphase states. The phase transformation manifests as the formation of secondary phases, whose volume fractions can be controlled through heat treatment. This feature presents an opportunity to produce oxide materials with highly controlled phase states, microstructures, and behavior.

Here, we explore the behavior and consequences of this phase transformation in (CoCuMgNiZn)O. First, we show that solid-state synthesis and sintering can be used to consolidate fully dense HEO ceramics with grain sizes spanning several orders of magnitude. After heat treatment, we observe that the phase transformation manifests as the formation of Cu-rich tenorite and Co-rich spinel secondary phases. We demonstrate that the phase heterogeneity can be controlled through heat treatment, while the as-consolidated grain size significantly influences the secondary phase evolution and morphology. Furthermore, we discuss our efforts to characterize the secondary phases using atom probe tomography (APT), X-ray diffraction (XRD), and electron microscopy. From these investigations, we find that the secondary phases exhibit several interesting behaviors, such as a complex nucleation sequence and a size induced morphological transition.

We then explore how the controllable phase heterogeneity can be leveraged to tailor the electrical and mechanical behavior. We observe that the electrical conductivity and dielectric constant increase significantly with increasing amount of secondary phase, due to the formation of a conductive percolative network. Conversely, the interplay between the various secondary phases and their morphological evolution results in complex changes to the mechanical behavior and failure mechanisms. Our results demonstrate that the entropic transformation is a powerful tool for engineering the microstructure and behavior of high entropy oxide ceramics.

Predicting Entropy-Enthalpy Compensation in Metal Hydrides Using Machine Learning Mark D. Allendorf, Vitalie Stavila, Pinwen Guan and Matthew Witman; Sandia National Laboratories, United States

Metal hydrides are among the most promising materials for hydrogen storage because of their high gravimetric and volumetric energy density. In some cases, the volumetric capacity is higher than even liquid hydrogen. This makes them attractive for transportation applications, where minimizing storage system volume is paramount. The primary challenge to implementing metal hydrides is a "Goldilocks" tradeoff between the thermodynamics of H_2 release and the reversible capacity.[1] One strategy to surmount this challenge is to reduce (i.e., make more negative) the free energy of dehydrogenation (ΔG°(dehyd)) by maximizing the dehydrogenation entropy (ΔS°(dehyd)) and minimizing the corresponding enthalpy change (ΔH°(dehyd)). However, entropy-enthalpy compensation,[2-3] in which a reduced ΔH°(dehyd) is counteracted by a smaller ΔS°(dehyd), could defeat this strategy. Therefore, understanding the extent to which ΔH° and ΔS° can be independently controlled is crucial to designing strategies for tailoring the thermodynamics of metal hydrides.

Here, we discuss our recent use of a machine learning model to identify features correlated with ΔS°(dehydr) and ΔH°(dehydr) for metal hydrides.[4] For intermetallic (interstitial) metal hydrides, our results indicate that the material features that best predict ΔH°(dehydr) can differ from those for ΔS°(dehydr). In particular, ΔS°(dehydr) is most strongly correlated with the corresponding volume change upon dehydrogenation, whereas ΔH°(dehydr) is strongly correlated with the mean ground-state atomic volume, which depends only on composition and not structure. For several other classes of metal hydrides, including high entropy alloys (HEA),[5] metal-substituted TiFe, and AB_2 (Laves-type) hydrides,[6] we find entropy-enthalpy compensation effects are present to varying degrees, but these correlations are rather weak, suggesting that independent ΔS° tuning may be possible.

Finally, we report a statistical analysis of entropy-enthalpy compensation effects in metal hydride nanoparticles. Uncoupling ΔS°(dehyd) of nano-MH from ΔH°(dehyd) may be possible using material formats that strongly immobilize nanoclusters, thereby reducing S°(nanocluster) and increasing ΔS°(dehyd). Data for hydride nanoparticles are much more limited than for the bulk counterparts, but our statistical analysis of the available nanohydride data suggests that ΔS°(dehyd) and ΔH°(dehyd) are correlated for MgH_2 and PdH_x and this is dependent on particle size. The results suggest a structure-property correlation indicating that uncoupling ΔS°(dehyd) from ΔH°(dehyd) may be possible for nanoscale hydrides using material formats that strongly immobilize nanoclusters, thereby lowering S°(nanocluster) and increasing ΔS°(dehyd).

Mw-plasma Produced High Entropy Borides Synthesized Based on Entropy Forming Ability and Mechanical Properties Bria C. Storr, Luke Moore, Cheng-Chien Chen and Shane A. Catledge; University of Alabama at Birmingham, United States

High entropy borides have favorable mechanical properties making them great candidates for materials that can withstand extreme conditions. This research seeks to look at samples with the entropy-forming ability for high entropy borides produced utilizing microwave-induced plasma. Precursors containing metal oxides and borons were annealed for a borothermal reduction resulting in an AlB2-type hexagonal crystal structure. The computationally predicted mechanical properties and first principle are compared to the synthesized high entropy borides (HEBs). Results from ongoing research have shown that MW-plasma synthesized HEBs are consistent with the calculated hardness and the entropy-forming ability (EFA) prediction. From ongoing research, the highest EFA does not correlate to the highest hardness. Therefore, this research focuses on the HEBs candidate with the highest and lowest EFA values. The MW-plasma HEBs microstructure, hardness, and oxidation resistance will be presented.

Tuning Magnetic and Catalytic Properties in a Family of Compositionally Complex ACo_2O_4 Spinel Nanostructures Katharine Page; The University of Tennessee, Knoxville, United States

Nanostructured materials offer promising physicochemical properties across diverse applications in the fields of energy storage, sensors, catalysis, biomedicine, and more. Compositionally complex oxides (CCO) may offer increased structure-property tunability due to their unique structure diversity, tunable compositions, and possible property enhancements/modifications through increased entropic disorder. Here, an eco-friendly low temperature soft-templating reaction route is applied to form a large family of spinel nanostructures with formula $A\mathrm{Co}_2\mathrm{O}_4$, where A includes n different equiatomic combinations of one to seven transition metal cations. The phase selectivity and temperature stability windows for the series of nano-compositions are found to be dominated by the inclusion (or exclusion) of specific cations, with the temperature required for formation influenced by increasing n (increasing configurational entropy). We apply a wide array of characterization techniques, including high resolution transmission electron microscopy, neutron diffraction and pair distribution function analysis, and Special Quasi-Random Structures Density Functional Theory approaches, to probe the influence of cation selection and processing parameters on structural, catalytic, and magnetic properties. Specifically, we demonstrate water splitting catalyst activity can be tuned through A cation selection and post heat treatment. Certain metastable $A\mathrm{Co}_2\mathrm{O}_4$ compositions are found to be novel precursor phases for synthesis of bulk hard-soft exchange magnets: we demonstrate that tunable magnetic performance can be achieved through control of the nanoscale heterogeneity of annealed products. Links between specific lattice defects, chemical short-range order, nanoscale heterogeneity and magnetic/catalytic performance in this ACo_2O_4 spinel family demonstrates a wider approach to promoting design principles and strategies for nanostructured CCOs and related materials.

2:00 PM SF01.12.02

Hydrogen Substituted Graphdiyne Assisted Ultra-Fast Sparking Synthesis of Metastable Nanomaterials for Li-S Batteries Xueli Zheng and Yi Cui; Stanford University, United States

Metastable nanomaterials, such as single atom and high entropy systems, with exciting physical and chemical properties, are increasingly crucial for next-generation technologies. The origin of these properties results from electronic and bonding structures far from equilibrium although the synthesis of metastable nanomaterials remains challenging. For example, extreme heating and cooling rates are often required to prevent cluster formation of single atoms and phase separation of high entropy alloys. Here, we developed a hydrogen substituted graphdiyne-assisted ultra-fast sparking synthesis platform for the preparation of metastable nanomaterials. Controlling the composition and chemistry of the hydrogen substituted graphdiyne aerogel framework, the reaction temperature can be tuned from 1640 K to 3286 K within milliseconds. We demonstrate the versatility of the ultra-fast high-temperature platform with the successful synthesis of single atoms, high entropy alloys, and high entropy oxides. Electrochemical measurements and density functional theories show that single atoms synthesized by the platform enhance the lithium-sulfur redox reaction kinetics, enabling high-performance all-solid-state lithium-sulfur batteries. Our design of the ultra-fast high-temperature platform offers a new powerful way to synthesize a variety of metastable nanomaterials.

2:15 PM SF01.12.03

High-Throughput Synthesis and Characterization of High-Entropy Oxides for Photosensitive Applications Mukesh Kumbhakar[1], Anurag D. Khandelwal[2], Ben Breitung[2], Shikhar K. Jha[1], Horst Hahn[2], Leonardo Velasco[3] and Simon Schweidler[2]; [1]Indian Institute of Technology Kanpur, India; [2]Karlsruhe Institute of Technology (KIT), Germany; [3]Universidad Nacional de Colombia, Colombia

High entropy materials have been widely investigated in recent years for their possibility to tailor functional properties. Unique interactions due to the presence of multiple elements in a single-phase structure give way to properties not generally seen in their binary counterparts.

Due to the inordinately large combinations available, the “trial and error” method becomes arduous while synthesising systems with four or more elements. A high-throughput approach to synthesising such systems can help fast-track this process by reducing the time and energy involved. This can be combined with characterisation techniques like XRD, SEM, UV-Vis spectroscopy etc., to help shortlist potential candidates for further investigation.

This talk focuses on the study of fluorite-type rare earth oxides with varying compositions of Ce, La, Pr, Sm, Y, Zr and Tb using the high-throughput approach to identify the impact of individual elements on the physical properties. The reversible tuning of their band gaps by changing the atmosphere and temperature of calcination was also examined. Further electrical and optical studies were conducted on a few chosen samples to compare their performance for potential photosensitive applications.

2:30 PM SF01.12.06

Development of TRIP-Maraging Steel with Excellent Fracture Toughness Through Complexion Precipitation Control Based on Segregation Engineering Jeongwon Yeh, Min Seok Kim and Eun Soo Park; Seoul National University, Korea (the Republic of)

Maraging steel is one kind of ultra-high strength steel, which is widely used in environments requiring high strength such as rocket engine, submarine hulls, aerospace and cryogenic missiles. However, it couldn’t overcome the strength-ductility trade-off issue and has brittle characteristics. Therefore, in this study, we tried to improve the ductility of the material by precipitating FCC austenite phase, which is a relatively ductile phase, in the grain boundary region through segregation engineering. Segregation engineering is represented by the value of grain boundary segregation enthalpy, and grain boundary segregation enthalpy is defined as the energy of the entire system that can be decreased when 1mol of a solid solution element is segregated to the grain boundary. In order to find the segregation element at grain boundary, it is necessary to search an element having positive segregation enthalpy value with the base system elements Fe, Ni and solid solution elements Co and Mo. As a result, it was confirmed that Mn has positive segregation enthalpy for all elements. In addition, the Mn element is known to greatly increase the stability of the FCC phase when dissolved in Fe based alloy. Therefore, Mn was finally selected as an optimal element for segregation engineering. Through this alloy design strategy, it was possible to design the alloys in which FCC austenite phase was locally precipitated. However, as the ductile FCC austenite phase was precipitated, the ductility increased but the strength decreased. To overcome strength-ductility trade-off, careful thermodynamic calculations were conducted to reduce the stability of the precipitated FCC austenite phase, resulting in martensitic transformation during deformation. This study provides a new pathway to design TRIP Maraging steel using relatively simply factors such as thermodynamic calculations, segregation enthalpy calculation, and comparing interphase relative stability. In addition, to obtain fracture toughness for the TRIP Maraging steels designed by the above strategy and to understand contribution of elastic and plastic in the process of crack growth, J-based crack-resistance curves, nonlinear-elastic fracture mechanics analysis method was conducted.

SESSION SF01.13: Virtual Session: High Entropy Materials

Autonomous Accelerated Workflow for the Discovery of High-Entropy Oxide Electrodes for Protonic Ceramic Fuel Cells Benjamin H. Sjølin and Ivano Eligio Castelli; Technical University of Denmark, Denmark

We develop and implement an autonomous multi-fidelity computational workflow to explore the chemical space of high-entropy perovskite oxide materials with general formula ABO_3, screening for stable, high-performance cathodes for low-temperature protonic ceramic fuel cells. The workflow, implemented in the framework of Density Functional Theory (DFT), is based on the calculation of thermodynamic, electric and kinetic properties, which include phase and electrochemical stability, electronic conductivity, and ionic diffusivity. To accelerate the calculation of the kinetic properties, we employ accelerated methods that leverage recent advances in machine learning for materials science to predict transition barriers for ionic diffusion. The computational cost of the workflow is additionally decreased, while retaining the quality of results, through a thorough examination of the required level of theory for all descriptive properties. Moreover, the aim is a general and chemistry-neutral approach that can be applied to other crystal prototypes and materials screenings.

9:30 AM SF01.13.02
Predicting Local Environments of Entropy Stabilized Oxides Using DFT and Machine Learning Lily J. Joyce, Kristen E. Johnson, Christina M. Rost and Kendra Letchworth-Weaver; James Madison University, United States

Entropy Stabilized Oxides (ESOs) are a novel class of materials which are enthalpically unfavorable, but entropically favorable due to high configurational disorder. The unique properties of these materials make them potentially useful as battery cathodes and in thermoelectric devices. Though not able to directly predict formation energies of ESOs, enthalpy based methods such as Density Functional Theory (DFT) remain useful for gathering bond length data, oxidation states, electronic band structure, and other statistics from the microstates representing the local environments of these materials. These statistics are useful for comparison to experimental methods such as XAS, provided that the microstates are representative of the real material. For representative systems, DFT can be quite computationally expensive, so instead we utilize Machine Learning (ML) algorithms to identify structural and energetic descriptors based on DFT. We aim to use these ML algorithms to scan through potential ESO candidates and predict which ones are the most promising for in-depth electronic structure calculations using the more accurate but computationally expensive DFT.

9:45 AM SF01.13.03
High-Entropy Materials Design: $A_6B_2O_{17}$-form Oxides Robert J. Spurling, Chloe Skidmore and Jon-Paul Maria; Pennsylvania State University, United States

High-entropy materials offer expanded opportunities for accessing unique and tunable property spaces via substantial structural disorder and compositional diversity. Exploring high-entropy single-phase stabilization in novel structural systems is essential for understanding structure-property relationships in these complex systems and promoting future materials design. Here, we probe the structure and thermodynamic stability of disordered $A_6B_2O_{17}$-form (A = Zr, Hf; B = Nb, Ta) oxides. Specifically, we report the synthesis of the novel multicomponent oxide $(Zr_3Hf_3)(NbTa)O_{17}$, which is structurally isomorphous with ternary and quaternary $A_6B_2O_{17}$ end members. This is accomplished through a bulk ceramic processing and sintering approach. Additionally, we employ high-temperature X-ray diffraction to study the single-phase transition *in situ*. We also report on bulk dielectric permittivity measurements on these $A_6B_2O_{17}$ species.

10:00 AM *SF01.13.05
Ultrafine Grain Formation, Grain Boundary Segregation and Phase Decomposition in CoCuNi Medium Entropy Alloy Koichi Tsuchiya; National Institute for Materials Science, Japan

FCC medium entropy alloys (MEAs), *e.g.*, CoCrNi, have been attracting much attention due to their excellent strength-ductility balance. The present talk will report the fabrication of an equiatomic CuCoNi MEA and its improvement of strength and ductility after high-pressure torsion (HPT).
An equiatomic CoCuNi MEA was produced by high-frequency melting and was hot-rolled and swaged into a cylindrical shape with a 10 mm in diameter. The samples were homogenized at 1150 °C for 1 hour and quenched into room temperature water. Severe plastic deformation by high-pressure torsion (HPT) was applied on the disk samples with a thickness of 0.85 mm at room temperature with a pressure of 5 GPa and a rotation speed of 1 rpm to 10 rotations. After the HPT, the sample was annealed at 400 °C, 600 °C for 100 h, and at 800 °C for 1, 10, and 100 h. XRD, SEM-EBSD, EDS, TEM, APT, Vickers hardness, and tensile tests were conducted to investigate the microstructures and mechanical properties.
The grain size of the sample before HPT was ~100 mm and was refined to ~90 nm after HPT. Tensile strength and elongation before HPT were 400 MPa and less than 10 %, respectively. HPT deformation improved both strength and elongation to over 1400 MPa and 16 %. The fracture surface observations revealed the intergranular fractured feature for the sample before HPT and ductile fracture for the one after HPT. APT analysis confirmed the segregation of a substantial amount of Cu along the grain boundaries in the sample before HPT. Severe deformation by HPT removed the grain boundary segregation, which may be the reason for the improved ductility.
We also investigated the effect of post-deformation annealing on microstructures and mechanical properties. XRD revealed that the sample after HPT, and then annealed at 400 °C showed the single FCC peaks while the sample annealed at 600 and 800 °C showed the splitting of the FCC peaks, indicating the phase separation. EBSD-EDS of CuCoNi annealed at 800 °C for 100 h showed typical recrystallized microstructure containing twin boundaries in equiaxed grain boundaries. EDS analysis visually and quantitatively identified the phase separation into Cu-rich (~80 at%Cu-20 at%Ni) and Cu-depleted (~55at%Co-40at%Ni) phases with the volume fractions of 0.34 and 0.66, respectively. The boundaries between the Cu-rich phase and Cu-depleted phase often coincide with the grain boundaries or twin boundaries. But the phase boundaries also exist within a single grain[ST1] , suggesting the simultaneous progress of phase separation and recrystallization. The tensile tests indicated that prolonged annealing at high temperatures leads to improved ductility at the expense of strength, compared to those after HPT.

10:30 AM *SF01.13.06
Tensile Creep Behavior of HfNbTaTiZr Refractory High Entropy Alloy at Elevated Temperatures An-Chou Yeh; National Tsing Hua University, Taiwan

This talk will present the tensile creep deformation of equiatomic HfNbTaTiZrr, we used the optical floating zone technique to fabricate sample with grain size larger than 1 mm on average; tensile creep tests under vacuum at 1100~1250^{o}C and stepwise loading of 5-30 MPa were performed. Creep of HfNbTaTiZr was dominated by solute drag creep behavior, and deformation was governed by a/2<111> type dislocations. Analysis suggests that creep rate of HfNbTaTiZr was controlled by Ta, which possesses the lowest intrinsic diffusivity in the system and contributes the most to drag dislocations. Findings in this work can provide a guideline to develop future high entropy alloys with creep resistance.

SESSION SF02.01: Spacecraft Materials
Session Chairs: Jacob Kleiman and Masahito Tagawa
Tuesday Morning, April 11, 2023
Marriott Marquis, B2 Level, Golden Gate C1

10:30 AM *SF02.01.01
Additive Manufacturing (3D Printing) Materials for Space Applications Eitan Grossman[1,2], Irina Gouzman[1], Yuval Vidavsky[1] and Nurit Atar[1]; [1]SOREQ and Noga 3D Innovations, Israel; [2]Noga 3D Innovations, Israel

Additive Manufacturing (AM) has recently adopted a wide variety of materials ranging from plastics, metals, composites, alloys, and ceramics to food, fabric, concrete, and cement. The growing consensus of adopting the AM system over traditional techniques is attributed to several advantages including fabrication of complex geometry with high precision, maximum material savings, flexibility in design, and unique geometries that are lighter and cheaper. Started as a technology used for demonstrators and prototypes, AM has evolved to produce functional engineering structures and parts as more and more printable materials were introduced to the AM market. Common printing techniques are stereolithography (SLA), Digital Light Process (DLP), Fused Deposition Modeling (FDM) or Inkjet used for printing polymers and ceramics, and powder bed fusion (SLS, SLM) and direct energy deposition (DED) used mostly for metals and alloys in the form of powder and ceramics. The use of AM for space applications can be categorized by (i) printing in orbit or on the moon or Mars, or (ii) printing on Earth, depending on the ability to apply specific printing technique in the space environment. Applying AM in-space has advantages, such as, printing tools and spare parts on-demand (thus reducing the need to fly spare parts from earth), building structures that would not survive the stresses of launch, or build habitats on planets suitable for potential colonization in the future using local materials (e.g., regolith). On Earth printing can use, on the other hand, a large variety of printing techniques that are not available for in-space usage thus allowing vast applications ranging from small parts to full satellites. Examples may include ceramic mirrors, turbine blades, space suits, nano satellites, and even thrusters, rocket engines, and fully functioning rockets. The presentation will describe various printing techniques, printed materials used in space and the development of materials to withstand the space environment as well as current and future space and planetary applications.

11:00 AM SF02.01.02
Polymer Aerogels for Lunar Applications and Beyond Stephanie Vivod, Haiquan Guo, Sadeq Malakooti and Ariel Tokarz; NASA Glenn Research Center, United States

As the Space Community endeavors to reach new heights of exploration, advanced materials for extreme environments are at the forefront of research. One such material would include polymer aerogels. Polyimides are often found in aeronautic and aerospace applications due to their ability to retain their physical and mechanical properties over a wide range of temperatures and in chemically demanding environments. Cross-linked polyimide aerogels retain these same characteristics with added attributes of very low thermal conductivities (~14 mW/m-K), high specific surface areas (~850 m^2/g), low dielectric constant (~ 1.1), low densities (0.005-0.15 g/cm^3), and high porosities (>85%). Due to these interesting properties, aerogels are ideal as thermal and vibro-acoustic mitigating systems but are by no means limited to these applications. The high porosity and surface area also make aerogels an ideal host system for particle incorporation for applications such as IR scattering filters, chemical sensors, and dust and radiation mitigating materials. Herein, current polymer aerogel research will be discussed as it pertains to Space exploration and applications.

11:15 AM SF02.01.03
Ceramic Aerogels for Space High Temperature Applications Haiquan Guo[1,2] and Jamesa L. Stokes[2]; [1]Universities Space Research Association, United States; [2]NASA Glenn Research Center, United States

Ceramic Aerogels for Space High Temperature Applications
Haiquan Guo[1], Jamesa L. Stokes[2]
1.Universities Space Research Association

2.NASA Glenn Research Center

Aerogels play an important role in thermal insulation systems for space application. They are light-weight materials with low thermal conductivity, effectively suppressing heat transfer by conduction, convection, and radiation.Silica aerogels sinter at 600°C and polymer aerogels generally decompose below 450°C, meaning they are not suitable for high temperature insulation needs.This presentation will detail aluminosilicate aerogels, YSZ aerogel, and YbSZ aerogels that we have designed and developed for space high temperature thermal insulation applications. Aluminosilicate aerogels can be used up to 1100°C without losing the mesoporous structure, whereas YSZ aerogels and YbSZ aerogels can be used up to 1000°C. With further modification using SiO_2 coatings, they also can be used at 1100°C by maintaining the mesoporous structure.Ceramic felts, mats, or papers were used to reinforce those aerogels in composites that do not flake and can be flexible.Hydrophobicity was also achieved by manipulation of the surface of those aerogels and their composites.

11:30 AM SF02.01.04
Tribological Behavior of Polyimide-Hexagonal Boron Nitride Nanocomposites at Elevated Temperature for Aerospace Applications Priscila Rodrigues De Oliveira, Abhijith K. Sukumaran, Luiza Benedetti, Denny John and Arvind Agarwal; Florida International University, United States

Polyimide (PI) has significantly been used in aerospace applications due to its high strength-to-weight ratio, thermal stability up to 330°C, and chemical resistance. However, confronting harsh environments in the presence of radiation, orbital debris, and Lunar and Martian regolith may result in critical failure. Given this scenario, (h-BN), a solid lubricating with radiation shielding effectiveness, was added to the PI matrix at different concentrations (PI-2wt.% hBN and PI-5wt.% hBN). The samples were prepared by direct forming using ball milling to facilitate the uniform distribution of hBN in the PI matrix. Densification and thermal stability results showed considerable improvement compared to pristine PI. Moreover, tribological characterization by the rotatory ball on a disk tester revealed a reduction in COF by adding h-BN to the neat PI structure. Furthermore, the improvement in wear rate at ambient temperature was 55.9% and 75.9% for PI-2wt.% hBN and PI-5wt.% hBN, respectively. The wear rate for the samples tested at high temperature (300°C) greatly improved by 55.8% for PI-2wt.% hBN and 70.3% for PI-5wt.% hBN, respectively. Adding h-BN nanoparticles has significantly enhanced the lubrication properties of the Polyimide matrix. This nanocomposite has the potential to be a great candidate for space applications and harsh environments.

11:45 AM SF02.01.05
Black Coatings for Space Instruments—A Comparison of Traditional Ebonol-C Processes, a Recipe for Repeatability in the Future and a Baseline for Comparison for New Ultra-Black Coatings Daniel E. Hooks, Bradley Carpenter, Courtney Clark, Michael McBride, Ilker Loza-Hernandez, Jamie Stull and Carlos Maldonado; Los Alamos National Laboratory, United States

Ultra-black coatings have served various roles in space instrumentation and hardware. The Ebonol C coating has been used for various missions requiring low reflectivity on aluminum. This coating is produced through the formation of a cupric oxide structure on an intermediate layer of copper applied to the aluminum. For many years, this commercial formulation has been used ubiquitously for space plasma instruments to minimize contaminating background counts due to forward scattering of photons. The coating relies upon details of the copper intermediate layer that have been trade secret at various finishing companies, and the availability of the Ebonol C formulated chemistry from the chemical supplier. In recent years, this product has been discontinued at various times, leaving vendors to either rely on expired stock or to formulate their own equivalents. Here, we detail the processing methods, chemistries, and resultant coating structures that produce reflectance performance equivalent to baseline historical reflectance data. This process detail will ensure equivalent performance for such coatings for future missions and link the performance to past and currently deployed instruments. Additionally, the results serve as a baseline for comparison to new coatings under development for reflectance optimization, two of which will be described.

SESSION SF02.02: Spaceflight Exposure Experiments I

Session Chairs: Irina Gouzman and Jonathan Volk
Tuesday Afternoon, April 11, 2023
Marriott Marquis, B2 Level, Golden Gate C1

1:30 PM *SF02.02.01
CNES Flight Experiments for Thermal Coatings Aging—THERME and SESAME Stéphanie Remaury, Sophie Perraud and Pascale Nabarra; CNES, France

The in-flight evolution of thermo-optical properties of thermal coatings is of great concern when defining the thermal control system (TCS) of spacecraft. Experience (in-flight measurements and aging tests in laboratory) demonstrates that the parameter really affected by the in-orbit aging is the solar absorptivity a_S, which often increases when coatings are under space environment conditions. To define spacecraft TCS, thermal engineers have to take into account, from beginning of life (BOL) to end of life (EOL), the thermo-optical properties evolutions of the external coatings they intend to use (a_S and e_{IR}). Radiative surfaces sizes cope with the hottest conditions of the mission, which generally depend on the EOL properties of external coatings. But the larger the surfaces, the higher the heating power needed for the coldest conditions of the mission, which generally depend on BOL properties. Improving the knowledge of the in-orbit evolutions of the solar absorptivity of thermal coatings is consequently of paramount importance to optimize the TCS designs, and then to better master the on-board heating power consumption.
In this context, CNES has developed since 1990 a very simple and low cost experiment, called “THERME”, to evaluate the degradation of space coatings in real orbital conditions[1, 2]. This experiment was previously carried on low Earth orbit (LEO) spacecraft such as SPOT 2 and 5, HELIOS 2A and 2B and Demeter, all removed from operational service. In the last few years, the THERME experiment design was extended for geostationary (GEO) mission typical constraints[2] and is now flying on ATHENA-FIDUS and KOREASAT from TAS and on a telecom mission from ADS.
Moreover, CNES and ESA recently collaborate to develop the Euro Material Ageing (EMA) experiment. This will offer recurrent testing opportunities for European institutes to perform materials sciences research and validate new materials technologies in the real space environment on the International Space Station. EMA is currently under development and includes two main experiments:
- SESAME for studying materials and coatings behavior in real space environment and recording in-orbit parameters such as atomic oxygen flux, contamination, radiation, for a better knowledge of the LEO space environment and its effects on materials.
- IR-Coaster for characterizing the stability or evolution of biological and organic compounds when exposed to UV solar radiation.

The intended duration of the EMA mission is between 12 and 18 months. For the first EMA flight opportunity, 141 passive materials samples and 8 active sensors are under the ISS ram direction, offering unrestricted view to space. Various European research groups samples have been selected following a competitive tender process managed by ESA. Exposed materials include novel types of innovative multilayer insulation (MLI), optical and thermal coatings, reinforced composites, 3D printed polymers and exotic metallic alloys... CNES and ESA are also providing samples from their own internal research programs and collaborations. Each material undergoes the measurements of their physical and chemical properties before and after flight. In particular, this allows the thermo-optical properties aging assessment of the new TCS coatings developed by CNES. The launch of the first EMA is planned by end of 2023.

In this paper, we present the overall concept and design of THERME and SESAME experiments. We discuss also in flight results of THERME and scientific objectives of SESAME for TCS coatings.

Shear Thickening Fluid Treated Space Suit Layups—MISSE-9, -10, and -13 Low-Earth Orbit Studies Overview Maria Katzarova[1,2,3], Norman J. Wagner[2,3], Richard D. Dombrowski[3] and Erik Hobbs[3]; [1]Lubrizol, United States; [2]University of Delaware, United States; [3]STF Technologies LLC, United States

The durability in low-Earth orbit (LEO) of the soft-goods portion of extra-vehicular activity space suit layups treated with a specially formulated, low-volatility, shear thickening fluid is investigated on the exterior of the International Space Station (ISS) as part of the Materials on the International Space Station Experiment (MISSE), missions MISSE-9, -10, and -13. Performance of a control layup and a shear thickening fluid treated layup exposed to LEO for nearly one year in the Ram-orbiting direction of the ISS on MISSE-9, informed the next iteration of materials tested on MISSE-10, Nadir-oriented, which in turn led to a design of materials tested on MISSE-13, Ram-oriented. The effect from exposure to atomic oxygen, space radiation, large temperature variations, and potential threat from micrometeoroid and orbital debris impact was assessed post-flight using a suite of techniques including spectroscopy, puncture resistance, and optical properties. Ground controls are used to compare both mechanical and optical properties to the flown samples and discussed relative to monitoring data from the MISSE experiments, including photographs, temperature data, UV intensity, and particle contamination. The cumulative data obtained from this multi-mission study of these state-of-the-art soft composite materials can inform their further development and possibly future crewed exploration efforts, including the Artemis program, Lunar Orbital Platform-Gateway, and subsequent Lunar and Martian surface missions.

Low Earth Orbit (LEO) Exposure Effects on Polyimide Aerogels During MISSE Missions Sadeq Malakooti, Ariel Tokarz, Jessica Cashman, Kim de Groh and Stephanie Vivod; NASA Glenn Research Center, United States

As part of 'Materials on the International Space Station Experiment' (MISSE) missions, polyimide aerogel samples at varying densities were part of a test series positioned on the exterior of the International Space Station (ISS) during MISSE-9 and MISSE-12 missions. At low Earth orbit (LEO), spacecrafts are subjected to extreme environmental conditions such as thermal cycling, cosmic ray, and solar wind charge particle radiations as well as atomic oxygen. Herein, the aerogel materials were characterized for changes in physical and mechanical properties as well as thermal and optical properties. Results were then compared with the corresponding data obtained from the baseline samples of similar batches stored under ambient conditions on Earth.

3:15 PM SF02.02.04
3D-Printed Polymers with High Resistance to Atomic Oxygen Erosion and Orbital Debris Impact Rishik Keshari, Kelly Chang, Debashish Das, Leon Dean, Lawrence Salvati, Dana Dlott, Nancy R. Sottos and Ioannis Chasiotis; University of Illinois at Urbana-Champaign, United States

There is increasing need to protect and repair structural material systems deployed to the adverse environment of Low Earth Orbit (LEO) from Atomic Oxygen (AO) erosion and damage due to orbital debris impact. Of special interest are polymer-based composites because of their lightweight properties and the new capabilities to directly 3D-print in Space. This presentation focuses on AO-erosion studies at the International Space Station (ISS) coupled with ground-based simulated debris impact experiments with tough polydicyclopentadiene (PDCPD) and its nanocomposites that were 3D printed via highly energy efficient frontal polymerization. The AO-erosion experiments were conducted through runs 13 and 15 of the Materials International Space Station Experiment (MISSE). Results from AO-erosion experiments with different PDCPD formulations and their nanocomposites at the ISS demonstrated a 10-fold reduction in erosion rate, setting a path for even further increases in AO erosion resistance. The same materials in both as-fabricated and AO-eroded form were subjected to ground-based impact experiments with sub-millimeter size aluminum projectiles propelled to hypervelocities approximating orbital space debris velocities. The experimental projectile velocity profiles and the residual impact crater geometries were utilized to calibrate a hydrodynamic computational model that provided damage predictions for different debris velocities. This combined experimental and modeling approach to debris damage opens new quantitative routes for predictive and efficient design of advanced lightweight materials for Space applications.

SESSION SF02.03: Poster Session
Session Chairs: Kim de Groh and Ryan Reeves

Moscone West, Level 1, Exhibit Hall

5:00 PM SF02.03.01
Radioprotectant Ceria Nanoparticle (CNP) Drug Delivery System to Prevent Reactive Oxygen Species (ROS) and Mitigate Spaceflight Osteopenia Balaashwin Babu, Elayaraja Kolanthai, Craig J. Neal, Shreya Pawar, Agastya Mittal, Melanie J. Coathup and Sudipta Seal; University of Central Florida, United States

Space exploration is reaching new heights as we traverse beyond low earth orbit. In this extreme environment, radiation induced health issues will be a major concern. The ability to induce higher levels of free radicals and reactive oxidative species (ROS) are factors to be addressed. Ceria nanoparticles (CNPs) can provide a means to scavenge ROS; free radicals known to cause cell apoptosis and thus may serve as a radioprotectant. Further, conjugation of

CNP to the drugs used to treat osteoporosis such as bisphosphonates, may offer a possible solution to space-induced osteopenia, and provide a dual functionality that can protect the bone cells from ROS and slow down overall bone loss. Current results indicate high Ce^{3+} structural confirmation of ceria nanoparticles using a wet-chemical synthesis. The synthesized nanoparticles were then conjugated with risedronate, a third-generation bisphosphonate. Three experimental combinations including, 1,1'-carbonyldiimidazole (CDI) linker only, CDI + polyethyleneimine (PEI), and CDI + diamine were confirmed to be successfully conjugated through UV/Vis characterization. Superoxide inhibition results show that all three conjugated products displayed higher antioxidant properties as tested using a superoxide dismutase assay inhibition kit. Preliminary microwave radiation studies indicated that CNP was able to be used as a radioprotectant as it prevented changes in drug chemistry as detected by UV/Vis spectra after exposure to 60 seconds of microwave radiation. Finally, in vitro cell studies using human mesenchymal stem cells showed excellent viability when exposed to all combinations of drug and CNP at 50ug concentration as demonstrated using an MTT colorimetric assay. These results indicate ceria nanoparticles show promise as a radioprotectant material that may also work well as a drug encapsulant. Further studies are necessary to investigate this further.

Evaluation of Out-Gassing Test(CVCM, TML) for EEE Parts Material in Space Wooje Han, Min-Seok Jeon, Kyunghee Kim, Woki Bae and Minhyeong Gil; Korea Testing Laboratory, Korea (the Republic of)

EEE (electrical, electronic, and electromechanical) parts, which are components for space, are being developed mainly in the US and Europe, and are still in their minor interesting in South Korea. In particular, in the case of the United States, the use of space parts is restricted their applications in many nations based on the regulations of ITAR and EAR, and the European replacement parts market to solve this problem is very active. In particular, various component companies, centering on ESA, are producing space components that meet the European space standard, and many satellites and launch vehicles are being developed using them. A lot of new parts are being tried in micro(nano-) satellites, which have recently been spotlighted, and ground environmental testing is essential to confirm that these parts are suitable for space.
In this atmosphere, expectations for the development of space-grade parts are concentrated in South Korea. Korea is a very strong leader in the semiconductor component market such as memory. It is the hope of most world-class space researchers to make these parts suitable for the space applications. Recently, in South Korea, the space parts test center of the Space testing center (Korea Testing Laboratory) has established a facility for professionally testing space parts. It is a specialized testing institute that develops device-grade component tests and confirms suitability for space applications.
In particular, the space-grade materials are being tested very strictly. The CVCM (collected volatile condensable mass) and TML (total mass loss) machines to test the characteristics of outgassed in space vacuum, including substances prohibited for use in space, have been set-upped. Through these equipment, suitable materials are tested in a vacuum environment in space. Some parts (transformer, inductor) are being introduced using these materials that have passed the test in South Korea. By providing such analysis technology, we would like to introduce our contribution to the determination of suitability for the space applications in ground test.

5:00 PM SF02.03.03
Complex Radiation Shielding Properties of Polyethylene Nanocomposites with Tungsten Nanoparticle Attached Boron Nitride Nanosheets Seulgi Kim, Yunhee Ahn and Dongju Lee; Chungbuk National University, Korea (the Republic of)

There has recently been an increase in demand for complex radiation shielding (neutron and γ-ray shielding) in the atomic energy, aerospace, and medical fields. In contrast to neutron shielding, which uses neutron absorbing materials (B or Gd), γ-ray shielding mostly employs heavy metals such as Pb, Fe, and W. Heavy metals are difficult to disperse in the polymer matrix due to the density differential with the polymer. However, when these materials are present as nanoparticles attached on the surface of two-dimensional (2D) materials, nanoparticle aggregation is reduced due to the large surface area of 2D materials, which can assist in matrix dispersion.
Herein, we prepared polyethylene (PE) nanocomposites incorporated with tungsten nanoparticles (W NPs) decorated on boron nitride nanosheets (BNNS) hybrids. The cross-sectional area of the reaction of W NPs was increased by uniformly attaching to the BNNS surface with interfacial chemical bonding. Furthermore, non-covalent functionalization of the hybrids leads to increase the dispersibility of the hybrids in the matrix. The W-BNNS/PE nanocomposites demonstrated improved mechanical characteristics and thermal conductivity due to the interfacial bonding between W and BNNS and the interconnection of W NPs. The nanocomposites provided excellent radiation shielding properties for neutron (4.80 cm^2/g) and gamma (γ) ray (0.093 cm^2/g) radiation; this confirmed its potential as a complex radiation shielding material.

Chemical and Morphological Evolution of Surface Conversion Coatings in Low-Earth Orbit Space Environment Ankita Mohanty[1], Cheng-Chu Chung[1], Xiaoyang Liu[1], Donald Vonk[2], Kim Kisslinger[3], Xiao Tong[3], Gary P. Halada[1], Bruce Ravel[4], Stanislas Petrash[2], Kate Foster[2] and Yu-chen K. Chen-Wiegart[1,5]; [1]Stony Brook University, United States; [2]Henkel Corporation, United States; [3]Center for Functional Nanomaterials, Brookhaven National Laboratory, United States; [4]National Institute of Standards and Technology, United States; [5]National Synchrotron Light Source II, Brookhaven National Laboratory, United States

Surface conversion coating is one of the most promising technologies for a wide range of industrial applications to protect the surface of alloy materials from corrosion, and to enhance the adhesion of decorative paints to treated metal components. Understanding the chemical stability and structural integrity of conversion coatings for their applications in an outer space environment for potential aerospace industry, is of great interest. Under extreme conditions of atomic oxygen, thermal cycling and ultra-high vacuum, the coating materials may undergo morphological and chemical changes. In this work, we utilized a multi-modal characterization method where synchrotron and laboratory X-ray techniques as well as electron microscopy, were combined to study the evolution of surface conversion coatings as a result of the exposure to the low-earth orbit environment in space. The samples were part of an MISSE mission, during which the samples were placed outside of the International Space Station and compared with the twin samples aged on Earth. We will discuss the influence of the space conditions on the surface conversion coatings.

5:00 PM SF02.03.05
UV-Initiated Healing of Punctures Due to Hypervelocity Impacts on Metal Composites for Space Applications Ashanti M. Sallee and Enrique Barrera; Rice University, United States

The space environment can have a severe impact on materials. In low Earth orbit (LEO) materials must withstand the effects of high vacuum, extreme temperature variations, micrometeoroid and orbital debris (MMOD), and exposure to atomic oxygen and UV radiation. Mechanical, chemical, and thermal degradation can occur due to exposure to a few or all these conditions. To help mitigate these damages, self-healing systems for the space environment are of interest. The objective of these systems is to autonomously repair damage without any external diagnosis, which can result in increased time/savings on repairs and the increased safety and reliability of materials. Our group is focused on designing metal composite self-healing pressure vessels for space that can heal hypervelocity impacts that occur due to MMOD. Many metallic self-healing systems require high temperatures for healing, which may not be effective in space due to the severe temperature variations. Our research group has designed a self-healing system that is more feasible for space. Instead of relying on heat, our system's healing is UV-initiated, exploiting the UV radiation in space and it can be done in ambient temperatures. We designed a metal composite that sandwiches a liquid solution between two aluminum plates. The liquid is a precursor solution for a poly(ethylene glycol) diacrylate (PEGDA) hydrogel that cures via UV irradiation for less than 5 minutes. Upon puncture of the composite using a hypervelocity light gas gun to simulate space impacts, the precursor solution will be released and exposed to UV light, forming a hydrogel that will serve as a solid plug and heal the damage. In my presentation, I will discuss the design and characterization of the composite, along with a comparison of the mechanical properties before and after healing. I will also examine further testing methods that can analyze the efficiency of the system in space.

5:00 PM SF02.03.06
The Influence of Oxygen and Temperature on Optical and Chemical Structure Changes by the UV Irradiation Kazuki Yukumatsu[1], Shogo Yamane[2], Yuki Horiuchi[2], Junji Mizukado[2], Hideaki Hagihara[2] and Yugo Kimoto[1]; [1]Japan Aerospace Exploration Agency, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

Polymeric materials are often used as thermal control materials in spacecraft. Many polymeric materials discolored under ultraviolet (UV) irradiation, which changed their solar absorptance affecting the thermal design of spacecraft. For this reason, many ground experiments have been performed to evaluate the solar absorptances during the end of life (EOL) of the spacecraft mission. However, it takes a long time to irradiate the same amount of UV fluence as the actual mission period, and it is difficult to perfectly simulate the UV irradiation conditions such as thermal cycle. Therefore, it is important to study the prediction of the solar absorptance after UV irradiation.
This study aims to quantitatively understand the correlation between the changes in the chemical structures and solar absorptances to make a prediction technique. In this presentation, we report the results of UV irradiation experiments focusing on the presence of oxygen, which has a significant effect on the degradation mechanism of the polymeric materials. We primarily focused on the polyetherimide film which is a relatively transparent material having a good tolerance to the radiation. The surface analysis used by X-ray photoelectron spectroscopy (XPS) and Fourier Transfer Infrared Spectroscopy (FTIR) were performed. We also measured the solar absorptance by a UV-Vis-NIR spectrometer. As a result, the irradiated samples in the air were observed the structure after oxidative deterioration. On the other hand, the irradiated sample in vacuum were not observed such structures. The solar absorptances of the irradiated samples in air were larger than the samples in vacuum. In vacuum, the solar absorptances of samples were not saturated at a maximum of 600 ESD. Moreover, the dependency of the sample temperature in vacuum UV irradiation condition was evaluated, and same analysis was conducted.
Finally, we will discuss the degradation mechanisms based on the surface structure analysis of each of these materials, and the prediction method of solar absorptances.

SESSION SF02.04: Radiation Effects, Electronic Devices and Photovoltaics

Introduction of the Radiation Hardening Activities on Semiconductor Devices for Space-Use Keita Sakamoto; Japan Aerospace Exploration Agency, Japan

The presentation will introduce the activities of enhancing semiconductor devices for space-use especially in digital devices against to the radiation effects. Although the categories of space-part has gradually been changing with the entry of new space players, a fundamental concept of the radiation hardening technology remains important, because the EEE component which is required high reliability like bus-system still needs high radiation torelance. In my presentation, the basic mechanisms and radiation hardening technology against to both Single Event Effects (SEE) and Total Ionization Dose (TID) effect will be introduced, together with our research activities.

9:00 AM SF02.04.03
Effects of 10-Month Low Earth Orbit Exposure on Hybrid Perovskite Thin Film Samuel Erickson[1], William; Delmas[1,2], Calista Lum[1,3], Jorge Arteaga[1], Kyle Crowley[4], Jennifer Williams[5,6], Lyndsey McMillon-Brown[4], Timothy Peshek[4] and Sayantani Ghosh[1]; [1]University of California, Merced, United States; [2]Sandia National Laboratories, United States; [3]University of California, Irvine, United States; [4]NASA Glenn Research Center, United States; [5]Wilberforce University, United States; [6]Ohio Aerospace Institute, United States

The high defect tolerance and potential for extremely high specific power in metal-halide perovskite (MHP) solar cells make them promising materials for space-based photovoltaics. Additionally, moisture, by far the most significant variable in MHP degradation, is negligible outside of the earth's atmosphere. In this work, we examine the effects of low earth orbit (LEO) on an MHP sample through high-resolution spectroscopic characterization. An encapsulated methylammonium lead iodide film was flown to the International Space Station as part of the 13th Materials International Space Station Experiment (MISSE-13) and exposed to the LEO environment for 10 months. Placed at zenith orientation, the sample underwent 45 minutes of AM0 illumination followed by 45 minutes of darkness a total of 4800 times, cycling between 100° C and -100° C each revolution. By comparing the spectral behavior, recombination lifetime, and phase transition temperature to a control sample, we quantified the changes in the flight sample.

Overall, the flight sample emitted a strong photoluminescence signal and showed little sign of degradation. The film was encapsulated with Dow Corning 93-500 silicone elastomer and a 1 mm borosilicate cover glass. Glass of this thickness blocked protons with energies up to 13 MeV in simulation, so galactic cosmic rays were unlikely to have affected the sample. The flight sample also showed no visual changes or significant lead iodide (PbI_2) formation under confocal microscopy, indicating that ultraviolet light transmitted through the cover glass was not damaging. Our analysis showed that the most significant and advantageous change in the film was a decreased tetragonal to orthorhombic phase transition temperature, likely caused by tensile strain from rapid temperature cycling. Calculations reveal in-plane tensile strain in the perovskite film at low temperatures due to the thermal expansion mismatch with its glass substrate. When this strain was relaxed through light soaking following 15 hours of AM1.5 illumination from a solar simulator, the flight sample's low phase transition temperature (56 K) increased to nearly match its control (130 K). The slightly larger bandgap of the MISSE-13 sample (1.612 eV) also red-shifted to match that of its control sample (1.594 eV). Likewise, confocal microscopy revealed a reduction in lead iodide regions of the flight film. Finally, the average charge recombination lifetime of the flight sample tripled after this illumination. These behaviors indicate a combination of photo-annealing and strain relaxation within the film, further improving its performance. Altogether, the excellent optical response and stability of the flight sample demonstrates that MHPs can be properly encapsulated to withstand space stressors.

9:15 AM SF02.04.04
Ultra-Thin and Ultra-Light Si Solar Cells with Hyperuniform Disordered Light Trapping Alexander Lambertz[1], Nasim Tavakoli[2], Richard Spalding[3], Stefan Tabernig[2], Marian Florescu[3], Jorik Van de Groep[4] and Esther Alarcon-Llado[2]; [1]NWO-i AMOLF / UvA Amsterdam, Netherlands; [2]AMOLF, Netherlands; [3]University of Surrey, United Kingdom; [4]University of Amsterdam, Netherlands

Ultra-thin crystalline silicon solar cells could, in contrast to their thick counterparts, simultaneously reduce levelized cost of electricity by a large factor and be deployed on curved or non-static surfaces, windows, as well as facilitate building integrated photovoltaics. Moreover, their light weight, integrability into systems or tandem devices, and robustness to (cosmic) radiation also renders them excellent candidates for space applications. Silicon at micron-scale thickness, however, suffers from poor light absorption and conventional light trapping approaches such as random KOH texturing fails due to the feature sizes produced.

We present hyperuniform disordered (HUD) light-trapping structures applied to ultra-thin solar cells via substrate-conformal imprint lithography. This approach enables rapid patterning of large areas (m2) at the nanoscale and can be performed on virtually any substrate and for any type of functional layer, such as the absorber, back-reflector, anti-reflection coating or carrier transporting layers. Correlated-disorder structures were shown to outperform periodic as well as random light trapping approaches [1] and the hyperuniform platform in addition offers tailored scattering to engineer light coupling to guided modes of ultra-thin absorbing layers [2]. To this end, we developed a coupled-mode theory (CMT) approach for estimating absorption with HUD patterns of arbitrary power spectral density distributions, which affords optimizations at low computational effort. CMT predictions are validated by determining the in-coupling rates per guided mods for different HUD designs, which we achieve through FDTD simulations. Furthermore, we show experimentally measured absorption in ultra-thin, free-standing, hyperuniform-patterned silicon slabs of thicknesses ranging from 1-30µm and compare with simulations. Finally, we show the performance of ultra-thin Si solar cells before and after the application of HUD light trapping structures.

In conclusion, our work exploits stealthy hyperuniformity for exceptional light trapping and aims to further expand the success of earth-abundant silicon to ultra-thin, flexible, semi-transparent, airborne, and off-planet PV devices, which can be produced with kerfless bottom-up technologies at significantly reduced capex and accompanying CO2 emissions while maintaining high power conversion efficiencies – A type of device that could literally pave all roads, roofs, walls, windows, and spacecraft by 2050!

Low Energy Ionizing Radiation and Plasma Contributions to Radiation Dose in Materials at Sun-Earth Lagrange Points Joseph I. Minow; NASA, United States

The relatively low energy (few MeV or less) component of the charged particle environments beyond the Earth's radiation belts represents a radiation source with potential impacts to materials used on the exterior surfaces of spacecraft for missions to the Sun—Earth Lagrange points. Sun-Earth L1 and L2 are of particular interest to mission designers since L1 provides opportunities for monitoring the Sun and incoming plasma and radiation events upstream of the Earth's magnetosphere and L2 is a low temperature thermal environment far from Earth and the Moon useful for astrophysics missions. The low energy radiation and plasma environments are generally considered relatively benign to materials with little or no threat to spacecraft operations even though the total ionizing dose generated by electrons, protons, and alpha particles to exterior surfaces and volumes of thin materials over a mission life can be in the megarad to gigarad range. Radiation damage of materials by the low energy charged particle environments may be a concern for current and future spacecraft designs using very thin materials or bulk materials where the surface properties are mission critical. Some examples where radiation dose from low energy particles should be evaluated include radiation degradation of solar sail propulsion systems, changes in thermo-optical properties of thermal control coatings, radiation damage to thin sunshield materials, and modification of surface charging properties for materials used on the exterior surfaces of spacecraft with requirements to be electrostatically clean. This presentation will first discuss the characteristics of ionizing radiation and plasma environments relevant to thin materials including solar wind and low energy contributions from solar particle events at Sun-Earth L1, L3, L4, and L5 and the additional contributions of magnetosheath and magnetotail plasmas at Sun-Earth L2. Next, low energy charged particle damage mechanisms for materials will be summarized including total ionizing dose, hydrogen blistering, changes in thermo-optical properties, and sputter erosion yields. Finally, examples of modeling techniques used to compute the charged particle fluence to material surfaces and volumes of thin materials will be described along with methodologies for estimating total ionizing dose as a function of depth for materials in the low energy environment.

10:30 AM SF02.04.06
Defect Pathways for Disordering of Oxide Electronics in High-Radiation Environments Bethany Matthews[1], Kayla H. Yano[1], Sarah Akers[1], Michel Sassi[1], Sandra Taylor[1], Le Wang[1], Rajendra Paudel[2], Ryan Comes[2], Yingge Du[1], Eric Lang[3,4], Khalid Hattar[4,5] and Steven R. Spurgeon[1,6]; [1]Pacific Northwest National Laboratory, United States; [2]Auburn University, United States; [3]University of New Mexico, United States; [4]Sandia National Laboratories, United States; [5]The University of Tennessee, Knoxville, United States; [6]University of Washington, United States

Due to lack of protection from the earth's magnetic field and atmosphere, space materials often experience high levels of irradiation from the sun's rays, cosmic rays, and solar winds. Because material properties are heavily tied to their microstructure, crystal structure, and atomic bonding, it is important to understand how materials progress in disorder and damage under irradiation and how defects and compositional changes may affect that progression. Oxide thin films make up crucial portions in many electronic components, therefore understanding disorder progression in them is of particular interest.

To begin to understand changes in a material, it is helpful to examine one that has been thoroughly studied, understanding viable defects, bonding, phase diagrams, etc. To that end, we chose to examine thin films of LaFeO3 (LFO) grown on SrTiO3 (001) (STO) substrates, both well-known perovskites. Films were grown by molecular beam epitaxy (MBE), known to allow for precise, and controlled film growth, to obtain the highest quality growth. To examine the effects of introducing defects and variation in microstructure, LFO films were grown by pulsed laser deposition (PLD) on STO. To probe effects of composition, alloyed films of $La_{1-x}Sr_x$FeO3 (LSFO) grown on STO (x = 0.25 and 0.5) were also grown by PLD. Prior to irradiation, cross-sections of the film were extracted by standard focused ion beam (FIB) preparatory procedures and examined by scanning transmission electron microscopy (STEM) imaging and STEM energy dispersive x-ray spectroscopy (EDS) to verify film quality.

To simulate the intensity of high energy particles in space and to induce different stages of disorder, films were irradiated *ex situ* at room temperature by Au^{2+} ions at 2.8 MeV at Sandia National Laboratories' Ion Beam Laboratory. A metal mask was used to selectively irradiate portions of the film to doses of 0.1 and 0.5 displacements per atom (dpa) (3.74E13 ions/cm^2 and 1.87E14 ions/cm^2 respectively). Post-irradiation, lamellae were extra by FIB and inspected by STEM imaging and STEM-EDS, then they were compared to pre-irradiation films.

Pre-irradiation, the LFO film grown by MBE and LSFO films were found to be uniform and smooth with a sharp interface at the substrate. The LFO film grown by PLD had small vertical domains that appeared Fe-poor in addition to occasional crystal defects. We found at 0.1 dpa, there was little difference in microstructure between the high-quality LFO film grown by MBE and the LSFO films. Films appeared less uniform near the surface of the film with some regions having fully amorphized; however, the LFO film with vertical defect domains was most amorphized in the top 2/3 of the film with small crystal domains embedded in the amorphous material, some of which had rotated. The regions that had amorphized most were similar in size to the Fe-poor domains in the unirradiated film, suggesting that the defective regions had broken apart first. After 0.5 dpa, the LFO film with vertical defect domains was fully amorphized, and the x=0.25 LSFO was nearly fully amorphous with only small portions at the substrate interface still crystalline. However, the MBE LFO was only roughly 2/3 amorphized, whereas the x=0.5 LSFO film was surprisingly not even ½ amorphized. This indicates that while composition can have a strong effect, compositional microstructural uniformity is more important for material robustness under ion irradiation.

Anisotropic Radiation Shielding and Thermal Properties of 2D Boron Nitride Nanoplatelet Foam via Freeze-Drying Kazue Orikasa[1], Cheol Park[2], Sang-Hyon Chu[2,3], Calista Lum[4], Tony Thomas[1] and Arvind Agarwal[1]; [1]Florida International Universtiy, United States; [2]NASA Langley Research Center, United States; [3]National Institute of Aerospace, United States; [4]University of California Merced, United States

Neutron radiation exposure and extreme thermal cycling are some of the main challenges faced during various aerospace missions. There is a critical need for advanced lightweight radiation shielding and thermally conductive materials. Polymer composites are commonly used in aerospace technology due to their low density, hydrogen richness, and ease of processing. However, polymers have limitations such as poor thermal conductivity, poor mechanical properties, and low neutron shielding properties. Two-dimensional (2D) Boron Nitride Nanoplatelets (BNNP) are excellent candidates for polymer matrix fillers due to their superior thermal neutron shielding and thermal properties. The 2D material anisotropic behavior unlocks the potential for composite property tailoring. However, the nanomaterial dispersion within polymer matrices is challenging due to their agglomeration tendency. In this study, a highly dispersed and lightweight BNNP foam (density 0.05 g/cm^3 and porosity 97.5%) was fabricated via Freeze-Drying processing. Freeze-Drying overcomes nanomaterial agglomeration challenges and enables the foam microstructure design through the control of the thermodynamic processing parameters such as mold geometry, mold material, and solid loading. The foam microstructure was designed to be lamellar, enhancing the anisotropic behavior of 2D BNNP. Subsequently, neutron radiation shielding and thermal conductivity tests were performed on the foams with different wall orientations with respect to the probing directions. The neutron radiation test results revealed excellent radiation shielding properties with an orientation-dependent shielding behavior. The neutron shielding effectiveness or mass absorption coefficient of the BNNP foams with walls perpendicular to the radiation source was significantly higher than those with a parallel configuration. Similarly, Flash Diffusivity studies revealed that the thermal conductivity of the foam with walls parallel to the heat source was much greater than those with a perpendicular configuration. The BNNP foam in this study has the potential to benefit advanced tailorable radiation shielding and thermal management for future aerospace missions.

SESSION SF02.05: Atomic Oxygen Exposure
Session Chairs: Eitan Grossman and Sharon Miller
Wednesday Afternoon, April 12, 2023

1:30 PM *SF02.05.01

Real-Time Atomic Oxygen Measurements—From Lab to Space Irina Gouzman[1], Ronen Verker[1], Asaf Bolker[1], Moshe o. Tordjman[2], Nurit Atar[1], Eitan Grossman[1], Brian Riggs[3] and Timothy K. Minton[3]; [1]Soreq NRC, Israel; [2]Technion–Israel Institute of Technology, Israel; [3]University of Colorado Boulder, United States

The atomic oxygen (AO) presence in a low Earth orbit (LEO) environment is one of the primary factors responsible for the degradation of spacecraft external surface due to its ability to cause severe oxidation and surface erosion. As a result, thermal, mechanical, and optical properties of AO-exposed materials, especially polymers, are vulnerable. Therefore, information concerning the flux of AO is very important for spacecraft design and mission lifetime assessment. Moreover, AO monitoring can be used to detect real-time changes in solar activity, thus providing data of great importance to "space weather" forecasts.

Many spectrometric, optical, gravimetric, and semiconductor-based methods to measure AO flux have been developed over decades of space research. Advantages, as well as shortcomings of some of the most useful methods, will be reviewed. Furthermore, two new, elegant, and cost-effective methods for AO monitoring in space, developed in our laboratory, will be discussed.

The first method is based on material erosion measurements using the on-orbit material degradation detector (ORMADD). The ORMADD is comprised of solar cells coated with a semi-transparent AO-sensitive layer. Recently an ORMADD, coated with amorphous carbon and Kapton, was integrated on the TAUSAT-1 nanosatellite. TAUSAT-1 mission was to study the low Earth orbit space environment and its effect on electronic components and materials. It was ejected from the international space station into its orbit in March 2021. Using ORMADD we were able to follow the erosion of the coatings in real-time and to calculate the AO flux at the TAUSAT-1 orbit. The flux calculated using ORMADD data was on-par when compared to the AO flux calculated using the SPENVIS software.

The second method is based on the unique electrical properties of diamond substrate overcoated with a thin transition-metal oxide (TMO) layer. This device, abbreviated as DTMO sensor, was implemented using type IIa (001) single crystal diamond and atomic layer deposited (ALD) tungsten oxide (WO_3). The TMO serves as an electron acceptor, promoting hole conductivity on the diamond surface through a process of transfer doping. When exposed to AO, the TMO goes through a redox process, thereby changing its band structure and reducing the hole concentration in the diamond surface. This process results in an increase in the diamond surface resistivity that can be monitored in real-time. The results of AO flux and fluence measurements with the DTMO, obtained during ground-based exposure using 5 eV AO laser detonation source, are very promising. The change in the diamond resistance, while exposed, was measured *in-situ* and compared to the LEO equivalent AO fluence, calculated based on polyimide mass loss as a standard. The results showed a linear increase in the diamond resistance as a function of fluence up to 2×10^{20} O-atoms/cm^2 without reaching saturation. The sensitivity of the DTMO sensor with 10 nm WO_3 coating was ~6×10^{14} O-atoms/cm^2 Ω. Our work demonstrated the potential of the DTMO sensor to enable fast and reliable real-time on-orbit AO flux monitoring.

2:00 PM *SF02.05.02
Real-time Observation of Polyimide Erosion in Very Low Earth Orbit (VLEO) and Its Impact on Space Environmental Effect on Materials Masahito Tagawa[1], Kumiko Yokota[1], Atsushi Fujita[1], Wataru Ide[1], Towa Ushijima[1], Koki Yao[1], Sasuga Horimoto[1], Santa Nishioka[1], Kaichi Nakayama[1], Yuta Tsuchiya[2], Aki Goto[2], Kazuki Yukumatsu[2], Eiji Miyazaki[2] and Yugo Kimoto[2]; [1]Kobe Univ, Japan; [2]JAXA, Japan

Superlow altitude test satellite (SLATS) was launched on Dec. 23, 2017 and recorded the lowest altitude for Earth observing satellite (167.4 km, Guinness World Record). SLATS carried the world first material erosion mission, atomic oxygen fluence sensor (AOFS), to measure polyimide erosion in real time in very low Earth orbit (VLEO) environment. This presentation describes the results of AOFS. It includes the correction method of shielding/shadowing effect by the SLATS fuselage, and enhancement of polyimide erosion by the simultaneous N2 collision in VLEO environment. The erosion yield (Ey) of polyimide, which has been believed to be 3.0E-24 cm3/atom in all altitudes as a reference value of material erosion, will also be re-evaluated based on the recently updated atmospheric model (MSIS2.0) and experimental results by SLATS/AOFS.

2:30 PM SF02.05.03
Atomic-Oxygen-Induced Microstructures Formed on Hydrocarbon Polymer Films Aki Goto[1,2], Takashi Tanji[2], Masahito Tagawa[3], Koji Michishio[4], Toshitaka Oka[5] and Shinichi Yamashita[2]; [1]Japan Aerospace Exploration Agency, Japan; [2]The University of Tokyo, Japan; [3]Kobe University, Japan; [4]National Institute of Advanced Industrial Science and Technology, Japan; [5]Japan Atomic Energy Agency, Japan

Atomic oxygen (AO) is a dominant constituent of the residual atmosphere in low Earth orbit (LEO). Spacecraft collides with AO at the relative velocity of 8 km/s, which corresponds to the translational energy of 5 eV. Polymers used for thermal control are oxidized and eroded by such AO collisions, degrading their mechanical and thermo-optical properties. In the erosion processes, AO forms nanoscale protrusions on the polymer surface. If the surface morphologies and physical properties (e.g., wettability and optical property) can be controlled by AO irradiation, it would be useful in modifying the surfaces for various polymers.
This study aims to clarify the factors that determine the characteristics of AO-induced microstructures (protrusions' size and numerical density). Hydrocarbon polymers with a simple chemical structure were selected for the samples: polyethylene (PE), polypropylene (PP), and polystyrene (PS). The polymer films (23–30 μm in thick) were irradiated with AO by a laser-detonation source at Kobe University (5–7 km/s). The mass losses were measured by an electronic microbalance. The changes in chemical bonds were evaluated by Fourier transform infrared spectroscopy (FT-IR). The surface morphologies were observed by a field emission scanning electron microscope (FE-SEM) and an atomic force microscope (AFM). The changes in depth profiles for the chemical structures and free-volume holes' sizes were evaluated by positron annihilation lifetime spectroscopy (PALS) at AIST (1.3–10 keV).
The three polymers had similar changes in masses (or erosion yields) and chemical bonds but different surface morphologies. The protrusions formed on PE and PP were larger and fewer than those formed on PS, which was irradiated with comparable AO fluences [Goto, A., et al. Langmuir 2022, 38, 3339-3349.]. The polymers are known to have different higher-order structures, so it might affect the spatial scales where interactions occur with AO, leading to the different morphologies. Further, the formed protrusions became larger and fewer with rising temperature of the polymer irradiated with AO (25–75 °C, controlled by the sample holder with a heater). The PALS evaluations indicated that the polymers have different radii in free-volume holes (PS (0.29 nm) < PP (0.31 nm) < PE (0.32 nm)) and different thicknesses of an oxidized layer formed by AO (PS < PE ≈ PP). Based on these results, the regions where AO interacts with the polymer would depend on the thermal motions of polymer chains and/or sizes in free-volume holes.

2:45 PM BREAK

3:15 PM *SF02.05.04
Low-Drag, Atomic-Oxygen Resistant Materials for Satellites in Very Low Earth Orbit Timothy K. Minton[1], Chenbiao Xu[1] and Thomas E. Schwartzentruber[2]; [1]University of Colorado, United States; [2]University of Minnesota, United States

The environment encountered by satellites in very low Earth orbit (VLEO, 180 – 350 km altitude) contains mostly atomic oxygen (AO) and molecular nitrogen (N_2), which collide with ram surfaces at relative velocities of ~7.5 km s^{-1}. Structural, thermal-control, and coating materials containing organic polymers are particularly susceptible to AO attack at these high velocities, resulting in erosion, roughening, and degradation of function. Copolymerization or blending of a polymer with polyhedral oligomeric silsesquioxane (POSS) yields a material that can resist AO attack through the formation of a passivating silicon-oxide layer. Still, these hybrid organic/inorganic polymers become rough through AO reactions as the passivating layer is forming. Surface roughness may enhance satellite drag because it promotes energy transfer and scattering angle randomization during gas-surface collisions. As potential low-drag and AO-resistant materials, we have investigated POSS-containing films of clear and Kapton-like polyimides that have an atomically smooth AO-resistant coating of Al_2O_3 that is grown by atomic layer deposition (ALD). Coated and uncoated films were exposed to hyperthermal molecular beams containing atomic and molecular oxygen to investigate their AO resistance, and molecular beam-surface scattering studies were conducted to characterize the gas-surface scattering dynamics on pristine and AO-exposed surfaces to inform drag predictions. The AO erosion yield of Al_2O_3 ALD-coated films is essentially zero. Direct simulation Monte Carlo (DSMC) simulatios of drag on a representative satellite structure, which are based on the observed scattering dynamics, suggest that the use of the Al_2O_3 ALD-coated POSS-polyimides on external satellite surfaces have the potential to reduce drag to less than half that predicted for diffuse scattering surfaces. These smooth and AO-resistant polymer films thus show promise for use in the extreme oxidizing and high-drag environment in VLEO.

3:45 PM SF02.05.05
Evaluation of the Effect of Space Debris Impact on Atomic Oxygen Protectant Materials for MLI Yuko Kubo[1], Yugo Kimoto[1], Kaori Umeda[2] and Sunao Hasegawa[1]; [1]Japan Aerospace Exploration Agency, Japan; [2]Advanced Engineering Services Co., Ltd., Japan

Multi-layer insulation (MLI) generally covers the surfaces of spacecraft, and it contributes to thermal control of that. Because of the excellent heat and radiation resistance, polyimide is often used as the outermost layer of MLI. But polyimide is known to be eroded by atomic oxygen (AO) in low earth orbit. Coating a polyimide with an inorganic layer is one way to improve AO tolerance of MLI, and this method is widely used. However, inorganic layers sometimes tend to contain manufacturing defects and they also tend to be fragile, and AO erosion occurs from these areas. To solve the issue mentioned above, we have been developing AO protectant materials, polyimide itself, and coating agent for MLI with keywords of self-organization and self-healing. Self-organization is the property which generates AO-resistant layer on the surface by the material itself with AO irradiation. In addition, if the AO-resistant layer is damaged, the material re-generates AO-resistant layer by itself with AO irradiation again. We call this property as self-healing. Our materials have been studied in orbital exposure experiments and self-organization property of our materials have been demonstrated. In addition, we

demonstrated that our materials have self-healing property in ground test.
However, we haven't known that whether our materials maintain self-organization and self-healing properties after collision with space debris. It is known that collision with debris occurs high heat, high strain rate etc. and some materials break in different destruction mode compared with that on the ground. Therefore, it is necessary to evaluate whether our materials have the same self-organization and self-healing properties after collision with debris and we conducted a series of the ground test. In this presentation, we will report our plans and experimental results obtained to date.

4:00 PM SF02.05.06
Approaches to Technological Challenges of the Space Elevator Yasuhiro Fuchita[1], Yoji Ishikawa[1], Takashi Hitomi[1], Yoku Inoue[2] and Naoko Baba[3]; [1]Obayashi Corporation, Japan; [2]Shizuoka University, Japan; [3]Japan Manned Space Systems Corporation, Japan

The space elevator is a future space transportation system that connects Earth and space by a cable and climber (vehicle) back and forth. When completed, the system will have the following advantages: "the cost of going to space will be greatly reduced," "space travel will be less physically demanding," "it will serve as a starting point for other celestial bodies," and "solar power generation will be possible without loss." However, the elevator's mass was too large, and the materials were not strong enough to make it feasible as a structure.
Carbon nanotubes (CNTs), discovered in 1991, are composed of carbon atoms and are lightweight (specific gravity is about half that of aluminum), and have high mechanical strength (tensile strength is about 20 times that of steel). CNTs as a material for cables have increased the feasibility of space elevators. However, to make it viable as a transportation system, it is necessary to manage the same processes as on the ground, such as design, construction, and maintenance, and to deal with the special movement mechanism that moves vertically through the Earth's gravity zone and exposure to the unique space environment.
This paper reports on the current status of efforts to test space elevator cable materials for exposure to the space environment. The space environment resistance of twisted CNT yarns, which are assumed to be the cable material for space elevators, was investigated using the Exposed Facility of the Japanese Experiment Module "Kibo" on the International Space Station (ISS) at an altitude of about 400 km. At altitudes between 200 km and 600 km, atomic oxygen (AO) is a major component of the atmosphere, accounting for more than 80% of the atmospheric composition at an altitude of 400 km, where the ISS orbits.
The 1-year exposure test specimens were placed at the rear and front of the ISS, and the 2-year exposure test specimens were placed at the rear of the ISS. For the ground control tests, the first test was conducted from November 12, 2014, to March 2, 2015, and the second from June 8 to 30, 2016, at the JAXA-owned vacuum complex environment test facility. The test conditions were full-period irradiation, with the irradiation dose corresponding to approximately six months of space environment exposure. Strength tests were not conducted on thin-stranded CNTs due to their serious damage. For thick-stranded CNTs, the tensile strength was measured to be lower on the front than on the back. The results of the ground control test were reproducible. The tensile strength of the flown product was lower than the pre-flight product. For the specimen of the flown product, the portion covered by the cover for fixing the specimen and the portion exposed to the space environment were compared. The diameter of the exposed part was smaller than that of the part covered by the cover. It was also found that CNTs were gouged from the surface to a depth of several CNTs in the exposed area.

SESSION SF02.06: Space Material Ground Testing and Modeling
Session Chairs: Timothy Minton and Stéphanie Remaury

8:30 AM *SF02.06.01
Combined Radiation and Environmental Effects Testing for ESA's Space Projects Adrian T. Tighe and Nuno Dias; European Space Agency, Netherlands

The Environmental Testing Team in ESA's Materials Physics and Chemistry Section is tasked with supporting ESA's space projects to verify the performance of exposed items in simulated space environments. For this purpose, the group's experimental capabilities include a wide range of radiation and environmental test facilities and associated measurement techniques, ready to adapt for new missions. Combined testing is performed to assess the impact of different environmental factors, using both simultaneous and sequential irradiation. Flight experiments are also undertaken when the opportunities are available to compare the performance of items exposed to the ground and space environment.

This paper will present results of radiation and environmental effects testing recently performed in our laboratories for various space projects and early phase technology development studies. This includes UV exposure of white ceramic coatings for the Earth Return Orbiter, high intensity solar illumination testing of optical coatings, combined radiation and atomic oxygen testing of thermal control paints and combined UV and particle radiation testing of deposited contamination layers on optical coatings.

An update will be provided on an activity being performed with ESA's industrial partners to test optical coating samples in a simulated space radiation environment. The testing will be complemented by numerical modelling and simulations, in order to establish a set of practical lessons learnt and best practices for radiation testing. In the future, this shall be used to support the development of a new European test standard on radiation testing of optical coatings for space applications.

The paper will also describe some of the new facilities and testing techniques under development within our team for future missions. This includes a multipurpose radiation simulation facility for combined environmental testing of cube-sat class items and small payloads, and a combined dust contamination and radiation effects simulation facility for lunar surface studies. To conclude, a new "open lab" campaign on Radiation and Environmental Effects Testing will be described. This campaign is being planned to provide opportunities for academia and small enterprises to make use of the environmental test facilities within ESA, in support of early phase developments for future space projects. A short update will also be provided on the on-going preparations for the EuroMaterialAgeing flight experiment, which will be expose materials to combined radiation environments in the real space environment.

9:30 AM SF02.06.02
Payload Carrying Capabilities of Ultralight Lightsail Spacecraft Michael Kelzenberg, Ramon Gao and Harry A. Atwater; California Institue of Technology, United States

Lightsails harvest the radiation pressure of incident light for the propulsion of spacecraft, eliminating the need to carry and expel reaction mass, and in principle allowing acceleration to relativistic velocities.[1] Recent efforts have sought to develop technologies for ultra-lightweight lightsail space probes that could be launched using an earth-based high-power-intensity laser, allowing execution of interstellar flyby missions on a time scale of a few decades.[2] This mission concept calls for a spacecraft comprising a ~1 g, ~10 m^2 lightsail, carrying a payload of similar mass, including all sensors, communications systems, and power sources.[3] Prior work has identified materials and technologies suitable for construction of lightsails and payload components within these extremely limited mass budgets.[4] However, the question remains as to whether such large-area ultrathin lightsail membranes could support the attachment of payloads without tearing or destabilizing during acceleration, owing to the changes in mass distribution and the concentration of inertial forces at the points of attachment.

Here, we study the effects of various payload integration schemes on the behavior of interstellar lightsail spacecraft during acceleration, to determine the limits on payload mass and distribution imposed by the strength and stability of the lightsail. Specifically, we look at lightsails made from silicon nitride (SiN_x), with either specific shape curvature or flat photonic metagrating patterned surfaces, which have been previously shown to achieve beam-riding stability in the absence of an attached payload.[5] We start with static structural analysis to determine the limits on localized mass loading for the membranes, concluding that for the nominal acceleration target of ~10^5 m/s^2, the membranes can support center-mass payloads on the order of 100 g. However, we show that localized reinforcement of the membrane, by increasing its thickness, can increase this limit several-fold with modest mass penalty to the sail. Furthermore, distributing the payload mass between multiple components spaced across the sail can further reduce the peak stress.

Then, a time-domain mesh-based simulation tool, specifically developed for lightsail modelling, is employed to study the behavior of unconstrained flexible membranes with integrated payload mass(es) during acceleration. This allows us to evaluate not only the mechanical integrity of the lightsail by observing the dynamic stress distribution, but also the effects of payload integration on the trajectory and ultimately the beam-riding stability of the integrated sailcraft. We have observed that modest (~100 g) center-located payloads can be carried by the previously reported self-stabilizing lightsail designs, with little reduction in stability or strength margins, and are working to further optimize designs to determine the limiting payload mass that can be carried in center-located and distributed-mass configurations. Results of the simulations will be presented, including acceleration trajectories, stress and temperature distributions, and animations of shape perturbations.

Demisability and Structural Performance Assessment of Novel Composite Systems for Spacecraft External Panel Assembly Alexandre A. Looten[1], Véronique Michaud[1], Muriel Richard[1] and Antonio Caiazzo[2]; [1]EPFL, Switzerland; [2]European Space Agency, Netherlands

With the recent awareness of the space sector on the fragile near-Earth space region and the forecast of the booming number of satellited objects, various mitigation approaches are currently being evaluated and starting to be implemented to limit the impact of space activities, and achieve a safe and sustainable space environment. Unfortunately, knowledge uncertainties and technology gaps delay our capability to act immediately, especially to apply a design-for-demise (D4D) approach, which aims to modify a spacecraft design and conception process to achieve the safest destructive reentry possible by material substitution, specific geometries, or dedicated subsystems.
As part of a Network Partnering Initiative launched by the Swiss Federal Institute of Technology in Lausanne (EPFL) and the European Space Agency (ESA), this work focuses on the design and experimental evaluations of novel composite components to improve the overall spacecraft demisability. The new system is compared to baseline critical systems, targeting higher altitude break-up while maintaining equivalent mission-relevant properties. The project's main attention landed on a complementary dual strategy with the material substitution of a benchmark system composed of an external sandwich panel and its fasteners. First, a hybrid reinforcement made of carbon and demisable flax fibers is evaluated to replace aluminium panel skins or critical full carbon composite skins. The integration of a thermally conductive and reactive metallic matrix filler composed of aluminium-magnesium alloy micro-powder has also been investigated. Second, a novel short carbon fiber reinforced polyetheretherketone (CF/PEEK) bolted joint design is evaluated to replace critical titanium or steel alloys currently used.
The demisability assessment is performed at material and lab scale component levels. This involves the measurement of material's mechanical properties under static loading at room temperature, and dynamic loading over a temperature range to detect their softening point. Static and dynamic reentry simulation tests were carried out using a laboratory-scale high-temperature creep test and a plasma wind tunnel test to evaluate on one-hand, the thermo-mechanico-physical property change over typical uncontrolled reentry conditions, in particular the material break-up point, and on the other hand, the composite degradation. Results to date led to the selection of a promising reinforcement architecture. An optimal ply-by-ply carbon-flax hybrid/epoxy shows the best trade-off in terms of demisability and specific mechanical properties for the skin, with respectively a 180% ablation rate improvement starting at a lower temperature as compared to CFRP, while having an equivalent specific bending modulus to CFRP or 40% higher as compared to aluminium. The addition of the AlMg filler improved the matrix degradation rate by more than 10% while reducing its onset by 40°K. The study of the joints demonstrated that stainless-steel bolts present no sign of effective demise under testing up to 1070°K, whereas the novel CF/PEEK bolts start to demise before reaching 670°K, while having a superior specific tensile, σ/ρ, and shear strength, τ/ρ, within a typical space mission temperature range (120-400°K).
The project's next phases will focus on the demisability sequence of a bolt-insert fastening system on a sandwich panel assembly to improve the technology readiness level of the concept.
This multi-collaborative project aims to reduce current uncertainties regarding composite materials' demise and implement these technologies on a typical spacecraft platform to move a step forward toward casualty risk mitigation.

SESSION SF02.07: Lunar and Martian Regolith and Environments
Session Chairs: Sara Rengifo and Debbie Senesky
Thursday Afternoon, April 13, 2023

1:30 PM *SF02.07.01

Lunar Dust and Dust Mitigation Testing Sharon K. Miller; NASA Glenn Research Ctr, United States

Lunar dust was one of the most persistent problems for the Apollo astronauts due to its' abrasiveness and strong adherence to surfaces. With the Artemis program, NASA is planning longer stays on the lunar surface, with more activities that have the potential to put the astronauts and equipment in contact with greater quantities of lunar dust. The success of these missions will depend on our understanding of material interactions with lunar dust and the development of ways to mitigate dust effects. This is particularly true in cases where exposure to dust will lead to failure of components, unacceptable loss of power or thermal control, unacceptable loss of visibility, or health issues. Lunar dust, issues with lunar dust, and ground testing with lunar simulant will be discussed as well as the development of and planned flight testing of optically transparent work function matching coatings to reduce adhesion of dust on the lunar surface.

2:00 PM *SF02.07.02
Evaluation of Lunar Dust Mitigation Technologies on the Moon and in Ground Simulators Jacob I. Kleiman and Zelina Iskanderova; Integrity Testing Laboratory Inc, Canada

The interaction of lunar dust and other environmental factors, like vacuum, temperatures, solar radiation, ultraviolet irradiation, and electron (e-) and proton (p+) irradiation with structures on the Moon and the outside of the future Gateway Lunar station may lead to permanent change or complete loss of the thermal, optical, and other functionalities that could potentially lead to catastrophic failures. Among the other factors, lunar regolith dust is the most aggressive, causing the main problems.
To evaluate the efficiency of passive dust mitigation techniques, a materials experiment that was funded by NASA and developed and built by Alpha Space Test and Research Alliance, named Regolith Adherence Characterization (RAC) Payload, will be launched to the Moon in 2023-2024 timeframe. The goals of the RAC Payload mission are to evaluate several materials and coatings with dust mitigation properties for their ability to repel or shed lunar regolith/dust, (e. g. solar cells, optical systems, coatings, sensors) and to determine regolith accumulation rates: 1) caused by landing, and 2) during routine lander operations.
ITL is taking part in this experiment with four samples. Through a series of experiments in the ITL-developed Lunar Simulator, ITL demonstrated that it is possible to mitigate accumulation of lunar dust simulant, and enhance surface durability of some important sensitive external structural materials using a special ITL dust mitigation technology.
To complement the information from the RAC samples on the Moon, ITL recently initiated a program to evaluate, further develop, and enhance its unique cornerstone lunar Dust Mitigation Technology (DMT) for sensitive materials on external space structures that ITL used for the RAC samples. In the framework of this program, ITL is preparing a set of DMT-treated samples as well as samples closely resembling the ones on the RAC Payload cassette. To understand the results of the RAC lunar exposure experiment, we will conduct an extensive set of experiments on interaction of lunar dust simulants with sample surfaces, similar to the RAC Payload experiments on the Moon, in our Lunar Environment Simulator that will be upgraded for this project.

2:30 PM BREAK

3:30 PM SF02.07.03
Additive Manufacturing of Regolith Composites Through UV-Assisted Direct-Ink-write in Simulated Space Environments Alexandra Marnot, Lena Konzelman and Blair K. Brettmann; Georgia Institute of Technology, United States

Direct-ink-write (DIW) of Lunar and Martian regolith simulants is of particular interest to promote in-situ resource utilization (ISRU) in the upcoming Artemis missions. The span of formulation design parameters for DIW of high solid suspensions of regolith is wide and offers a lot of freedom for additive manufacturing in space environments. Regolith simulants, incorporated in a polymeric binder and used in conjunction with UV-curing solidification after extrusion, enable reduced energy demands for construction of parts, but require precise formulation characterization to successfully cure these dense inks. In this work we investigate several regolith simulants, including LHS-1, LMS-1, and MGS-1, in acrylate-based binders. We utilize photo-DSC in conjunction with the ISO 4049 method to assess cure degree and cure depth respectively, while rheological assessments give us insights into the flowability of these inks. The results from these preliminary tests allow us to produce dense and opaque suspensions which can be printed both at ambient and in a simulated space environment at -30°C. The adhesion at the regolith-binder interface is evaluated through tensile testing on as-printed parts and parts subjected to thermal cycling imitating the typical Lunar or Martian weather conditions. These efforts aim to help guide the future of additive manufacturing through formulation design for both processing and end-use on the Moon and Mars.

3:45 PM SF02.07.04
***In Situ* 3D Lunar Manufacturing Using Digital Light Processing** Brandon A. Aguiar, Ambreen Nisar, Tony Thomas, Cheng Zhang and Arvind Agarwal; Florida International University, United States

As the thirst for space exploration has creeped back into the public zeitgeist, the aerospace industry is gearing up to become residents of our closest celestial neighbor. A lunar expedition to the south pole offers a multitude of challenges. The logistics and cost of getting resources from Earth to the moon clearly enables the need for predominantly in-situ part and structure additive manufacturing (AM) using locally available materials. In this regard, Greenland Anorthosite lunar regolith was three-dimensionally (3D) printed using Digital Light Processing (DLP). Complex and intricate geometries with high dimensional accuracy were printed and sintered with no signs of delamination. The solid loading of Greenland regolith was 60 wt% with a shrinkage post sintering of less than 6% in all three directions. The mechanical integrity and thermal stability of the printed part has also been studied. The compressive failure of the sintered sample was validated using Finite Element Analysis (FEA). This research is a step towards validating the use of lunar regolith for part and colonist habitat manufacturing.

4:00 PM SF02.07.05
Tribological and Radiation Shielding Response of Novel Titanium-Boron Nitride Coatings for Lunar Structural Components Abhijith K. Sukumaran[1], Cheng Zhang[1], Sara Rengifo[2], Sang-Hyon Chu[3], Cheol Park[4], Michael Renfro[5], Calista Lum[6], Katie Stephens[7] and Arvind Agarwal[1]; [1]Florida International University, United States; [2]NASA Marshall Space Flight Centre, United States; [3]National Institute of Aerospace, United States; [4]Advanced Materials and Processing Branch, NASA Langley Research Center, Hampton, VA, United States; [5]Plasma Process, United States; [6]University of California, Irvine, United States; [7]University of California Merced, United States

Lightweight alloys of Aluminum (Al) and Titanium (Ti) are significant components of space systems because of their high strength-to-weight ratio. However, their poor tribological response in the presence of lunar regolith and lack of space radiation shielding ability can result in premature failures. Hexagonal Boron Nitride (hBN) reinforced titanium coatings were produced by atmospheric and vacuum plasma spray methods at low and high-volume concentrations of hBN to counter these undesirable results after powder preparation by cryo-milling. The microhardness results showed that coating hardness was 3.0 times that of conventional Ti6Al4V (335 HV) substrate in the case of low vol.% hBN (900 HV) concentration and 1.5 times in the case of high vol.% hBN coating (516 HV). Furthermore, tribological characterization by ball-on-disk tests in the presence of JSC-1A lunar regolith simulant revealed a 70% reduction of wear volume on the Ti/low vol.% hBN coatings compared to conventional material. The science of boron nitride retention and secondary phase effect in the coatings were examined using characterization techniques such as SEM, XRD, and Raman spectroscopy. Developed coatings were subjected to the simulated extreme lunar condition of neutron radiation. The coatings exhibited effective radiation shielding ability up to 31.8 % with an increase in % hBN content. Computational studies indicate that the presence of boron-based inclusions can effectively suppress generation of undesirable secondary radiations through the metal alloys against galactic cosmic rays (GCR) and solar particle events (SPE) as well. The coatings will be subjected to harsh erosive conditions on a custom-made high-velocity dust impact setup to evaluate erosion performance.

4:15 PM SF02.07.06
Investigating the Adhesion Force of Lunar Regolith Particulates on Air Plasma Sprayed Alumina Coatings Perla C. Latorre-Suarez[1], Quentin Fouliard[1], Christopher J. Wohl[2], Valerie Wiesner[2] and Seetha Raghavan[1]; [1]University of Central Florida, United States; [2]NASA Langley Research Center, United States

Ceramic materials, often used to protect components due to their high strength, and wear resistance, have combined benefits of being lightweight and providing multifunctional properties. They are, therefore, significant to provide durability and support during long-duration missions to the moon's surface for rovers, landers, robotic systems, habitats, and many other components. Materials such as aluminum oxide with high mechanical strength and hardness can help to improve the durability of structures used in space exploration. Devices used for space exploration require the use of materials with the ability to withstand exposure to extreme environments. Lunar regolith is a constituent with the ability to adhere electrostatically and damage the components used to perform these missions due to adhesion of lunar dust projectiles that can cause delamination on surfaces, which may not be physically visible. The particulates of lunar dust are classified as corrosive material, leading to the degradation of structures. Aluminum oxide presents excellent resistance to different types of wear due to its high strength and hardness. Air plasma sprayed (APS) aluminum oxide coatings have demonstrated the potential to protect the surface to which they are applied. However, the parameters of roughness and porosity of the coatings need to be considered to establish if they can protect the components from extreme environments. Considering the electrostatic forces that the components are exposed to, the adhesion between the lunar regolith and the surface of the components needs to be investigated. In this work, the adhesion forces of lunar dust simulants with an average size of 30 µm are investigated considering the roughness of the surface of the APS aluminum oxide. The centrifugal technique utilized here offers the advantage of establishing the adhesion force between particles with different shapes on smooth or rough surfaces. The simulants were deposited on the surface of APS aluminum oxide using an aerosolization technique to achieve a monolayer coating in three different locations across the specimen to determine the increments in adhesion force at the centrifuge. Using a profilometer, the roughness of the APS aluminum oxide was determined to be around 2.25 µm. The specimen was tested under an incremental centrifugal speed from 100 rpm to 3000 rpm for 20 seconds. Low magnification microscopy images were collected to cover a larger surface area of the tested coating. The adhesion force was measured considering the distance from the centrifugal axis and the rotational speed. Due to the coating roughness, and the distance from the centrifugal axis, the results demonstrated a larger adhesion force in locations closer to the centrifugal axis. Smaller particles were entrapped within the roughness of the coating, and a stronger adhesion force was measured. In order to continue designing wear-resistant coating for structural protection in space missions, press-on experiments using a centrifuge will be performed. Future experiments will allow us to determine the design parameters for APS aluminum oxide coating to protect the structures from harsh space environments.

Exposure of Polyphenylsulfone and Polyphenylsulfone-Hexagonal Boron Nitride Composite Films in the LEO Wake Environment Tiffany Williams[1], Witold Fuchs[1], Baochau Nguyen[2,1], Kim de Groh[1] and Diana Santiago[1]; [1]NASA John H. Glenn Research Center, United States; [2]Universities Space Research Association, United States

Polyphenylsulfone (PPSU) is a high-performance thermoplastic with one of the highest glass-transition temperatures (T_g) in its class that is currently being evaluated for potential use as an electrical insulation material in high power dense motors in electrified aircraft. Polymeric electrical insulators can experience degradation caused by UV radiation induced by corona discharge, which is exacerbated at altitude, and would further contribute to aging in the polymer. In addition, although PPSU is reported to be resistant to gamma radiation and unstable in UV radiation according to literature, not much information exists related to its exposure in space environments, which are difficult conditions to replicate on Earth. As of now, UV exposure reported for this family of polymers has only been limited to short-term exposure. This study describes a post-flight assessment of PPSU after 0.44 years of exposure to the low Earth orbit (LEO) wake environment. The PPSU sample was flown as part of the Polymers and Composites Experiment-4 (PCE-4) on the Materials International Space Station Experiment-13 (MISSE-13) mission [1]. In addition, a sample of PPSU extruded with 10 wt% hexagonal boron nitride (h-BN) was also flown to determine whether or not any improvement to its resistance to UV radiation occurred when exposed to the wake environment. A post-flight visual inspection of both samples of virgin PPSU and PPSU- 10 wt% hBN showed film discoloration from colorless to amber, which is likely attributed to light absorption in the wavelength of the chromophoric structures from aromaticity in PPSU [2, 3] and is not believed to cause changes to Young's modulus and tensile strength [4]. A series of tests were used to characterize the samples pre-flight and post-flight, such as attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy to identify changes in molecular structure, microscopy to observe changes in morphology, as well as thermogravimetric analysis and differential scanning calorimetry to identify changes in thermal stability and T_g, respectively, which could have occurred due to changes in chain length, branching, or chain rearrangement in the matrix.

10:45 AM SF02.08.02
Chemcial and Physical Characterisation of Aerogel-Phosphor and PDMS-Phospor Composites after Exposure to Low Earth Orbit Conditions Atul Regmi[1,2], Sagar Ghimire[1], Steve Allison[1] and Firouzeh Sabri[1]; [1]University of Memphis, United States; [2]University of Florida, United States

Aerogel-phosphor and PDMS-phosphor composites containing La_2O_2S: Eu and $Mg_3F_2GeO_4$: Mn thermographic phosphors were flown on the MISSE-14 mission and completed 5,408 orbits. Phosphor thermometry is a versatile, accurate, noncontact, and rapid method of thermometry that uses the luminescent properties of phosphors to measure temperature. This precise, remote, and instantaneous method of thermometry covers temperatures ranging from cryogenic to 1700 C and potentially beyond. Thermographic phosphors were embedded superficially in either a polyurea crosslinked silica aerogel host, or a RTV 655 siloxane host. The spectral, mechanical, and luminescing behavior of these composites were thoroughly characterised pre and post flight and results will be presented. The study presented here focuses on evaluating the effect of atomic oxygen and UV radiation on these composites. Post exposure tests ranged from -50 to 250 C for luminescence excited by 365 and 405 nm. It is expected that decay time should be a sensitive indicator of radiation damage. Examination and comparison of results of decay time versus temperature for both exposed and unexposed samples appears to indicate no discernible change for these characteristics within measurement uncertainty. This suggests little or no damage to the thermographic phosphors. The spectral and mechanical tests performed on the composites however indicate radiation damage and will be thoroughly discussed.

11:00 AM SF02.08.04
Effect of Defects on the Mechanical Properties of Boron Nitride Nanotubes (BNNT) Nachiket Makh[1] and Ajit D. Kelkar[2]; [1]North Carolina A&T State University, United States; [2]North Carolina A & T State University, United States

High-energy radiation hazards is the major concerns for flights involving long term durations in space, as exposure to high energy radiation particles can cause serious biological damages and also can result damages to the structural materials and electronic components of the spacecraft. Typical radiation shielding materials are heavy, bulky and not able to block the emission of secondary neutrons. As such considerable efforts are being made to develop efficient, lightweight, cost effective multifunctional radiation shielding materials, which can provide structural integrity and damage tolerance. One of the leading materials that being explored is the use of Boron Nitride Nanotubes (BNNT) in conjunction with fiber reinforced material that can not only provide radiation shielding but also help to improve mechanical strength of the aerospace structures. BNNTs are polymorphs of boron nitride arranged in a hexagonal atomic structure in a tubular form. Their structure is very much like carbon nanotube (CNT) having the carbon atoms replaced by boron and nitrogen atoms. These nanotubes are classified as arm-chair nanotubes and zig-zag nanotubes. The type of nanotube can be defined by the chiral vector of the original hexagonal lattice. The nanotube is chiral if it is represented as (n,m) where $m>0$ and $m\neq n$. Since its discovery in 1995, BNNTs have come a long way, and due to the advancements in their synthesis, their properties have been improved leading them to be used for promising applications. Radiation shielding is one of the important applications of BNNT owing to its good mechanical properties. These properties get compromised if the BNNTs are having defects. Point defects are very common in boron nitride nanotubes. This study presents the effect of defects on the mechanical properties of BNNTs with different chirality using Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) and Visual Molecular Dynamics (VMD) software. The study would help to understand effects of defects in BNNTs when dispersed in polymer matrix composites for radiation shielding applications.

11:15 AM SF02.06.03
Acrylic Adhesive Contamination Testing and Mitigations for James Webb Space Telescope (JWST) and Roman Space Telescope (RST) Elaine Stewart[1], Eve Wooldridge[1], Alan Abeel[1] and Kelly Henderson-Nelson[2]; [1]NASA Goddard Space Flight Center, United States; [2]KBR, United States

Acrylic adhesive has been used as an alternative to silicone adhesives due to molecular contamination concerns causing degradation in infrared and UV wavelength ranges. Tape with Y966 adhesive is used to attach thermal blanketing to structures, wrap electrical cabling, and secure thermocouples and diodes. The James Webb Space Telescope (JWST) operates at Lagrange Point 2 (L2) at temperatures between -223. 15 to -243.15 °C for near and mid-infrared observations. Through initial thermal vacuum (TVAC) testing of ground support equipment at cryogenic temperatures for JWST, acrylic adhesive was found to become brittle, facture, and generate acrylic foreign object debris (FOD) and particles. Since the glass transition temperature is -40°C, missions operating at cold temperatures are at risk of adhesive contamination generated during cryogenic TVAC testing and on-orbit operations. Tests were conducted at Goddard Space Flight Center studying exposed adhesive in vacuum chambers. Black Kapton tape was found to be a more significant particle generator than regular Kapton tape. Mitigation techniques included cleaning and removing exposed or excess adhesive, proper cleaning of surfaces prior to application of tape, burnishing the tape to the surface, and securing it with tie wraps around beams and circular structures. Additionally, inspections and cleanings were conducted to ensure there was no adhesive in or near deployment mechanisms. The Roman Space Telescope (RST) will launch in late 2020 and operate also at L2. RST observes in the visible and infrared wavelengths but not cryogenic temperatures. Testing was conducted for RST at -60°C and no adhesive contamination was identified. Mission wavelengths and temperatures must be carefully considered when choosing acrylic over silicone tape adhesive to reduce the risk of contamination from this material during TVAC testing and on-orbit operations.

8:00 AM SF03.01.01
Thermal Transport Across Dry and Wet Interfaces with Voids Husam Walwil and Yee Kan Koh; National University of Singapore, Singapore

Due to challenges to quantify nanometer-sized voids at the interfaces, the effects of voids to interfacial thermal transport is yet to be experimentally determined. In this talk, we present our recent experimental results of how nano-voids impact the thermal transport across wet and dry transferred interfaces. We first employ a picosecond acoustic technique to experimentally quantify void density at the interfaces. To verify our approach, we transfer Pd films unto a series of holey SiO_2 substrates, and compare the void densities derived from our approach to those derived from scanning electron microscope (SEM); a good agreement is achieved. We then prepare a series of interfaces of Pd films transferred unto Al_2O_3, Si and GaN substrates, by wet and dry transfers. We systematically reduce the void densities of the interfaces, from 90% to 40%, by annealing the samples at different temperatures and durations. We then measure thermal conductance of the interfaces by time-domain thermoreflectance (TDTR). We found that the measured thermal conductance is void-density-weighted average of the thermal conductance of the solid/solid contacts and thermal conductance through the voids. We found that for the wet transferred films, the voids are mostly filled with water and thus relatively large thermal conductance is achieved. Our results provide fundamental understanding on heat transport across imperfect interfaces with voids.

8:15 AM SF03.01.02
Observation of the Chiral Phonon Activated Spin Seebeck Effect Kyunghoon Kim[1], Eric Vetter[1], Liang Yan[2], Cong Yang[1], Ziqi Wang[1], Rui Sun[1], Andrew Comstock[1], Yu Yang[3], Xiao Li[3], Lifa Zhang[3], Jun Zhou[3], Wei You[2], Dali Sun[1] and Jun Liu[1]; [1]North Carolina State University, United States; [2]University of North Carolina at Chapel Hill, United States; [3]Nanjing Normal University, China

Utilization of the interaction between spin and heat currents is the central focus of the field of spin caloritronics. The recent emergence of chiral phonons possessing angular momentum arising from the broken symmetry of the lattice creates the potential for generating spin currents at room temperature in a non-magnetic material in response to a thermal gradient, precluding the need for a ferromagnetic contact. In this talk, we will show the observation of spin currents generated by chiral phonons in a two-dimensional layered hybrid organic-inorganic perovskite implanted with chiral cations when subjected to a thermal gradient. Identified by transient magneto-optical Kerr effect measurements, the generated spin current shows a strong dependence on the chirality of the film and external magnetic fields, of which the coefficient is orders of magnitude larger than that produced by the reported spin Seebeck effect. Our findings indicate the potential of chiral phonons for spin caloritronic applications and offer a new route toward spin generation in the absence of magnetic materials.

8:30 AM SF03.01.03
Oscillating Gadolinium Thermal Diode Using Temperature-Dependent Magnetic Forces Qing Zhu, Kaitlyn Zdrojewski, Lorenzo Castelli and Geoffrey Wehmeyer; Rice University, United States

High-performance thermal diodes would enable improved waste heat scavenging, thermal energy storage, and thermal management systems. Although prior work indicated that the temperature (T)-dependent magnetic response of ferromagnetic materials near the Curie temperature provides a potential mechanism for thermal rectification via thermally-induced mechanical oscillations, this mechanism has not been investigated in a macroscopic thermal device.
Here, we construct a centimeter-scale oscillating gadolinium thermal diode and measure steady-state thermal rectification ratios as large as 23 in air and 16 in vacuum. In the forward mode when the top surface is warmer than 26°C and the bottom surface is colder than 20°C, an unstable balance between gravitational forces and T-dependent magnetic forces causes a shuttle containing gadolinium to oscillate and transfer thermal energy. In the reverse mode, the shuttle does not oscillate and energy is transferred via parasitic conduction and radiation.
Our measurements show that the diode is durable over $>10^3$ oscillation cycles and can be used in thermal circuits to achieve rapid and asymmetric thermal regulation. In addition, thermal circuit modeling shows that the device can achieve half-wave thermal rectification with up to 50% of the ideal-diode performance. Thus, our experiments and models show that oscillating gadolinium thermal diodes can achieve large rectification ratios in a convenient geometry and tempearture range for applications in thermal management and control.

GPU-Accelerated Simulations of Thermal Transport Using Machine Learning Force Fields Anders Johansson, Jennifer Coulter, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Controlling thermal conductivities of materials is important for a wide range of applications, from thermoelectrics for clean energy generation to electronic devices and thermal barrier coatings. The thermal conductivity is commonly estimated using molecular dynamics simulations within the Green-Kubo formulation. This requires a force field that is both 1) an accurate estimate of the interatomic interactions and 2) fast enough to allow simulations with sufficiently large length and time scales. An accurate force field can also be used to accelerate the calculation of force constants for transport simulations via the Boltzmann transport equation.

In this work, we employ the Gaussian Process-based FLARE force field, which automatically learns the interactions of more complex materials than empirical force fields. The resulting model can then be mapped to a low-dimensional, computationally efficient model. Through GPU-acceleration with LAMMPS and the Kokkos library, we achieve excellent performance and obtain well-converged estimates for the thermal conductivity with Green-Kubo molecular dynamics. Our newly developed transport code, Phoebe, computes the thermal conductivity with force constants calculated by FLARE. The data efficiency of FLARE reduces the total number of DFT calculations required, and Phoebe has been highly optimized to solve the Boltzmann transport equation efficiently on GPUs using the Kokkos and cuSOLVER libraries.

9:00 AM SF03.01.05
Probing Coupled Electron-Phonon Transport at 2D Atomic Junctions Using Femtosecond Diffraction Thermometry Aditya Sood; Princeton University, United States

Van der Waals (vdW) layered 2D materials offer unique opportunities to create designer 3D solids with tailormade properties. To predict the emergent behaviors arising from heterostructure formation, it is necessary to understand how different degrees of freedom interact at individual atomic junctions. In particular, what is the role of lattice degrees of freedom (phonons) on electron transfer at vdw interfaces? Or more generally, how does electron-phonon coupling influence thermal transport across a heterojunction? Here, using a combination of femtosecond electron diffraction and ab initio theory, we uncover a new regime of coupled electron-phonon transport at vdW interfaces [1]. Our system of interest is a type-II heterojunction comprising vdW monolayers of WSe_2 and WS_2. Following selective photo-excitation of WSe_2, and using ultrafast electron diffraction as a probe, we measure surprisingly concurrent heating of both WSe_2 and WS_2 on a picosecond timescale. This corresponds to an *apparent* thermal boundary conductance that is >100x larger than that due to phonons alone. Using DFPT, we identify a fast channel, involving an electronic state hybridized across the heterostructure, enabling phonon-assisted interlayer transfer of photoexcited electrons. Phonons are emitted in both layers on femtosecond timescales via this channel, consistent with the simultaneous lattice heating observed experimentally. Taken together, our work indicates strong electron-phonon coupling via layer-hybridized electronic states – a novel route to control thermal transport across interfaces.

9:15 AM SF03.01.06
Liquid Heat Capacity From Instantaneous Normal Modes Ethan Meitz, Gerald J. Wang and Alan McGaughey; Carnegie Mellon University, United States

Liquid heat capacities fall below the Dulong-Petit limit, with a deviation that increases with increasing temperature. Existing nanoscale models for a liquid's heat capacity require fitting parameters and cannot explain how energy is partitioned across the liquid's degrees of freedom. Liquids pose a unique challenge because their molecules are not bound to lattice sites (like in a solid) and do not weakly interact (like in a gas). We hypothesize that deviations from the Dulong-Petit limit in liquids originate from anharmonicity in molecular interactions and present an approach for calculating a liquid's heat capacity that is based on its instantaneous normal modes (INMs) and explicitly includes anharmonicity.

Starting with a single anharmonic oscillator, we calculate its expected potential energy and its heat capacity. The results provide insight into how anharmonicity can either increase or decrease heat capacity compared to the Dulong-Petit limit. We then consider a simple monatomic liquid, whose dynamics can be decomposed into a set of coupled anharmonic oscillators. We propose an approach using INMs that decouples the system of anharmonic oscillators and allows us to treat them as single oscillators. The coefficients of the anharmonic terms in the potential energy for each oscillator can be calculated from atomic trajectories acquired in a molecular dynamics simulation. The contribution to heat capacity from each INM is then calculated independently. The modal contributions are summed to give the total heat capacity, which is compared to the heat capacity calculated from system-level energy fluctuations. This approach can be extended to molecular liquids and applied to predict the properties of novel liquid compositions and accelerate materials discovery.

9:30 AM SF03.01.07
A Cavity Optomechanical Platform for GHz Phonon Amplification via Anderson-Localized Optical Modes Pedro D. García Fernández; Instituto de Ciencia de Materiales de Madrid (ICMM), Consejo Superior de Investigaciones Científicas (CSIC), Spain

We explore [1] Anderson-localized cavity optomechanics in a two-dimensional optomechanical platform: a waveguide etched in a suspended silicon membrane that incorporates a slotted line air defect. Inherent and unavoidable fabrication imperfections are adequate to induce sufficient backscattering to realize Anderson-localization of optical modes. The introduction of an air slot allows for a strong confinement of the electromagnetic field that is guided along the slot, and enhances the ability for light to couple to in-plane mechanical motion. The resulting tightly confined Anderson-localized modes can be driven to enable mechanical amplification and self-sustained phonon lasing via optomechanical back-action. We design the photonic and phononic band structures [2,3] to realize mechanical lasing up to 6.8 GHz that results from confinement of the mechanical mode. We confirm the existence of this mode through a combination of cavity optomechanical techniques and Brillouin light scattering spectroscopy. The role of disorder in cavity optomechanics has thus far been largely overlooked but our results show that disorder plays a crucial role, which in part can have a decisive impact on device functionality and in part opens perspectives for studies of multiple scattering and Anderson localization of bosonic excitations with parametric coupling to mechanical degrees of freedom.

Coupling Between Conduction and Near-Field Radiative Heat Transfer in Tip-Plane Geometry Chams Gharib Ali Barura, Philippe Ben-Abdallah and Riccardo Messina; Laboratoire Charles Fabry, CNRS, France

Two bodies at different temperature separated by a vacuum gap exchange an energy flux mediated by photons. This radiative heat flux is limited at large distance by the well-known Stefan-Boltzmann's law. Nevertheless, the development of fluctuational electrodynamics (thanks to the pioneering works of Rytov, Polder and van Hove) allowed to show that in the near field, i.e. at distances smaller than the thermal wavelength (some microns at ambient temperature), the flux can dramatically increase because of photon tunneling. Although this prediction has been confirmed in many experiments, some of them have observed deviations from theoretical results, both in near field and in extreme near field (nanometer and sub-nanometer range of distances). In this sense, one possibly relevant aspect could be the coupling between exchanged radiative flux and conduction. We have shown that in the configuration of two parallel slabs this coupling can induce a temperature profile in each body (neglected in most previous works) and induce, in turn, a saturation of the exchanged flux. This result was later generalized to the configuration of two nanorods, for which the different spectral behavior and the participation of volume modes of the field increases the exchanged flux and induces a non-linear temperature profile even in the diffusive regime. Finally, we present a recent work in which we addressed the coupling between two concentric cylinders of different radii, allowing us to simulate the configuration of a sharp tip in front of a planar substrate. We obtained analytical expressions for both the temperature profiles and the exchanged flux, showing that also in this scenario the conduction-radiation coupling can induce a significant temperature change in the smaller cylinder (the tip), up to tens of degrees in the case of polar materials, along with a strong reduction of the flux (of more than two orders of magnitude) with respect to the scenario of absence of coupling. Our results show that, with an appropriate choice of the materials and geometrical configuration, the effect of conduction-radiation coupling could be within experimental observability.

SESSION SF03.02: Nanoengineering for Energy and Electronics

Session Chairs: Yongjie Hu and Dimos Poulikakos

Moscone West, Level 3, Room 3009

10:15 AM *SF03.02.01
Leveraging the Physics of Sunlight-Surface Interactions to Architecture Transparent Materials Preventing Fogging Dimos Poulikakos; ETH Zurich, Switzerland

Interfaces separating different kinds of matter, or different phases of the same matter, abandon in nature and technology. What is more, they invariably play a critical role in all systems where they occur, from regulating transport of energy and species, to dictating system shape and form. Interfaces differ in their structure and properties from the bulk matter they surround and can be engineered to effect remarkable outcomes in a broad palette of applications. Here, I will primarily focus on liquid/gas and liquid/solid interfaces and their interaction with sunlight, employed in the rational design of photothermal materials, to control atmospheric water condensation, according to our will (1-3). I will discuss the design and architecture of energy neutral photothermal metasurface coatings, which, when material transparency is required, prohibit condensation and resulting “fogging” of surfaces. These coatings function with selective sunlight absorption, which enables them to maintain surface transparency to visible light. The photothermal coatings are unprecedented in their thinness (less than 10 nm) and performance, absorbing about one third of the solar energy selectively, mostly in the near infrared range (3), where half of the energy of sunlight resides. They can be easily deposited also on deformable and soft materials and are fabricated with common industrial processes. These combined capabilities render them a perfect candidate for a host of applications such as eyewear, car windows and windshields, mirrors and building windows. Finally, I will discuss the surface architecting of transparent materials able to maintain transparency alone, in the case of most severe condensation conditions and vapor influx, such as in the direct neighborhood of boiling liquids (4). Again, such architectures can be readily fabricated and up-scaled via simple molding or roll-to-roll processes.

10:45 AM SF03.02.03
Integration of Boron Arsenide with Gallium Nitride Devices for High-Performance Thermal Management Man Li, Joonsang Kang, Huan Wu, Huuduy Nguyen and Yongjie Hu; University of California, Los Angeles, United States

Thermal management is critical in modern electronic systems. Efforts to improve heat dissipation have led to the exploration of novel semiconductor materials with high thermal conductivity, including boron arsenide (BAs) and boron phosphide (BP). However, the integration of such materials into devices and the measurement of their interface energy transport remain unexplored. Here, we show that BAs and BP cooling substrates can be heterogeneously integrated with metals, a wide-bandgap semiconductor (gallium nitride, GaN) and high-electron-mobility transistor devices. GaN-on-BAs structures exhibit a high thermal boundary conductance of 250 MW/m^{2}K, and comparison of device-level hot-spot temperatures with length-dependent scaling (from 100 micrometer to 100 nanometer) shows that the power cooling performance of BAs exceeds that of reported diamond devices. Furthermore, operating AlGaN/GaN high-electron-mobility transistors with BAs cooling substrates exhibit substantially lower hot-spot temperatures than diamond and silicon carbide at the same transistor power density, illustrating their potential for use in the thermal management of radiofrequency electronics. We attribute the high thermal management performance of BAs and BP to their unique phonon band structures and interface matching.

11:00 AM SF03.02.04
Superdiffusive Thermal Transport in $Si_{0.4}Ge_{0.6}$ Thin Films Fengju Yao[1], Deyu Li[2], Hong Lu[3] and Dongyan Xu[1]; [1]The Chinese University of Hong Kong, Hong Kong; [2]Vanderbilt University, United States; [3]Nanjing University, China

Superdiffusive thermal transport represents a unique phenomenon in heat conduction, which is characterized by a size (L) dependence of thermal conductivity (κ) in the form of $\kappa \sim L^{\beta}$ with a constant β between 0 and 1. Although superdiffusive thermal transport has been theoretically predicted for SiGe alloys, direct experimental evidence is still lacking. Recently, we conducted a systematic experimental study of the thickness-dependent thermal conductivity of $Si_{0.4}Ge_{0.6}$ thin films grown by molecular beam epitaxy (MBE). The cross-plane thermal conductivity of $Si_{0.4}Ge_{0.6}$ thin films spanning a thickness range from 20 to 1120 nm was measured in the temperature range of 120-320 K *via* a differential three-omega method. Results show that the thermal conductivity follows a consistent $\kappa \sim t^{0.26}$ power law with the film thickness (t) at different temperatures, providing direct experimental evidence that alloy-scattering dominated thermal transport in SiGe is superdiffusive.

Nanoscale Laser Flash Measurements of Ballistic Heat Currents in AlN Heterostructures Samreen Khan[1], Wanyue Peng[1], John Wright[2], Yongjin Cho[2], Debdeep Jena[2], Huili G. Xing[2] and Richard Wilson[1]; [1]University of California, Riverside, United States; [2]Cornell University, United States

This study aims to understand the interplay of ballistic heat currents, interfacial phonon scattering, and mean-free-path distributions on heat conduction in AlN heterostructures. On submicron length-scales, theory predicts that heat transfer will be carried across an AlN heterostructure by a combination of ballistic and diffusive heat-currents [1,2]. The fraction of ballistic vs. diffusive heat currents is expected to depend the mean-free-path distribution of AlN and the frequency dependence of interfacial phonon scattering rates. Experimental metrologies like time-domain thermoreflectance and frequency-domain thermoreflectance cannot test such theoretical predictions because they struggle to differentiate ballistic vs. diffusive heat-currents. In this talk, we describe a new experimental approach that overcomes this challenge. Our approach relies on integrating an epitaxial buried heater layer into an AlN heterostructure during sample growth. We used MBE to grow an epitaxial 60nm-TiN/650nm-AlN/60nm-NbN tri-layer on sapphire. We then performed nanoscale laser flash measurements of heat conduction [3,4] across the AlN between 80 and 600 K. We monitor the time-evolution of the surface TiN layer’s temperature after ultrafast heating of the buried NbN layer. Energy carried ballistically traverses the AlN layer at the speed of sound, while energy transported diffusively arrives more slowly. By comparing our experimental data to theoretical simulations, we were able to quantify the importance of sub-continuum ballistic transport effects. At room temperature, we observe that approx. one quarter of the heat-current across the 650nm AlN layer is ballistic. Our experimental study improves fundamental understanding of how heat evolves as a function of time and space in sub-continuum heat transfer problems, and improves understanding of the frequency-dependence of interfacial phonon scattering.

Interfacial Bonding and Thermal Conductivity in Polymer-Glass Nanocomposites with Ultra-High Interfacial Density David W. Collinson[1], Yang Wang[1], Heungdong Kwon[1], Robert D. Miller[1], Krystelle Lionti[2], Kenneth E. Goodson[1] and Reinhold H. Dauskardt[1]; [1]Stanford University, United States; [2]IBM Almaden Research Center, United States

Manipulating and controlling heat flow across the interface between two materials is a significant issue for modern devices and materials where the small length scales result in a high density of interfaces that dominate the effective thermal conductivity (*k*). To control nanoscale heat transport between dissimilar materials, a deeper understanding of how the underlying chemistry and interfacial structure manipulates the thermal boundary conductance (TBC) of the interface is required. While many experimental techniques have been described for studying thermal transport in thin films, and specifically polymer nanocomposites, there is a lack of experimental investigations that can directly link the interfacial bonding to the resulting TBC between amorphous materials. The dearth of experimental data is caused by poor TBC measurement sensitivity in the case of the single interface in a substrate-supported polymer thin film structure due to the low polymer intrinsic thermal conductivity and due to the complexity of the analysis in the case of particle-polymer nanocomposites with high interfacial density. Separately, particle-based nanocomposites tend to have an unstable structure as the relative strength of particle-particle and particle-polymer interactions determines the dispersion of particles throughout the nanocomposite. As a result, changes in the TBC of the particle-polymer interfaces in the nanocomposite becomes highly convoluted with changes to the particle dispersion and particle-particle contact.

In this study, we show that the thermal conductivity of a polymer-glass nanocomposite with polymer molecules under nanometer scale confinement in an organosilicate matrix can be characterized using time-domain thermoreflectance spectroscopy. The thermal conductivity characterization is made possible by the ultra-high internal interfacial density and can be further quantitatively linked to the nature of the organosilicate matrix surface chemistry. The TBC at the polymer-organosilicate interface is extracted by comparing the measured thermal conductivity with effective medium and numerical model calculations. Fourier transform infra-red spectroscopy and X-ray photoelectron spectroscopy (XPS) were used to characterize the hydrogen bonding between the polymer molecules and organosilicate matrix. Thin-film fracture measurements were used to quantify the molecular polymer bridging contribution to the cohesive fracture resistance and its dependance on interfacial bonding. This new experimental metrology provides a direct experimental link between thermal and mechanical properties and the nature of interfacial bonding between polymer molecules and surfaces.

***Ab Initio* Studies of Coupled Electron-Phonon Transport and Drag Enhanced Thermopower** David Broido[1], Chunhua Li[1], Nakib H. Protik[2], Pablo Ordejón[3] and Miguel Pruneda[3]; [1]Boston College, United States; [2]Humboldt-Universität zu Berlin, Germany; [3]Catalan Institute of Nanoscience and Nanotechnology, Spain

In doped semiconductors and metals under an applied electric field or temperature gradient, momentum transfer between charge carriers and phonons through electron-phonon interactions boosts the thermoelectric power, a phenomenon known as electron-phonon drag [1, 2]. Using a recently-developed first principles approach to solve the coupled electron and phonon Boltzmann transport equations [3], we have examined the thermoelectric transport coefficients (electrical conductivity, Seebeck and Peltier thermopowers, and electronic and phonon thermal conductivities) in doped semiconductors. Excellent agreement is obtained with the measured thermopower of Si across a wide range of charge carrier densities and extending to the strong drag regime at low temperatures. Enormous enhancements to the thermopower, *S*, and thermoelectric power factor, *PF*, of lightly doped diamond are revealed [4]: Around 100 K, *S* and *PF* values of around 100,000 $\mu V\ K^{-1}$ and 7000 $\mu W\ K^{-2}\ cm^{-1}$, respectively, are achieved. These values are much larger than the corresponding previously reported record measured values in the correlated metal, $FeSb_2$, and they also occur at significantly higher temperatures. The remarkable behavior stems from exceptionally weak anharmonic phonon decay at low *T* that minimizes dissipation of the phonon current, a feature that also gives large thermal conductivity thereby preventing diamond from being a useful thermoelectric material, and even when accounting for phonon frequency filtering [5].

Novel Vistas in Thermal Transport: Relaxons, Viscosities and Coherences Nicola Marzari[1,2]; [1]EPFL, Switzerland; [2]Paul Scherrer Institute, Switzerland

First, we examine the emergence of correlated transport phenomena in systems described by the linearized Boltzmann transport equation (LBTE), with examples centered around heat transport. We show how phonons are only a high-temperature approximation to the exact carriers, that we term relaxons, and that the thermal conductivity can be mapped exactly into a kinetic theory of the relaxon gas. We also calculate the viscosity of this gas, and coarse-grain the LBTE into coupled viscous equations that describe the hydrodynamic regime of heat propagation. Then, we discuss thermal transport in materials with low conductivity (thermoelectrics, thermal barrier coatings, glasses), highlighting the importance of a broader formulation - in the form of a Wigner transport equation - that includes also the tunnelling of phonon wavepackets.

Anomalous Thermoelectric Transport Phenomena from Interband Electron-Phonon Scattering Boris Kozinsky[1,2], Natalya Fedorova[1], Andrea Cepellotti[1], Jackson Weaver[1] and Jennifer Coulter[1]; [1]Harvard University, United States; [2]Bosch Research, United States

The Seebeck coefficient and electrical conductivity are two central quantities to be optimized simultaneously in designing thermoelectric materials, and they are determined by the dynamics of carrier scattering [1]. We uncover a new regime where the presence of multiple electron bands with different effective masses, crossing near the Fermi level, leads to strongly energy-dependent carrier lifetimes due to intrinsic electron-phonon scattering. In this anomalous regime, electrical conductivity decreases with carrier concentration, Seebeck coefficient reverses sign even at high doping, and power factor exhibits an unusual second peak [2]. We explain the origin and magnitude of this effect using a general simplified model as well as first-principles Boltzmann transport calculations in recently discovered half-Heusler alloys. We identify general design rules for using this paradigm to engineer enhanced performance in thermoelectric materials. We performed detailed first-principles electron-phonon transport calculations for several candidate materials to investigate the potential for increased thermoelectric performance based on this light-heavy band mechanism.

Million-Scale Atomic Data Integrated Deep Learning for Predicting Thermal Transport Properties of 100,000 Structures Ming Hu; University of South Carolina, United States

Existing machine learning potentials for predicting phonon properties of crystals are limited to either small amount of training data or a material-to-material basis, primarily due to the exponential scaling of model parameters with the number of atomic species or elements. This renders high-throughput infeasible when facing large-scale new materials. Unlike previous machine learning models with inherently limited training on small data and global properties, we develop Elemental Spatial Density Neural Network Force Field (Elemental-SDNNFF) with abundant atomic level environments as training data. Benefiting from this innovation, we integrate ~30 million atomic data to train a single deep neural network without increased expensive ab initio simulations. The effectiveness and precision of the Elemental-SDNNFF approach is demonstrated on a set of ~100,000 inorganic crystals spanning 63 elements in the periodic table by prediction of complete phonon properties. Our algorithm achieved a competitive force root mean square error of less than 10 meV/Å and a speed-up of 3 – 4 orders of magnitude in comparison to first principles. Self-improvement schemes such as active learning and data augmentation techniques are also incorporated allowing human-free refinement of the force accuracy on arbitrary combinations of chemistries. As case studies of our predicted phonon properties, deep insight into the ultralow lattice thermal conductivity (<1 W/mK) of predicted structures are gained by p-d orbital hybridization analysis and charting the thermal conductivity data in the bonding-antibonding map, which offers a quick approach for future screening of crystals with strong intrinsic phonon anharmonicity. Our algorithm is promising for accelerating discovery of novel phononic crystals for emerging applications, such as heat dissipation in electronics, thermoelectrics, and coherent phonons for quantum information technology.

12:00 PM SF03.03.05
Efficient Calculation of Nanoscale Thermal Conductivity Using Equilibrium Monte Carlo Simulations That Bridge the Boltzmann Transport Equation and the Green-Kubo Formalism S Aria Hosseini[1], Alathea E. Davies[2], Laura de Sousa Oliveira[2], Jackson R. Harter[3], Giuseppe Romano[1] and Alex Greaney[4]; [1]Massachusetts Institute of Technology, United States; [2]University of Wyoming, United States; [3]Idaho National Laboratory, United States; [4]University of California, Riverside, United States

We present a novel approach for computing phonon mediated thermal conductivity in nanoscale systems using Monte Carlo simulations of the system at equilibrium. In this approach the thermal conductivity is computed from the autocorrelation function of the equilibrium heat current fluctuations using the Green-Kubo (GK) method. We show that the heat current autocorrelation function can be constructed from the average of the autocorrelation function of individual phonons, making convergence of its calculation very efficient. The approach has the advantage that, being at equilibrium, it does not require convergence of the temperature at every point in the simulation domain and thus the equilibrium approach can be significantly less computationally intensive than traditional non-equilibrium Monte Carlo simulations. We further show that the theoretical framework underpinning this work can be used to derive the analytic expressions for the thermal conductivity in a thin slab that comes from solving the Boltzmann transport equation (BTE), providing a bridge between the BTE and the GK approaches. However, our stochastic model can also be used to obtain analytic predictions for the thermal conductivity in other geometries, and helps us to understand transport through systems with two different and orthogonal characteristic length scales.

12:15 PM SF03.03.06
Heat Transfer Modelling in the Crossover Regime Between Conduction and Radiation Mauricio Gómez Viloria, Philippe Ben-Abdallah and Riccardo Messina; Laboratoire Charles Fabry, France

Fluctuational electrodynamics (FED) theory describes the near field radiative heat transfer for separation distances below the thermal wavelength (some microns at ambient temperature), where the heat flow between two solids at different temperatures can exceed the far field limit by several orders of magnitude, in particular when the bodies exchanging heat support surface resonant modes, such as surface phonon-polaritons or surface plasmons.
At even smaller distances, in the so-called extreme near field (distances in the nanometer range and below) the physics is expected to change radically. Interestingly, two recent scanning thermal microscopy (SThM) experiments, approaching gold tips to gold substrates, reach apparently opposite conclusions. While one of them shows large deviations from FED for separation distances of few nanometers, another experiment shows no deviations from FED even at sub-nanometer gaps, where acoustic phonons and electrons are expected to contribute as further channels to the heat exchange.

Here we introduce a theoretical framework to investigate the heat transfer mediated by photons, phonons and electrons between two metallic bodies. We quantify the role of electron tunnelling currents by paying attention to the role played by the shape of the electronic barrier in the presence of electron-electron screening interactions. Using an approach based on the elastic theory, we address the role of acoustic phonons coupled through the Van der Waals and the electrostatic forces. Finally, we employ FED to study the role played by photons, by taking into account the contribution of non-local effects. This theoretical work allows us to outline the relative weight of the different carriers with respect to the separation distance, and to highlight the crucial role played by the external bias voltage on the heat flux carried by the three types of carriers.

SESSION SF03.04: Thermal Properties of Materials

1:30 PM *SF03.04.01
Passive Sub-Ambient Cooling with an Evaporation-Insulation Bilayer Jeffrey C. Grossman; MIT, United States

Passive evaporative cooling, which does not rely on electricity, shows promise to alleviate the ever-increasing global cooling needs but has been largely limited by environmental heating. Once sub-ambient temperatures are reached, the environmental heat gain accelerates the dry-out of evaporative materials, which is also detrimental to the cooling performance. Here, we address this critical challenge with an evaporation-insulation cooling design based on hydrogels and aerogels, inspired by the fur layer on the sweating skins of desert animals. Our transparent bilayer structure relies on water evaporation from hydrogels through highly porous aerogels for heat removal. At the same time, the low thermal conductivity of aerogels minimizes the parasitic heat gain. We establish a comprehensive model for heat and mass transfer in the system, which shows good agreement with our experimental data. We demonstrate that the addition of the porous insulation layer allows for optimization between the temperature drop from the ambient and the effective cooling time. Our bilayer structure can extend the lifetime of the cooling package by 400% compared to the conventional single-layer design. We further identify the relationship between the performance metrics and material properties of the insulation layer and provide design guidelines for various cooling applications including thermal regulation of food, pharmaceuticals, and buildings.

***Ab Initio* Determination of New Ultrahigh Thermal Conductivity Materials** Huan Wu, Hang Fan, Man Li and Yongjie Hu; University of California, Los Angeles, United States

Discovering new materials with ultrahigh thermal conductivity has been a critical research frontier and driven by many important technological applications ranging from thermal management to energy science. Conventional materials with ultrahigh thermal conductivity are prototyped by single-element materials, i.e., diamond. Binary compounds such as boron arsenide has been predicted to have ultrahigh thermal conductivity based on first-principles calculations, and later on experimentally verified to show thermal conductivity at 1300 W/mK, as a record high beyond common semiconductors. Now the question is whether such an HTC can exist in even complicated crystal structure, perhaps ternary compounds, which has not yet been explored. Here we have rigorously investigated the fundamental lattice vibrational spectra in ternary compounds and determined groups is systematically quantified with different crystal structures and high order anharmonicity involving the thermal conductivity using a predictive *ab initio* approach. Phonon transport in B-X-C (X = N, P, As) four-phonon process. Our calculation found an ultrahigh room-temperature thermal conductivity through strong carbon-carbon bonding up to 2100 W/mK beyond most common materials and the recently discovered boron arsenide. This study provides fundamental insight into the atomistic design of thermal conductivity and opens opportunities in new materials searching towards complicated compound structures.

Finding Locons is a CINCH: Classifying and Identifying Normal Modes using Convex Hulls Daniel Xiao, Ethan Meitz, Gerald J. Wang and Alan McGaughey; Carnegie Mellon University, United States

We propose a new methodology for quantifying the spatial localization of the collective atomic vibrations (i.e., normal modes) in a disordered material. The normal modes can be classified into three categories: propagons (non-localized, propagating), diffusons (non-localized, non-propagating), and locons (localized, non-propagating). It is important to classify the normal modes because each type makes a different contribution to thermal conductivity. A failure to account for non-propagating modes is why the phonon gas model cannot describe thermal transport in amorphous solids.
Reliably identifying propagons, diffusons, and locons remains an open challenge. Here, we focus on the distinction between localized and non-localized modes. The standard method for quantifying localization is through the mode participation ratio (PR), which reflects how many atoms participate in a given mode. The PR ranges between 1/N (fully localized) and 1 (fully delocalized), where N is the number of atoms in the system. Localization is specified by placing an arbitrary cutoff on the PR and any modes with PRs below this cutoff are considered localized. This methodology, however, has a significant shortcoming: the PR contains no spatial information. For example, the PR for a mode with only two participating atoms does not depend on the relative positions of the two atoms. Such a mode may be *constrained* to two atoms, but is not necessarily *localized*.
Our new method works as follows. We construct a set of convex hulls for each normal mode, starting with the four atoms with the largest participation. Atoms are then added in the order of highest to lowest participation. At each step, the volume of the convex hull and the PR of the contained atoms are calculated. By considering the entire convex hull expansion process, we can describe how much volume is needed to reach a given PR. The algorithm is applied to amorphous silicon and silica systems of various sizes. Strongly localized modes have a steep initial slope of PR versus number of atoms before saturating, indicating that they approach their total PR at small volume. Non-localized modes approach the total PR linearly with volume. This method is easy to apply to a set of normal modes obtained from a lattice dynamics calculation and provides a quantitative parameter that accurately classifies their localization.

2:30 PM SF03.04.04
Causal Green's Function Method for Simulating Nanoscale Heat Transport Vinod K. Tewary and Edward J. Garboczi; National Institute of Standards and Technology, United States

Heat management in semiconductor devices at nanoscale is a subject of strong topical interest. It requires materials of high as well low thermal

conductivities and involves phonons of a wide frequency range. Robust mathematical tools are needed for simulation at the nano length scales, that are comparable to or even less than the phonon mean free path. At these scales, the continuum theory is not valid, and a fully discrete lattice or multiscale simulation must be carried out.
In addition to the length scales, simulation at multiple time scales is also a challenging problem. The conventional molecular dynamics (MD) is usually limited to a very small temporal range for reasonable convergence. In practice, the integration of the temporal part of the MD equations needs the integration interval to be less than a few femto seconds, whereas the physical processes of interest require simulation up to nanoseconds or even microseconds. This requires at least a few million temporal iterations, may be closer to 100 million iterations. That is computationally too expensive. Various schemes for accelerating the MD are available in the literature but much more is needed for the proper simulation of nanoscale heat transport.
We show that the use of causal Green's function (GF) in MD can accelerate its temporal convergence by several orders of magnitude. To see this, we recall that in MD, at every time step, we expand the potential energy of the system to first order in atomic displacements and then use the linear Newtonian solution to calculate the atomic displacements at the end of that time interval. The process is continued iteratively until the displacements converge. The process of iteration effectively accounts for the nonlinear terms in the potential. Attempts to improve upon the temporal convergence consist of better solution of the temporal part of the MD.
We approach the problem by a totally different technique. We expand the potential energy up to quadratic terms in displacements and not just linear terms as in MD. It would appear at first sight that the quadratic terms would make the solution of the temporal problem more difficult. We show that the temporal equations can still be solved exactly by using the GF. To ensure causality, we use the retarded GF, for which we use the Laplace transform. We show that the Laplace as well as inverse Laplace transforms are obtained analytically.
Cubic and higher order terms in the potential are accounted through MD type iterations, but the advantage is that much fewer iterations are needed and the time interval can be much larger. We show in certain idealized test cases that the temporal convergence can be improved by 7-8 orders of magnitude. Physically, the improvement is significant for phonons and elastic properties materials because the phonons' characteristics of a material are determined by the quandratic terms in the potential. Our GF technique includes the phonon terms exactly, whereas the MD accounts for these term only through computaionally expensive iterations.
We will illustrate our causal GF technique by applying it to real 2D solids of contemporary interest such as graphene or silicene. This will bring out the important characteristics of the nanoscale heat transport such as the size effect, non-Fourier heat conduction and show the power of the causal GF technique for simulating nanoscale heat transport.

2:45 PM *SF03.04.05
Thermal Properties of Complex Semiconductors G. J. Snyder; Northwestern University, United States

Thermal transport in complex semiconductors is often analyzed using the phonon gas model including several scattering terms [1]. Experimentally it is hard to uniquely determine which scattering mechanisms are truly dominating. Combining experiment and theory can elucidate the contributing effects that can help engineer thermal conductivity in complex materials. For example, dislocation scattering now appears to be an important mechanism in thermoelectric materials and may even have been overlooked as the primary mechanism for scattering of grain boundaries as evidenced by the temperature dependence of thermal conductivity at low temperature being closer to *T2* experimentally rather than the *T3* traditionally expected for boundary scattering. In addition to scattering, phonon soften can also be important to achieve very low thermal conductivity. Ultra-low thermal conductivity in solids appears to be dominated by diffusions rather than wave like phonons which suggests a better understanding of diffusion heat transport is needed to further engineer low thermal conductivity materials. A reexamination of the traditional phonon gas model with the rigid distinction between harmonic and anharmonic contributions may also be needed as there appears to be a harmonic contribution to thermal expansion which is often assumed to only arise from anharmonic terms that appears to be connected to gas-like phonon pressure. Strategies to find materials with low phonon speed and high scattering rates can be used to engineer good thermoelectrics but also thermal barrier coatings and high power electronics.

3:30 PM *SF03.05.01
Spatial and Frequency-Domain Multiplexing Approaches to Thermal Property Mapping in 2D and 3D Chris Dames[1,2]; [1]Univ of California-Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Thermal property mapping in 2D and 3D has diverse applications, from identifying buried voids to property screening for combinatorial materials development. Here I will describe two efforts in this regard, which are respectively based on the superposition of multiple heat forcings in space (i.e., multiple heating pixels in x,y) and in frequency (multiple heating frequencies, omega). First, we are developing the next generation of an all-optical "structured illumination, thermal imaging" (SITI) method [Q. Zheng et al., Appl. Phys. Rev. 9, 021411 (2022)] for spatially-multiplexed thermal measurements, here with simpler hardware, a larger field of view, and new algorithms for extracting the property map. Second, the thermal property variation as a function of depth into a sample (z direction) can be probed by varying the frequency of a periodic surface heat source and thus its thermal penetration depth. While this can be done by sequentially sweeping the frequency of a pure sinusoidal excitation, a more information-dense approach is to simultaneously apply multiple sinusoids of several different frequencies and study the superposed system response. To demonstrate the latter scheme we developed an electrothermal "3-omega" apparatus using a fine wire suspended horizontally in a shallow oil bath, which measured the depth of the oil with accuracy around ±18 microns [W. Hodges et al., Rev. Sci. Instrum. 90, 094903 (2019)]. A common theme across both studies is the need to condition the property fitting by thoughtfully incorporating prior knowledge about the allowed variabilities of the unknown thermal property field.

4:30 PM *SF03.05.03
Thermal Transport in Amorphous Materials with *Ab Initio* Machine Learning Potentials Davide Donadio[1], Zekun Chen[1], Giuseppe Barbalinardo[1], Alfredo Fiorentino[2] and Stefano Baroni[2]; [1]Univ of California-Davis, United States; [2]Scuola Internazionale Superiore Studi Avanzati, Italy

Glassy materials are found ubiquitously in nature and are essential components in technological applications. Their thermal conductivity controls heat flows from planetary-level macroscales down to the microscale of electronic components. While lattice thermal conduction in crystals has been extensively studied, much less is known about the relation between structural properties and heat transport in glasses.
Here we exploit the recently developed quasi-harmonic Green-Kubo approach based on lattice dynamics to investigate heat conduction in two systems of broad interest at both the fundamental and the applicational level: diamond-like carbon and amorphous ice. Both systems exhibit structural transitions as a function of the vitrification conditions. In the case of amorphous ice, there are at least two forms separated by a first-order phase transition. Using machine learning potentials trained on ab initio density functional theory datasets enables accuracy and transferability over the broad range of local structures encountered in these materials and allows us to probe vitrification at various thermodynamic conditions.
Through our lattice dynamics approach, we sort out the structural features that lead to vibrational modes diffusion and localization, which modulate the nature and the magnitude of heat conduction in the different forms of glassy carbon and amorphous ice.

5:00 PM SF03.05.04
Identifying Materials for Ultrathin Conduction via Polaritonic Thermal Transport Jacob Minyard and Thomas Beechem; Purdue University, United States

Microelectronics no longer gain efficiency as they are made smaller. Dennard scaling is dead. With every uptick in clock speed or node size reduction, heat load increases. Balancing the thermal budget necessitates dissipating these continually increasing heat loads. It hasn't happened. As a result, heating now limits performance, shortens lifetimes and requires that up to ≈ 50% of an integrated circuit is turned off, or dark, at any given time. Improving computing requires not just smaller, more capable, devices but more capable methods of moving heat at extremely small scales.

The most obvious solution points to merely utilizing higher thermal conductivity materials. Along these lines, the development of high thermal conductivity synthetic diamond and BAs have been successful. While attractive for larger power electronics (> 1 μm), their utility is limited at the < 100 nm sizes characteristic of Si-based devices. This is a consequence of phonon physics—and thus endemic to materials in general—and therefore not a defect that can be "fixed."

Thermal conductivity increases when phonons move further at higher speeds. As the size of a material decreases, phonons are effectively fenced in. They scatter off the closely spaced boundaries reducing thermal conductivity. Circumventing this so-called size-effect in the thermal conductivity requires a means of either increasing the speed of the heat carriers or in some way making them less sensitive to material boundaries.

Polaritons–quasiparticles created by the hybridization (i.e., mix) of photons and material dipoles—can do both. Their photonic character provides a path to heat transfer closer to that of the speed of light than of sound. Polaritons also localize at material boundaries and therefore skate along interfaces rather than crashing into them. Recognizing these facts, we compare the potential of several dielectrics for moving heat in extremely thin films (t<100 nm) via polartonic transport and compare their utility relative to standard phonon-based conduction. Using established analytical expressions for deriving polaritonic dispersion in conjunction with kinetic theory of polariton transport, a material map is derived linking optical properties with potential for thermal transport in ultrathin films.

SESSION SF03.06: Poster Session I
Session Chairs: Yongjie Hu and Lucas Lindsay
Tuesday Afternoon, April 11, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM SF03.06.01
Enhanced Near-Field Radiative Heat Transfer Between Planar Membranes Thinner Than the Vacuum Gap Spacing—Theory Livia Correa[1], Lei Tang[2], Chris Dames[2] and Mathieu Francoeur[1]; [1]University of Utah, United States; [2]University of California, Berkeley, United States

It is well-known that near-field radiative heat transfer (NFRHT) between two flat surfaces surpasses the blackbody limit owing to the tunneling of evanescent electromagnetic waves (e.g., Song et al., *Nature Nanotechnology* 11, 509-514, 2016; DeSutter et al., *Nature Nanotechnology* 14, 751-755, 2019; Tang et al., *ACS Photonics* 7, 1304-1311, 2020). Modeling of NFRHT in layered media relies on an exact solution valid for infinite surfaces, such that NFRHT between surfaces facing laterally smaller than the vacuum gap spacing has never been investigated. We recently developed the discrete system Green's function (DSGF) method (Walter et al., arXiv:2204.05399, 2022), which is a numerically exact framework based on fluctuational electrodynamics. The DSGF can accommodate arbitrary geometries since thermal sources are discretized into cubic subvolumes electromagnetically related to each other via a system Green's function. In this work, we analyze for the first time the impact of surface size on NFRHT. Specifically, we calculate NFRHT between two planar silicon carbide (SiC) membranes thinner than their vacuum gap spacing using the DSGF. The results show that the radiative heat transfer coefficient in the near field exceeds the predictions for two infinite surfaces when the membrane thickness to vacuum gap spacing ratio is approximately equal to or smaller than 6. For a fixed vacuum gap spacing of 100 nm, the radiative heat transfer coefficient between two 600-nm-thick SiC membranes is 165 W/m^2-K, which slightly exceeds the infinite surface predictions of 151 W/m^2-K. For 100-nm- and 10-nm-thick membranes, the radiative heat transfer coefficients are respectively 274 W/m^2-K and 1511 W/m^2-K. These are substantial enhancement of ~1.8 and ~10 with respect to the infinite surface case. We hypothesize that the enhancement is mediated by surface phonon-polaritons localized at the edges of the membranes. These localized surface phonon-polaritons are always present, but dominate NFRHT only when at least one dimension of the surfaces is smaller than the vacuum gap spacing. Furthermore, the DSGF predictions are in good agreement with experiments performed between two coplanar SiC membranes characterized by thickness and gap spacing smaller than respectively 100 nm and 500 nm. The additional enhancement of NFRHT between thin membranes may find application in energy conversion and non-contact cooling.

5:00 PM SF03.06.02
Radiative Thermal Diode Enabled by Guided-Modes of Surface Phonon-Polaritons in Silicon-Silica Heterostructures Byunggi Kim[1], Saeko Tachikawa[2], Laurent Jalabert[1,1], Jose Ordonez-Miranda[1,1], Maelie Coral[1,3], Yunhui Wu[1], Roman Anufriev[1], Sebastian Volz[1,1] and Masahiro Nomura[1]; [1]The University of Tokyo, Japan; [2]University of Basel, Switzerland; [3]Université PSL, France

A thermal diode enables the rectification of the heat flow depending on the temperature gradient, thereby playing a key role in directional thermal management. For radiative heat transport, a near-field thermal diode has been realized using materials with temperature-dependent thermophysical properties. Recently, Thomson et al. demonstrated that the Planck's black body limit can be overcome by two orders of magnitude in the far-field regime between two nanoscale membranes (Nature 561 (2018)). For membranes with thickness significantly smaller than radiation wavelengths, out-of-plane Poynting flows are greatly suppressed by guided modes. The same team showed active switching of heat flow via guided far-field radiation (Nature Nanotechnology 15, 99–104 (2020)), which hints the route for controlled far-field heat transfer. However, no experimental demonstration has yet been presented for the thermal rectification in the far-field regime. Here, we provide the experimental evidence of a far-field thermal diode using a silicon (Si)-silica (SiO$_2$) heterostructure in which guided resonant modes can be excited by the hybridization of optical phonons and photons, namely Surface Phonon-Polaritons (SPhPs).

In this study, we designed a SiO$_2$/Si/SiO$_2$ layered structure to observe the SPhP-guided radiation. We deposited 60-nm-thick SiO$_2$ layers on a 10-um-thick single-crystalline Si micromembrane. The thin SiO$_2$ layers activate SPhP-guided modes inside the Si micromembrane, which is transparent in most of the spectral range of the infrared radiation. We conducted the 3-omega measurement to obtain the gap thermal conductance between the SiO$_2$/Si/SiO$_2$-layered structure and the pristine silicon membrane. The gap size was 10 um, which satisfies the far-field criteria. We show that the gap thermal conductance from the pristine silicon to the layered structures ($G_{forward}$) is breaking the black-body limit and is three times larger than the flux in the opposite direction ($G_{backward}$), thereby showing that the rectification factor, $R = (G_{forward}-G_{backward})/G_{forward}$, is over 0.7 for temperatures ranging from 300 K to 500 K. In this temperature range, the rectification factor is outperforming the existing experimental results of the thermal diodes based on near-field heat transfer (ACS Nano 12, 6, 5774-5779 (2018)) and thermal conduction (Nano Energy 78, 105261 (2020)). We analytically derived the dispersion relation of the SiO$_2$/Si/SiO$_2$-layered structure, and calculated the in-plane Poynting flows considering the multiple branches of the SPhP-guided modes. The mid-infrared photons could be guided inside the SiO$_2$/Si/SiO$_2$-layered structure, to enhance absorption of the oblique modes generated from the pristine Si micromembrane. On the other hand, the pristine Si membrane does not absorb the SPhP-guided radiations from the SiO$_2$/Si/SiO$_2$-layered structure, which leads to the experimentally observed asymmetry of the gap thermal conductance.

In conclusion, we experimentally showed thermal rectification using a heterostructure based on a SiO$_2$ thin film and a Si micromembrane. The theoretical model attributes the diode effect to the absorption mediated by the SPhP-guided modes. Our study is the first experimental demonstration of a far-field thermal diode with a significant rectification factor larger than 0.7. Furthermore, the Si micromembrane-based design ensures incorporation in integrated circuits with better mechanical stability than sub-micron scale membrane devices. We believe that our results pave a reliable way for the control and functionalization of thermal radiation in the applications of radiative cooling and thermal circuits.

5:00 PM SF03.06.03
Impact of Molecular Weight of Conjugated Polymers on Molecular Doping Efficiency, Electrical Conductivity and Resulting Thermoelectric Performances Bomi Kim[1], Sang Eun Yoon[2], Jong Hyun Kim[2] and BongSoo Kim[1]; [1]Ulsan National Institute of Science & Technology (UNIST), Korea (the Republic of); [2]Ajou University, Korea (the Republic of)

In this study, we investigated the effect of molecular weight of a series of conjugated polymers (CPs) on the doping efficiency, electrical conductivity, and related thermoelectric properties of doped CPs. Low (L), medium (M), and high (H) molecular weight batches of PDFD-T polymers, based on difluorobenzothiadiazole and dithienosilole moieties, were synthesized and denoted as PDFD-T(L), PDFD-T(M), and PDFD-T(H), respectively. Furthermore, to compare the effects of different donor moieties, donor units of PDFD-T(L) were structurally modified from thiophene to thienothiophene (TT) and dithienothiophene (DTT), denoted as PDFD-TT(L) and PDFD-DTT(L), respectively. After doping the CPs with FeCl$_3$, doped(d) PDFD-T(H) exhibited an electrical conductivity of 402.9 S cm^{-1}, which is significantly higher than those of d-PDFD-T(L), d-PDFD-T(M), d-PDFD-TT(L), and d-PDFD-DTT(L). Furthermore, the drastic increase in σ of d-PDFD-T(H) sufficiently compensated for its reduced Seebeck coefficient, which resulted in a high power factor of up to 101.1 μWm^{-1}K^{-2} of the thermoelectric devices fabricated using d-PDFD-T(H).
Systematic characterizations were performed on both pristine and doped CPs, including spectroelectrochemical ultraviolet-visible-near infrared (UV-Vis-NIR) absorption, Raman spectroscopy, conductivity and Hall effect measurements, grazing incidence wide-angle X-ray scattering (GIWAXS), conductive atomic force microscopy (C-AFM), and so on. The doping efficiency of FeCl$_3$ on CPs was analyzed from the UV-Vis-NIR spectra of the doped CP films by Gaussian fitting, estimating the concentration of [FeCl$_4^-$] which is an indicator of the amount of generated charge carriers after doping. [FeCl$_4^-$] gradually increased from 2.67 (d-PDFD-T(L)) and 3.00 (d-PDFD-T(M)) to 6.27 M (d-PDFD-T(H)) according to the increasing order of the molecular weight. The higher molecular weight of CPs, the more charge carriers were generated in the doped CPs, implying the molecular weight of CPs affects the doping efficiency of the CPs. In addition, through GIWAXS analysis, it was revealed that the molecular weight of CPs also critically affects the crystallinity of CPs after doping, which is directly related to their charge transport properties. After doping, the crystallinity of CPs with low molecular weight decreased significantly due to structural disorders resulting from the infiltration of dopant molecules, causing low charge carrier mobility. However, d-PDFD-T(H) maintained its original crystallinity the most among the CPs and good charge transport pathways. In conclusion, these results highlight that the high molecular weight of polymers is necessary to achieve high crystallinity, high charge carrier mobility, and charge carrier concentration simultaneously.
This work demonstrates that the increased molecular weight of CPs strongly suppresses the crystallinity degradation of doped CPs and optimizes their doping efficiency and electrical conductivity. Therefore, we suggest that optimizing the molecular weight of CPs is an essential strategy for ultimately high thermoelectric performances from their doped CP films.

5:00 PM SF03.06.04
Tailored Phonon Transport in Heterogenous van der Waals Structures Zihao Qin, Man Li, Lingyun Dai, Suixuan Li, Huan Wu and Yongjie Hu; University of California, Los Angeles, United States

Heterogenous two-dimensional materials provide a unique platform study transport physics under high controllability and extreme conditions. Here through the design of layered control over van der Waals structures and atomic design at the interfaces, we find extremely anisotropic and structural dependent thermal conductivity control. In particular, our spectroscopy measurements and first-principles simulations show consistent observation of the localizations and atomic tailored phonon spectra. The resulted phonon structure provides heat transfer in a unique and controllable manner that are not available in other systems. We attribute this behavior to the enhanced coupling phase space that suppress phonon flux. This study probes complex phonon transport physics and opens the way for the understanding of microscopic energy transport mechanisms in heterogenous van der Waals structures.

5:00 PM SF03.06.05
Electrospinning-Assisted Radiative Cooling Composite Films Heegeom Jeon[1], Choyeon Park[2], Byung-il Choi[3], Seokjun Kim[3], Chanil Park[2], Sungmin Park[2], Yong Seok Kim[2] and Youngjae Yoo[1]; [1]Chung-Ang University, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of); [3]Korea Testing & Research Institute, Korea (the Republic of)

The rapid increase in annual cooling energy demand has a significant adverse impact on global warming. To overcome this, several studies have been conducted, and interest in passive radiative cooling that can be cooled without energy consumption has increased. Recent research on passive radiative cooling using various materials to reduce energy use for cooling has been reported. Previous studies focused on solar reflection and mid-infrared (IR) emission based on photonic crystal materials that are expensive and difficult to achieve large areas. Passive radiative cooling research is shifting from inorganic materials to organic materials and requires better solar reflectivity and mid-IR selective emissivity. In this study, an experiment was conducted to increase the solar reflectance of the existing PRC cooler to generate high emission at wavelengths in the atmospheric window range. Wave-selective emitters in the atmospheric window range were fabricated using glass bubbles (GBu) and barium sulfate ($BaSO_4$) in polydimethylsiloxane (PDMS). Then, polyacrylonitrile (PAN) nanofibers were electrospun on the prepared coolers. The optical properties and cooling power according to the ratio of GBu and $BaSO_4$ contained in the cooler and PAN electrospinning conditions were analyzed. Compared with the PDMS/GBu and $BaSO_4$ cooler, the cooler with the added electrospinning layer exhibited higher reflectivity and cooling power.

5:00 PM SF03.06.06
A Three-Terminal Magnetic Thermal Transistor Lorenzo Castelli, Qing Zhu, Trevor J. Shimokusu and Geoffrey Wehmeyer; Rice University, United States

Three-terminal thermal analogies to electrical transistors have been proposed for use in thermal amplification, thermal switching, or thermal logic, but have not yet been demonstrated experimentally. Here, we design and fabricate a three-terminal magnetic thermal transistor in which the gate temperature controls the source-drain heat flow by toggling the source-drain thermal conductance from ON to OFF. The centimeter-scale thermal transistor uses gate-temperature dependent magnetic forces to actuate motion of a thermally conducting shuttle, providing thermal contact between source and drain in the ON state while breaking contact in the OFF state. We measure source-drain thermal switch ratios of in high vacuum with gate switching temperatures near . Thermal measurements show that small heat flows into the gate can be used to drive larger heat flows from source to drain, and that the switching is reversible over >150 cycles. Proof-of-concept thermal circuit demonstrations show that magnetic thermal transistors can enable passive or active heat flow routing and Boolean thermal logic gates. This work will allow thermal researchers to explore the behavior of nonlinear thermal circuits using three-terminal transistors, and motivates further research developing thermal transistors for advanced thermal control.

5:00 PM SF03.06.08
Achievement of High Thermal Conductivity in Polyphenylene Sulfide Composites by Adding Amine-Functional Polysiloxide Coated ABN and Silane Treated Graphene Oxide Dabin Park, Youngsung Cho, Jooheon Kim, Minsu Kim and Wondu Lee; Chung-Ang University, Korea (the Republic of)

Polyphenylene sulfide (PPS) is a material with strong mechanical properties and chemical stability. However, PPS has a low thermal conductivity of 0.18 W/m K, which limits its applications in fields requiring heat dissipation properties.
In this study, to improve the thermal conductivity of the PPS/GF composite, aggregated boron nitride (ABN) was selected to create a heat path between the glass fiber fillers. ABN is a material that is physically aggregated with hexagonal BN (h-BN). H-BN has a high in-plane thermal conductivity of 180–300 W/m K and high chemical resistivity, which makes h-BN suitable as a filler for the improvement in thermal conductivity of various matrices. H-BN is difficult to handle due to its poor interfacial adhesion with composite matrix. For this reason, the surface modification of BN is necessary to improve adhesion with the PPS matrix. And to prevent the destruction of the ABN morphology in the extrusion and injection molding processes, amine-functional polysiloxide was selected to cover the ABN surfaces and was heat-treated at a high temperature of 973 K to provide thermal stability to withstand the high temperatures of the molding process. In addition to adding ABN, graphene oxide (GO) was also added to the composite to improve the adhesion between the glass fiber and the PPS matrix. Glass fiber and ABN in a PPS matrix have cylindrical and spherical morphologies; therefore, 2-dimensional GO was selected to improve the interface adhesion between the two fillers and the PPS matrix. In previous reports, silane-modified GO improved the dynamic mechanical and thermal properties by improving the adhesion between the filler and matrix. Furthermore, 3-mercaptopropyl trimethoxysilane (MPTMS) is a silane coupling agent which has a thiol functional group (R-SH). The R-SH in MPTMS can induce hydrogen bonding with the sulfur from PPS. The tri-filler-contained PPS composites were fabricated, and the mechanical and thermal properties were measured.
This study improves the mechanical and thermal properties of PPS-based composites. Because ABN and GO could not endure the melting extrusion and injection molding processes at a high temperature of 573 K, it was necessary to treat ABN and GO for the successful fabrication of the composites. ABN was coated with amine-functional polysiloxide and underwent the annealing process to transform into SiOC ceramics. In addition, MPTMS silane material was attached to the surface of GO. By adding PSZABN and MGO into the PPS/GF system, the dynamic mechanical property, more specifically, the storage modulus was increased by 50 times compared with neat PPS, and the mechanical tensile strength was increased from 60 MPa to 84 MPa. The thermal conductivity of the composite was 0.7 W/m K, which is 3.8 times greater than that of neat PPS. These improvements are due to the surface modification of the matrix and the improvement in adhesion with the glass fiber and PPS matrix by adding MGO. The above results demonstrate the application potential in various fields including the automotive field, which requires heat dissipation properties, by improving the thermal conductivity of the PPS matrix containing strong mechanical properties.

5:00 PM SF03.06.09
Thermal Transport in Fluid-Filled Si Nanocomposite Films Bayan A. Kurbanova[1], Azat Abdullaev[1], Ali Belarouci[2], Vladimir Lysenko[2] and Zhandos Utegulov[1]; [1]Nazarbayev University, Kazakhstan; [2]Université de Lyon, France

Although the investigation of dynamic properties of liquids within spatially confined solid spaces has drawn a considerable amount of research and

practical interest, a comprehensive understanding of the effect of fluid confinement in solid nanoporous media on the thermal transport properties of the fluid-infiltrated nanocomposite systems is still lacking [1]. Moreover, a study of easily controllable heat transfer using hybrid-like porous materials across solid-fluid interfaces is an important technical issue in engineering nanofluidic devices and nanoelectro-mechanical systems (NEMS) infiltrated with fluids [2,3].
We demonstrate experimental results of the femtosecond pulse laser-based time-domain thermo-reflectance (TDTR) and continuum laser wave-based micro-Raman spectral thermometry techniques measuring the thermal conductivity of nano-porous Si films infiltrated with various fluids. These heat conduction measurements were employed to validate finite-element mesh (FEM) simulations of laser-induced heating temperature distribution across these fluid-filled Si nanocomposite films of various porosities (30 - 70%) and fluid fillers (silicone oil and air).
It is established that the presence of liquid in the pores leads to a significant rise in due to the increase of the specific surface area of the liquid/solid interfaces. However, the fluid infiltration into the porous solid Si network induces a substantial reduction in compared to continuous bulk single-crystalline Si due to the presence of topologically interconnected thin solid Si walls of the porous medium [4]. Also, the obtained values were found to be higher than those of Si nanogranular films owing to the lack of additional interface thermal resistance across neighboring nanoparticle boundaries [5]. Additionally, our experimental results are in good agreement with earlier theoretical molecular dynamics (MD) calculations [6] and photoacoustic (PA) measurements in liquid filled Si nanocomposites [7, 8].
This work was supported by Nazarbayev University CRP grant 11022021CRP1504.

TBC Degradation Behavior Analysis Based on CMAS Sol for Evaluation of CMAS Resistance of TBC Janghyeok Pyeon, Bong-Gu Kim, Junseong Kim, Hyeryang Choi, Tserendorj Khadaa, Jung-Hun Son, Byungil Yang, Yeon-Gil Jung and SeungCheol Yang; Changwon National University, Korea (the Republic of)

Thermal barrier coatings (TBCs) have been generally applied to the blades and vanes of the gas turbine to protect alloy substrate from high temperature environment. CMAS (32CaO-7MgO-12Al2O3-49SiO2) material, existing in sand, volcanic ash, etc., is easily penetrates the pores inside the top coat under high temperature operation of gas turbine. The penetrated CMAS induces to thermal conductivity increase of top coat, and additional stress between bond coat and top coat due to the difference in their thermal expansion coefficient. Therefore, CMAS attack on TBC negatively affect the life time of the gas turbine blades and vanes. In this work, we synthesized CMAS sol, which can be uniformly penetrated in the top coat, to set up a new CMAS evaluation method. For the synthesis, the CMAS sol was prepared through pH control after dissolving the precursor of CMAS materials in nano-sized Si sol. The fixed amount of CMAS sol was uniformly applied to the surface of the YSZ specimen. Thereafter, the test piece was heat-treated at 1,300 ° C for melting the CMAS sol and infiltration of melted CMAS into the YSZ. As a result of microstructural analysis, penetration depth of the CMAS in the top coat increased with time increase of heat treatment. In addition, it was conformed that CMAS in the top coat was uniformly distributed. In addition, porosity of the YSZ top coat was decreased by a reaction between YSZ and CMAS. As a result of XRD analysis, we confirmed that monoclinic phase in YSZ increased with an amount increment of CMAS coated on YSZ.

5:00 PM SF03.06.12
Full Predictive Heat Transport Model for Electronic Devices at the 20 nm Scale Jordi Tur Prats[1], F. Xavier Alvarez[1], Lluc Sendra Molins[1], Juan Camacho[1], Javier Bafaluy[1] and Albert Beardo Ricol[1,2]; [1]Universitat Autònoma de Barcelona, Spain; [2]University of Colorado Boulder, United States

Simulation of the thermal evolution of actual electronic devices is a very challenging topic. Heat transport at the nanoscale does not behave as in the macroscale [1-2]. This is a problem for engineers, as they cannot predict the thermal response of their devices with accuracy.

In the last years, the Kinetic Collective Model (KCM) has been used to develop a finite element tool to describe the thermal evolution of electronic devices with great accuracy using the Guyer and Krumhansl hydrodynamic equation. The results obtained from this approach fit extraordinarily to experiment with characteristic scales up to 400 nm using only ab initio parameters [1-2], but for smaller devices, effective values for the parameters are required. In these situations, some corrections are required in order to predict the experiments.

We present the Higher Order Perturbation (HOPE) an improvement of the KCM-hydrodynamic approach [4-5]. This new method allows to obtain a full predictive finite element model for thermal transport at the 20nm scale. The model is obtained from the split of the Boltzmann Transport Equation (BTE) in two terms, a first one that describes the hydrodynamic behavior and a second one with the residual terms that describes the evolution of the perturbations of higher order. From the solution of the residual term using a Monte Carlo approach we derive a boundary correction term that modifies the hydrodynamic boundary conditions. With this correction, the applicability of our finite element tool is significantly improved. We compare the results obtained from our simulations with experimental data of devices in the 200-20 nm range.

Effect of Mechanical Alloying Methods on Nanostructured Aluminum-Graphite Composites Fabricated by Spark Plasma Sintering—Thermal Conductivity, Microstructure, Mechanical Property Bum Soon Park, Jeong-Han Lee, Hyun-Kuk Park and Jae-Cheol Park; Korea Institute of Industrial Technology, Korea (the Republic of)

In an effort to secure superior thermal conductivity compared to conventional metal heat-dissipating materials such as copper and aluminum, aluminum-graphite (Al-Gr) composites were prepared, and then mechanical and thermal properties depending on graphite contents were closely investigated. In this study, the graphite contents were changed to 20, 30, 40, 50, and 60 vol.% in order to sinter aluminum-graphite composites having different graphite content ratios. The Al-Gr composite powders mechanically synthesized by mixer milling were sintered under the following process conditions; sintering temperature of 480 °C, sintering pressure of 40 MPa, and duration of 2 minutes at the temperature of 480 °C. The relative density of the sintered body gradually decreased as the graphite content increased and showed the highest value of 94% when the Al-Gr content ratio was 8:2. The phase change and hardness of the Al-Gr sintered body depending on the graphite contents were investigated by XRD and Vickers hardness analysis, respectively. Furthermore, thermal conductivity as a function of the graphite content, which is the most important indicator of this study, was systematically investigated.

Pore Size Dictates Anisotropic Thermal Conductivity of Two-Dimensional Covalent Organic Frameworks with Adsorbed Gases Muhammad Akif Rahman and Ashutosh Giri; University of Rhode Island, United States

Two-dimensional covalent organic frameworks (COFs) are an emerging class of porous crystals that have already established themselves as game-changing materials due to their exceptional physical properties such as high porosities, large surface areas and flexibility of controlling the functional building blocks which make them ideal candidates for a plethora of applications, such as gas separation, adsorption and storage, drug delivery, and as solid-state electrolytes for upcoming energy storage technologies. However, the excessive heat generation due to the adsorption of guest species is one of the major bottlenecks for their alrge scale incorporation in aforementioned applications. Therefore, it is crucial to find innovative ways to modulate the thermal properties of COFs, which is contingent upon fully comprehending the essential characteristics that dictate the effectiveness of energy transfer in these materials. Herein, we carry out a detailed analysis of the influence of pore geometry on the overall heat transfer mechanisms in 2D COFs through systematic atomistic simulations demonstrating the thermal conductivity can either be increased due to additional heat channels introduced by the gas adsorbates or decreased due to the phonon scattering resulting from the interactions between the gas and the solid pore walls of the COFs.

We perform molecular dynamics simulations on pristine and gas adsorbed COF structures by varying the pore sizes and gas densities and reveal that for COFs with relatively larger pore sizes (>2 nm), despite the reduction of the thermal conductivity of the solid framework due to solid-gas scattering, the overall cross-plane thermal conductivity dramatically increases, which is attributed to the additional heat transfer pathways introduced by the low-frequency vibrations (<0.5 THz) of the gas adsorbates. On the other hand, for COFs with relatively smaller pores (<2 nm) both the cross-plane and in-plane thermal conductivities decrease monotonically due to the increase in phonon scattering resulting from the solid-gas interactions at the pore walls. Our simulations on COF/methane systems reveal the intricate relationship among gas diffusivities, pore geometries, and solid–gas interactions dictating the modular thermal conductivities in these materials. Furthermore, our results can also help guide the design of efficient 2D polymeric crystals for applications with improved gas storage, catalysis, and separation capabilities.

5:00 PM SF03.06.17
Investigating Optical and Thermal Properties in Novel Rare Earth Zirconates for Radiative Barrier Coatings William T. Riffe[1], Hunter Schonfeld[1], Milena Milich[1], Victor Champagne[2], Jeroen Deijkers[1], Haydn Wadley[1], David R. Clarke[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Harvard University, United States

Rare earth zirconates show promising optical and thermal properties required of next generation radiative barrier coatings (RBCs) for ultrahigh temperature (1500K+) applications. A fundamental mode of heat transfer that has been neglected in current barrier coatings is radiative heating between hot components. New research aims to mitigate both conductive and radiative heating by doping standard barrier coating materials with rare earth metals that are optically opaque in the spectral range of the emitted radiation.

In this work, we perform a series of thermal and optical studies via pump-probe thermoreflectance techniques and spectroscopic ellipsometry to elucidate temperature-dependent thermal conductivity, wavelength-resolved ultrafast electronic transitions, and optical constants of rare earth zirconates. Understanding the trends and thresholds of thermal conductivity is of utmost importance in selecting RBCs that can endure cycling to ultrahigh temperatures. Furthermore, we directly measure electronic excitations as a function of wavelength and incident fluence to relate non-equilibrium relaxation of electrons to the optical constants associated with peak blackbody emission at ultrahigh temperatures. By investigating the pertinent physical scattering mechanisms, we deconvolute key design considerations for next generation RBCs.

5:00 PM SF03.06.18
Application of Refractory Plasmonic Nanomaterials to Enhance 3D Printability of Thermoset Resins Madeline Finale, Sanchari Chowdhury and Youngmin Lee; New Mexico Institute of Mining and Technology, United States

Additive manufacturing of thermosets is attractive due to their potential for structural applications, especially for automotive and aerospace parts. However, additive manufacturing of thermosets using methods such as selective laser sintering could be challenging as the conventional thermosets do not exhibit thermoplastic-like melt flow behavior. We modify the chemistry of thermosets such as epoxy with Diels-Alder reaction to make it flowable at high temperatures. We added photothermal plasmonic refractory titanium nitride nanoparticles (TiN) to the epoxy. These photothermal nanoparticles can absorb light efficiently to generate heat instantly at the nanoscale. This can bring down the light intensity required for the printing significantly. Another important parameter for successful layer-by-layer printing is the time required to melt and solidify the thermosets. We developed an optical microscopy-based method to study the in situ melting of the epoxy composites under light and the time it takes to solidify when the light source is turned off. The nanoparticle loading, light intensity, and heat dissipation were studied to determine the optimal conditions for application in selective laser sintering. We could reach temperatures as high as 1500°C and start melting within 10 seconds with 0.78 W/cm^2 halogen lamp light source for the epoxy sample with 0.5 wt% titanium nitride nanoparticle loading. The sample without the nanoparticles could only reach 750°C when exposed to similar intensity via halogen lamp.

Gallium Arsenide Telescopic Nanowire-Based 'Thermal Diode' Yashpreet Kaur[1], Saeko Tachikawa[1], Miquel López-Suaréz[2], Milo Yaro Swinkels[1], Matteo Camponovo[1], Anna Fontcuberta i Morral[3], Riccardo Rurali[2] and Ilaria Zardo[1]; [1]University of Basel, Switzerland; [2]Universitat Autònoma de Barcelona (Spain), Spain; [3]EPFL, Switzerland

Photonics and electronics have reached a high level of control and sophistication in technology today, but heat manipulation continues to be a challenge. While nanoscale devices have made their way to industry, the problem of heat management still hinders their performances and is a limiting factor [1]. To achieve ultimate control over heat flow and cool down densely packed systems in current microchips, a thermal diode must be realized. A thermal diode is a device that enables heat to flow preferentially in one direction, thus, giving rectification.

Efforts have been made as early as the 1930s to study heat rectification theoretically and experimentally by exploring several mechanisms, including combining materials with the different temperature dependence of thermal conductivity [2]. Nanostructuring further helps tune the thermal conductivity due to phonon scattering effects, which was explored in nanowires for thermal rectification through molecular dynamic simulations in 2015 [3].

Here, we have exploited the size and temperature dependence of the thermal conductivity to manipulate heat flux and study thermal rectification experimentally. For this purpose, we investigate the thermal properties of semiconducting gallium arsenide nanowires with an abrupt change in diameter [4], also called telescopic nanowires. To perform precisely controlled thermal transport measurements on these nanowires, suspended silicon nitride platforms with Joule heaters are used to apply thermal gradients and measure thermal conductivity [5, 6]. Further, to obtain the temperature profile along the nanowire axis, Raman thermometry is performed upon applying a thermal gradient. Mapping the temperature of the heat channel provides us with the thermal conductivity of each section of the nanowire, as well as the interface resistance. We measured rectification values ranging from 2 to 7% at a range of ambient temperatures, with rectification values increasing for larger temperature gradients. The direction of rectification and its dependence on temperature gradient is confirmed by numerical calculations of the one-dimensional heat equation, based on thermal conductivities computed ab initio. Interface thermal resistance, calculated within the acoustic mismatch model, is explicitly accounted for. This work is the first experimental indication of rectification using a telescopic nanowire. Our findings make an impact in the direction of efficient thermal management and in the development of thermal circuit elements.

Investigation of Bond Quality and Interfacial Strain at a Room Temperature Bonded GaN-Diamond Interface via Raman Spectroscopy William; Delmas, Matthew Bahr, Anthony McDonald, Wyatt Hodges, Amun Jarzembski, Zachary Piontkowski and Luke Yates; Sandia National Laboratories, United States

Vertical gallium nitride (GaN) power devices have the potential to improve power conversion efficiency in electrical circuits due to enhanced mobility and high critical electric field. Since device performance and reliability are directly related to thermal performance, there is significant interest in improving options for passive thermal management. To this end, the heterogeneous integration of diamond with vertical GaN devices is explored. In this current work, the bond quality of a bulk GaN substrate with single-crystal diamond via an intermetallic surface activated Au bond is investigated. The intermetallic layer in the GaN-diamond stack potentially creates a phonon bridge for enhanced heat dissipation out of GaN and into the diamond. However, it is unclear whether/how the bonding will introduce strain in the GaN crystal, which can negatively impact electrical performance and device reliability. Here, we use high-resolution micro-Raman spectroscopy to characterize the strain in the GaN near the interface. The quality of the interfacial bonding between GaN and diamond is evaluated via Scanning Acoustic Microscopy (C-SAM). The C-SAM images are referenced to bonded and non-bonded regions for further investigation via micro-Raman. The micro-Raman maps revealed localized regions of strain when moving from a non-bonded to bonded area. This result highlights two important aspects of the interface when optimizing for thermal boundary conductance: 1) Interfacial bonding is not necessarily uniform and requires spatial mapping for full characterization. 2) Although bonded and non-bonded regions of an interface may not show strain changes post bonding, the transition between these regions may be strained and have an impact on the device performance. Moving forward, Raman strain maps and C-SAM images of bonded and non-bonded regions will be combined with thermal mapping, via frequency-domain thermoreflectance (FDTR), to fully characterize the thermal and mechanical properties across an entire interfacial region. This work will provide additional insight into the inhomogeneity of a room temperature bonded GaN-diamond interface and the subsequent non-uniform strain profiles that exist near bonding sites. Measurement of Electronic Thermal Conductance in Low Dimensional Materials with Nonlocal Noise Thermometry Philip Kim; Harvard

University, United States

In low-dimensional systems, the combination of reduced dimensionality, strong interactions, and topology has led to a growing number of many-body quantum phenomena. Thermal transport, which is sensitive to all energy-carrying degrees of freedom, provides a discriminating probe of emergent excitations in quantum materials. However, thermal transport measurements in low dimensions are dominated by the phonon contribution of the lattice. An experimental approach to isolate the electronic thermal conductance is needed. In this presentation, I will discuss how the measurement of nonlocal voltage fluctuations in a multiterminal device can reveal the electronic heat transported across a mesoscopic bridge made of low-dimensional materials. By using graphene as a noise thermometer, we demonstrate quantitative electronic thermal conductance measurements of graphene and carbon nanotubes up to 70K, achieving a precision of ~1% of the thermal conductance quantum at 5K. Employing linear and nonlinear thermal transport, we observe signatures of long-range interaction-mediated energy transport in 1D, in agreement with a theoretical model.

8:30 AM SF03.07.02
Thermoelectric and Photovoltaic Energy Conversion in Interlayer Exciton Structures Yajie Huang[1], Sizhe Weng[2], Yu Wang[2], Steve Cronin[2,2] and Li Shi[1]; [1]The University of Texas at Austin, United States; [2]University of Southern California, United States

Excitons are bound electron and hole pairs. Recent spectroscopic and electronic transport measurements have observed potential Bose-Einstein condensation signatures of interlayer excitons in van der Waals heterostructures of transition metal dichalcogenides (TMDs). Thermoelectric measurement can provide unique insight into unusual collective energy transport behaviors associated with the bosonic nature of excitons. Here, we explore thermoelectric and photovoltaic measurements in two-dimensional TMDs heterostructures separated by a hexagonal boron nitride insulating layer. With their charge carrier concentration controlled by separate bottom and top gates, an n-type material and a p-type material can be connected electrically in series and thermally in parallel, similar to a thermoelectric couple. A lateral temperature gradient drives the diffusion of the electrons and holes from the hot side to the cold side, giving rise to a thermoelectric current. These thermoelectric and optoelectronic properties are measured at different combinations of the electron and hole concentrations to search for signatures of exciton binding and improved energy conversion.

8:45 AM SF03.07.03
Engineering Spin Coherence in Core-Shell Diamond Nanocrystals Peter Maurer; The University of Chicago, United States

Diamond nanocrystals can harbor spin qubit sensors capable of probing the physical properties of biological systems with nanoscale spatial resolution. These diamond nanosensors can readily be delivered into intact cells and even living organisms. However, applications beyond current proof-of-principle experiments require a substantial increase in sensitivity, which is generally limited by surface-noise-induced spin dephasing and relaxation. In this talk, I will discuss a novel strategy to significantly reduce the surface noise by engineering core-shell structures, which on average result in a 3.5-fold increase in spin coherence and spin-lattice relaxation time. Probing qubit dynamics at a single particle level, furthermore, reveals that the noise characteristics change from a model consistent with a two dimensional dipole fluctuator model to a more dilute three dimensional bath. Our results shed light on the underlying mechanisms governing spin dephasing in diamond nanocrystals and offer an effective noise mitigation strategy based on engineered core-shell structures.

9:00 AM SF03.07.04
Tuning and Probing Interfacial Thermal Conductance between Moiré Superstructures Devika Mehta, Emma Martin, Nemin Wei, Yajie Huang, Allan MacDonald and Li Shi; The University of Texas at Austin, United States

The operating temperature of emerging two-dimensional (2D) electronic and optoelectronic devices is sensitive to the interfacial thermal conductance of the 2D layered materials. In past work, this thermal transport property has been probed by time-domain thermal reflectance (TDTR) measurements and tuned by electrochemical intercalation. Here we report an experiment that probes interfacial thermal transport between twisted bilayer graphene (TBG) moiré superstructures separated by a thin hexagonal boron nitride layer with the use of steady state resistance thermometry measurements. Besides the thin film platinum gates that can serve as the resistance thermometers, the large temperature coefficient of resistance of TBG enables sensitive measurements of the small temperature drops between the two moiré superstructures. The improved sensitivity allows for the observation of the dependence of the measured interfacial thermal conductance on the gate electric fields applied to the two moiré superstructures. The measurement results are compared to theoretical calculations to understand the field effects on the lattice contribution to the interfacial thermal conductance through the van der Waals interfaces, and to search for an additional contribution due to a predicted Coulombic interaction mechanism.

9:15 AM SF03.07.05
Universal Heat Flow Behavior in Highly-Confined Semiconductor Nanosystems Albert Beardo Ricol[1,2], Brendan McBennett[1], Emma Nelson[1], Begoña Abad Mayor[1], Travis Frazer[1], Yuka Esashi[1], Baowen Li[1], Henry Kapteyn[1], Margaret Murnane[1] and Joshua Knobloch[1]; [1]University of Colorado Boulder, United States; [2]Universitat Autònoma de Barcelona, Spain

The thermal evolution of nanostructured semiconductor devices has been shown to exhibit non-diffusive behaviors that cannot be interpreted using effective forms of Fourier's law [1]. Predicting and understanding this phenomenology using models solvable in arbitrary geometries is key to developing efficient thermal management strategies for nanoelectronic and thermoelectric applications.

Here, we study the process of energy release from nanoscale heat sources towards a silicon substrate using an infrared pump laser to excite the sample and an extreme ultraviolet probe to dynamically monitor its relaxation. We perform these experiments both in a semi-infinite substrate [1], and a 3D nanostructured metalattice substrate, consisting of a Si crystalline nanostructure with periodically distributed spherical nanovoids [2]. To develop a unifying description of heat flow from both nanoscale hotspots and in nanostructured materials, we use a hydrodynamic heat equation recently derived from the Boltzmann Transport equation (BTE) [3]. For a semi-infinite substrate, the heater temperature follows a double-exponential decay that cannot be fit using effective Fourier modeling, but can be predicted using the hydrodynamic equation with ab initio calculated parameters. For a nanostructured substrate, an analogy to rarefied gas flow in porous media can be used to distinguish a geometry-dependent *permeability* contribution to thermal conduction from an intrinsic *viscous* component, which scales universally with porosity across all systems where feature sizes are much smaller than the dominant phonon mean free paths. This leads to an analytic description of thermal conduction in highly-confined silicon nanosystems, extensible to nanomeshes, porous nanowires or nanowire networks [2], thus enabling their representation as effective media for engineering design applications.

Finally, we compare the hydrodynamic modeling of the experiments with alternative approaches such as direct solvers of the BTE with simplified forms of the Collision operator. In particular, we discuss the validity of some assumptions commonly used to solve the BTE in the presence of boundaries, which prevent the emergence of collective phonon evolution in highly-confined conditions in materials such as silicon.

SESSION SF03.08: Thermal Transport Under Extreme Conditions

Session Chairs: Raymond Jeanloz and Thomas Pfeifer
Wednesday Morning, April 12, 2023
Marriott Marquis, B2 Level, Golden Gate A

10:00 AM *SF03.08.01
Ultrahigh-Pressure Experiments on Thermal Transport—Linking Theory to Applications Raymond Jeanloz and Mercedes Vasquez; University of California-Berkeley, United States

Ultrahigh-pressure experiments reveal significant changes in the stability, elasticity and transport properties of crystalline and fluid matter, challenging first-principles theory and helping in the development of new materials. Compression into the high energy-density regime (pressures exceeding 10^11 Pa or 10^6 atmospheres) causes electronic as well as crystal-structural transitions due to the thermodynamic perturbation being comparable to valence electron energies (~ eV): insulators become metals (and vice-versa), ions change shape as well as size, and chemical bonding is altered. Recently, time-domain thermoreflectance (TDTR) and other pulse-probe measurements have been integrated with diamond cells to quantify thermal transport under static high pressures. The connection between thermal and electron transport is currently receiving particular attention, the results to date being in agreement with established theory of electron and phonon scattering, and providing important constraints on our planet's early evolution. Future experiments using dynamic compression may allow measurements to be extended into the realm of atomic pressures (10^{13} Pa), at which the structure of the atom is fundamentally altered and compressional energies exceed core-electron values (keV). Experiments at such extreme conditions are part of a strategy for advancing theory and producing new materials of interest under practical, near-ambient conditions.

10:30 AM SF03.08.02
High-Pressure Thermal Transport Physics in Extreme Materials Suixuan Li, Zihao Qin, Huan Wu, Man Li and Yongjie Hu; University of California, Los Angeles, United States

High pressure represents extreme environments and provides opportunities for materials discovery. Thermal transport under high hydrostatic pressure has been investigated for more than 100 years and all measurements of crystals so far have indicated a monotonically increasing lattice thermal conductivity. Here we report in situ thermal transport measurements in the newly discovered semiconductor crystal boron arsenide, and observe an anomalous pressure dependence of the thermal conductivity. We use ultrafast optics, Raman spectroscopy and inelastic X-ray scattering measurements to examine the phonon bandstructure evolution of the optical and acoustic branches, as well as thermal conductivity under varied temperatures and pressures up to 32 gigapascals. Using atomistic theory, we attribute the anomalous high-pressure behaviour to competitive heat conduction channels from interactive high-order anharmonicity physics inherent to the unique phonon bandstructure. Our study verifies ab initio theory calculations and we show that the phonon dynamics—resulting from competing three-phonon and four-phonon scattering processes—are beyond those expected from classical models and seen in common materials. This work uses high-pressure spectroscopy combined with atomistic theory as a powerful approach to probe complex phonon physics and provide fundamental insights for understanding microscopic energy transport in materials of extreme properties.

10:45 AM SF03.08.03
Hydrodynamic Experimental Observations in Bulk Semiconductors F. Xavier Alvarez[1], Lluc Sendra Molins[1], Albert Beardo Ricol[1,2], Juan Camacho[1], Javier Bafaluy[1] and Jordi Tur Prats[1]; [1]Universitat Autonoma de Barcelona, Spain; [2]University of Colorado Boulder, United States

A large number of experimental observations incompatible with the classical Fourier description of thermal transport at the nanometer and in the picosecond scales has been reported in the last decade [1,2]. Despite the theoretical efforts done in the topic, a model able to describe the gathered data at all length and time scales is still not available.
Two different descriptions have been proposed. Phonon hydrodynamics has been used as a framework to model thermal transport in materials where momentum conservation in phonon-phonon collisions is important. For other situations, a kinetic description based on the propagation of independent phonons, in what is called quasiballistic description, has been developed. The fundamental difference between them is in the number of length or time scales required to describe the observations. While in the hydrodynamic approach, a single scale is enough, in the quasiballistic description, the full set of phonon scales is necessary.
Traditionally, for graphene and other 2D materials, the hydrodynamic approach has been the traditional main stream, while the quasiballistic approach has been more used for classical bulk semiconductors. But in the last years, some experiments and theoretical descriptions seems to be challenging this traditional splitting. On the one side, some predictions of the hydrodynamic regime for 2D materials like the second sound velocity have put on doubt the standard approach. On the other side, collective phonon behavior like the use of a single time scale to describe thermal decay in a silicon substrate [3] or the observation of second sound in germanium [4] seem to indicate that the hydrodynamic description could be used in these semiconductors. This could be an indication that a more unified framework could be proposed.
The talk will cover some of the most recent evidences in the theoretical and experimental research on thermal transport and we will analyze them in the framework of the Kinetic/Collective model (KCM) [5], developed to give a more generalized framework to describe thermal experiments.

11:00 AM SF03.08.04
Accurate Prediction of Thermal conductivity of Crystals at Ultra-High Temperatures Janak Tiwari and Tianli Feng; University of Utah, United States

Many cutting-edge applications have been pushing thermal transport to ultra-high temperatures (e.g., 1000 - 3000 K), such as thermal management of hypersonic aircraft and re-entry vehicles, thermal barrier coatings of the next-generation turbine systems operating at higher temperatures, and the development of next-generation higher-temperature nuclear power plants and fusion plants. However, the fundamental thermal transport processes at ultra-high temperatures in solids remain unclear and in debate, and the predicted thermal conductivity ( ) cannot match with the experiment in most materials at high temperatures. Without a good understanding or accurate prediction of thermal transport, many potential revolutions in materials and technologies may not be realized. Phonon, a quantized mode of lattice atomic vibrations, is the main heat carrier in most solids, especially in nonmetallic materials (e.g., dielectrics and insulators), where there are no free electrons. Phonons carry heat through interatomic interactions, which can be predicted from density function theory (DFT) solely based on the atomic structure. The prediction of thermal conductivity from first principles without any fitting parameter or any help from the experiment has achieved great success in recent years for a vast number of systems but usually fails at high temperatures. In this work, we used the first-principles method to predict the thermal conductivity of several crystals including UO2, ZrC, and HfC, most important ultra-high temperature ceramics, by including both three and four-phonon scattering as well as the temperature-dependent force constant, for the first time. We find that, at ultra-high temperatures, four-phonon scattering significantly reduces thermal conductivity but the temperature-dependent anharmonic force constants tend to bring it up. The predicted thermal conductivity is compared to various experimental data. The impact of grain size and defects are also studied. This work sheds important light on the fundamental thermal transport in ultra-high temperature ceramics and will pave the way towards the engineering and development of next-generation technologies with thermal management at ultra-high temperatures.

11:15 AM SF03.08.05
Nominal Negative Contact Thermal Resistance between Boron Nitride Nanotubes with a Gold Interlayer Zhiliang Pan, Guanyu Lu, Joshua D. Caldwell and Deyu Li; Vanderbilt University, United States

Thermally conductive polymer composites are competitive candidates for thermal interface materials, which find extensive applications in the thermal management of modern electronic devices. To date, numerous filler materials have been explored, including carbon nanotubes, ceramic particles, and metal nanowires. In particular, the requirement of electrical insulation in electronic devices warrants the rising attention paid to boron nitride nanotube- (BNNT) and nanosheet- (BNNS) based composites. One key issue in understanding the performance of polymer composites is the contact thermal resistance between nanofillers, with and without a polymer interlayer between the fillers. Previous studies have revealed interesting transport phenomena such as non-intrinsic ballistic contact resistance due to phonon reflection and bi-directional modulation of the contact thermal resistance from a polymer interlayer between BNNTs, which provide insights into enhancing the thermal performance for BNNT-based polymer composites.
Here we report on efforts towards further reducing the contact thermal resistance through introducing a gold interlayer at the contact region, which could help eliminate phonon reflections with minimal added diffusive thermal resistance. Systematic measurements have been done to compare the contact thermal resistance between bare BNNTs (R_{C}) with those including a gold interlayer ($R_{C,Au}$). As the low resistance gold interlayer removes phonon reflection resistance, $R_{C,Au}$ is smaller than R_{C} in the entire measurement temperature range. For example, the contact thermal conductance is enhanced by ~200% for a 50 nm BNNT at room temperature and the enhancement decreases with increasing tube diameter as the phonon reflection effect is smaller for larger tubes. Surprisingly, opposite to the trend for R_{C}, $R_{C,Au}$ starts to decrease quickly as the temperature drops below 150 K and becomes negative below 80 K for the 50 nm BNNT sample. This negative $R_{C,Au}$ indicates that some interesting transport mechanism has been introduced by the inclusion of the gold interlayer. Since the gold interlayer is not included in the thermal pathway, the observed nominally negative contact thermal resistance must occur through altering the thermal transport along the tube. One possible reason is that the gold interlayer boosts thermal transport along the tube through introducing surface phonon polaritons (SPhPs) into the tube. As a quasi-particle comprised of a photon strongly coupled with polar optical phonons, this hybrid mode benefits from the high heat capacity associated with optical phonons and the non-negligible group velocity of the optical phonons. A nominally negative $R_{C,Au}$, extracted by subtracting the thermal resistance of the corresponding bare BNNT from the total measured thermal resistance of the contact sample, could occur if the inclusion of the gold interlayer provides an additional thermal transport pathway, here we propose that the inclusion of the gold interlayer serves as a launcher for stimulating SPhPs which in turn can carry heat along the BNNT. This hypothesis is further supported by the fact that the propagation length of SPhPs increases as temperature drops. Therefore, the relative contribution of SPhPs enhances at lower temperatures and indeed, $R_{C,Au}$ becomes smaller as temperature drops and after $R_{C,Au}$ turns negative, its magnitude keeps increasing ($R_{C,Au}$ becomes more negative) as the temperature drops further. The above findings disclose rich physics in thermal transport through BNNTs and their contacts with a gold interlayer, which could be utilized to improve thermal performance of BNNT-based polymer composites.

11:30 AM SF03.08.06
A Nanoscale Thermometry Technique for the Measurement of Enthalpy of Melting Thomas W. Pfeifer, Sara Makarem and Patrick E. Hopkins; University of Virginia, United States

Differential Scanning Calorimetry (DSC) is used for the measurement of the enthalpy of melting within phase change materials (PCM), however it requires the use of semi-bulk samples, which may be difficult to obtain in the case of bleeding edge materials. In order to characterize these, as required for advancements in energy storage or novel electronic storage devices, alternative methods must be pursued.
We present the development of a nanoscale thermometry technique wherein we use a high power laser to induce a phase change in a PCM. The laser is focused to a micron-sized spot on the sample, which is elevated in temperature and eventually melted. The changes in temperature are monitored via a second laser in a similar manner as existing thermoreflectance experiments (TDTR, FDTR, SSTR). By recording the resultant temperature rise waveform, the thermal arrest due to melting can be observed, and a numerical model (capturing heating, melt pool formation and growth, and subsequent melt heating) can be used to back out the enthalpy of melting associated with the phase change.
Several additional experimental considerations are also captured. For example, as with all thermoreflectance experiments, an optically-reflective transducer is required. Similarly, thermal properties may also vary following melting. Finally, we note that this technique is not limited to solid-liquid phase changes only. While crystalline solid-solid phase changes may have a lower enthalpy associated, the fundamental principles of operation still apply.

11:45 AM SF03.08.07
Are Niobium Oxide Dihalide Materials Good Thermoelectrics—The Study Case of $NbOI_2$ Bastien F. Grosso and David O. Scanlon; University College London, United Kingdom

Thermoelectric materials offer the possibility to transform heat waste directly into electrical energy. Finding such materials is challenging since they should have simultaneously a large electrical conductivity and a low lattice thermal conductivity. These almost mutually exclusive conditions are usually encountered in materials containing Pb, making them not sustainable. Therefore, we study oxide dihalide materials as a sustainable alternate option.
We propose here to evaluate the potential for thermoelectric applications of the niobium oxide dihalide materials. Our study is motivated by the chemical abundance and ease of fabrication of oxyhalides, and the wide range of properties offered by the presence of mixed anions. We consider the case of $NbOI_2$ and find that this material has a relatively large electron affinity, making it likely to be a good n-type semiconductor. We calculate the electronic transport properties and lattice thermal conductivity through the third-order force constants and discuss its potential for thermoelectricity.

SESSION SF03.09: Nanoscopy and Non-Equilibrium Transport

Near-Field Ultrafast Nanoscopy of Energy Transport in Semiconductor Nanowires Jingang Li[1], Rundi Yang[1], Yoonsoo Rho[2] and Costas Grigoropoulos[1]; [1]University of California, Berkeley, United States; [2]Lawrence Livermore National Laboratory, United States

Carrier distribution and dynamics in semiconductor materials often govern their physical properties that are critical to functionalities and performance in industrial applications. Conventional pump-probe microscopy has limited spatial resolution due to the optical diffraction. Recently, ultrafast infrared-terahertz nano-spectroscopy was developed through the integration of scanning near-field optical microscopy and pump-probe optics. However, given the limited photon energy, the efforts have been primarily focused on studying carrier dynamics in narrow bandgap semiconductors or graphene plasmons. Here, we first report near-field ultrafast optical nanoscopy in the visible-near-infrared spectral region to access the carrier dynamics in silicon, one of the most prevalent materials in current semiconductor technology. Our pump beam has a wavelength of 400 nm (3.1 eV), which is sufficient to excite carriers in common optoelectronic semiconductors, including silicon (bandgap of 1.12 eV) and GaAs (bandgap of 1.42 eV). By combining ultrafast nanoscale measurements and theoretical modeling, we unravel the local photocarrier recombination dynamics in silicon nanowires. Moreover, we demonstrate the spatial mapping of carrier lifetime in silicon with a sub-50 nm resolution. Our results provide the capability to probe carrier behaviors in nanoscale materials and devices. By utlizing this experimental platform, we can experimentally access the nonequilibrium regime of energy transport in the nanoscale. In this context, we will show spatially and temporally resolved probing of transient energy transport in nanowires and nanobeams.

2:00 PM SF03.09.02
µ-Raman Thermography on Epitaxially Integrated NWs Confirms Negligible Thermal Contact Resistance Jose Manuel Sojo Gordillo[1,2], Carolina Duque Sierra[2], Yashpreet Kaur[1], Saeko Tachikawa[1], Nicolas Forrer[1], Nerea Alayo[2], Marc Salleras[3], Luis Fonseca[3], Alex Morata[2] and Albert Tarancón[2,4]; [1]University of Basel, Swaziland; [2]Catalonian Institute for Energy Research, Spain; [3]Institute of Microelectronics of Barcelona, Spain; [4]Catalan Institution for Research and Advanced Studies (ICREA), Spain

Currently employed materials in Thermoelectric Generators (TEGs) such as bismuth telluride or lead telluride are scarce, expensive, toxic, and environmentally harmful. In recent years, the thermoelectrics paradigm has changed mainly due to the introduction of low-dimensional materials able to reduce the thermal conductivity by phonon scattering. Semiconductor nanowires (NWs) have demonstrated fascinating properties with applications in various fields, including energy and information technologies. In particular, increasing attention has been focused on Si and silicon alloy NWs for applications in thermoelectric generation after recent successful implementation in miniaturized devices. Despite this interest, a proper evaluation of such nanostructures' thermoelectrical properties still represents a great challenge, especially when the complete characterization of the device-integrated NW is desired.

In this work, we describe the thermal analysis of epitaxially suspended rough Si NWs fabricated using a bottom-up approach following the Vapour-Liquid-Solid (VLS) method. The thermal analysis is carried out using a technique that simultaneously combines the Joule self-heating of the nanowire with micro-Raman thermometry for their thermal profiling. This sub-micrometer-resolved temperature profiling is achieved using a custom-made set-up for the acquisition of the Raman spectra within a temperature-controlled vacuum chamber. The high resolved signal of the nanostructure can be measured thanks to specifically devoted silicon-based microstructures with though trenches that eliminate the background signal of the substrate. This device also enables the analysis of the same NW with Transmission Electron Microscopy (TEM) for an accurate morphological and structural analysis.

This experiment allows to characterize the electrical and thermal conductivity of individual Si NWs and the effects of a high rough surface on these properties. The defect-free crystalline structure of the NWs and the nature of their roughness is studied with TEM. Complementary, the shape of the obtained thermal profiling yields information about the absence of electrical or thermal contact resistance between bulk and nanostructure, confirming the double-side epitaxial attachment expected for a VLS-grown NW. Finally, the combination of Joule and laser power tests required for the calibration permits to estimate the light absorption coefficient of such rough surfaces.

In conclusion, the combination of this set of techniques allows us to verify the integration of VLS NWs in the very same configuration as those used into micro-thermoelectric generators, yielding accurate thermoelectric property values that can be directly applied on the improvement in the output power of the latter.

High-Performancee Planar-Type Nanophononic Si Thermoelectric Generator with a Double Cavity Structure Ryoto Yanagisawa[1], Patrick Ruther[2], Oliver Paul[2] and Masahiro Nomura[1]; [1]The University of Tokyo, Japan; [2]University of Freiburg, Germany

Thermoelectrics energy harvesting is one of the key technologies for carbon neutral. We demonstrate the planar-type silicon thermoelectric generator (TEG) with phononic nanostructures based on phonon-engineered design. The planar-type device was fabricated in an SOI wafer with CMOS and MEMS processes so that the device can be largely integrated. By using phononic nanostructures and three-dimensional thermal design, we achieved 200 μWcm^{-2} output power density at a temperature difference of 12.5 K, which is the highest-performing planar-type Si thermoelectric generator reported to date.
We fabricated the Si TEG in an SOI wafer with a 1.1-μm-thick n-type poly-Si device layer and a 1.5-μm-thick BOX layer. The poly-Si layer was doped with phosphorous at 2.0×10^{20} cm^{-3} carrier density, and the Seebeck coefficient is 100 μVK^{-1}. The phononic crystal (PnC) nanostructures were formed by electron beam lithography and reactive ion etching of poly-Si. The PnC structures are an array of circular holes with a period of 300 nm with a neck size between 8 and 100 nm. It was designed to reduce the thermal conductivity of poly-Si by considering the phonon mean free path spectrum. The cap wafer, which was designed for efficient cooling of the device, was fabricated and bonded on the TEG by flip-chip bonding. This double-cavity thermal design leads to a high-power density of the device. The single unit of the TEG has an area of 44 μm by 73 μm, and 2,400 units are integrated into a 2.64 mm by 2.92 mm area with 120 series and 20 times parallel connections.
The TEG performance was measured in the air around room temperature. We found that more than 30% of the temperature difference between the upper and bottom of the device was applied in the thermoelectric material thanks to the careful thermal design of the double cavity structure. Since the power density of the TEG is proportional to the square of the temperature difference, this thermal design is an important key factor, as well as the ZT of the thermoelectric material. Our TEG showed the output power density of about 200 μWcm^{-2} at a 12.5 K temperature difference between the device (about 4 K in thermoelectric material). The obtained normalized performance of 1.3 $\mu Wcm^{-2}K^{-2}$ is, to our knowledge, the highest-performing planar-type Si thermoelectric generator reported to date.

Differential Multi-Probe Thermal Transport Measurements of Individual Carbon Nanotubes Grown by Chemical Vapor Deposition Qianru Jia, Yuanyuan Zhou and Li Shi; University of Texas at Austin, United States

As a transport property important for thermal management applications, the solid thermal conductivity of graphitic materials can potentially exhibit peculiar behaviors that deviate from Fourier's law description of diffusive thermal transport. In nonmetallic solids, the thermal conductivity is dominated by the contribution of phonons. Ideal one-dimensional (1D) lattice can exhibit the Fermi-Pasta-Ulam-Tsingou (FPUT) paradox, for which the recurrence of excited phonon modes is accompanied by the extremely slow decay of heat flux correlation and a divergence of the effective thermal conductivity (k) with length (L) according to a power law relationship, $\sim L^{\alpha}$ with $0<\alpha<1$ even at room temperatures. In three-dimensional bulk crystals, in comparison, the divergence is reduced or removed by elastic anisotropy at low temperatures and by four-phonon scattering at high temperatures.
Carbon nanotubes (CNTs) are quasi-1D nanostructures that can behave differently from idealized 1D lattice chains and 3D crystals. According to recent theories, momentum-conserving normal scattering of phonons can dominate Umklapp processes in graphitic materials including CNTs to produce hydrodynamic phonon transport behaviors and length-dependent thermal conductivity due to the hydrodynamic entrance effect. Based on a prior theoretical study, in comparison, first-order three phonon scattering alone yields a $L^{1/2}$ divergence of the calculated k of a single-walled CNT, whereas additional higher-order phonon-phonon scattering results in a saturation of k when L is increased to about 10 μm. While there exist different theories on the length dependence, ultrahigh room-temperature thermal conductivity values, up to 6000 $Wm^{-1}K^{-1}$ at room temperature, have been calculated for individual single-walled CNTs (SWCNTs) by both first principles based phonon transport models and molecular dynamics simulations. These theoretical predictions have motivated both thermal transport measurements and thermal management applications of CNTs. However, existing reported experimental thermal conductivity values of individual SWCNTs and multi-walled (MW) CNTs vary by one order of magnitude due to the variation of sample quality and uncertainty in the measurement methods.
Here we report recent progress in differential four-probe thermal transport measurements of individual CNTs grown by methane chemical vapor deposition (CVD). Individual CNTs synthesized over long trenches are transferred and assembled on multiple suspended thin film metal resistance thermometer lines. A recently reported multi-probe thermal transport measurement method is employed to separate the thermal resistance of suspended CNT segments from the contact thermal resistance. A theoretical model is established to obtain the non-equilibrium temperature distribution along the contacted and suspended segments of the CNT and to extract the intrinsic thermal conductance of the suspended segments. The signal-to-noise ratio is enhanced with the use of a differential Wheatstone bridge based measurement scheme and Fast Fourier transform analysis of the data, which are measured with discrete heating levels in the heaters. The crystal structure and dimension of the suspended CNT segments are characterized by transmission electron microscopy. This method has been employed to measure the thermal transport properties of different suspended segments of the same CNT samples in the temperature range between room temperature and 10 K. The effects of metal coating on either the contact areas or the suspended segments of the CNTs are observed. The measurement method and obtained results help to advance the understanding of the peculiar phonon transport behaviors in quasi-1D CNTs.

Phase Identification in Cryopreserved Systems via Thermal Conductivity and Crystal Symmetry Effects Spencer P. Alliston and Chris Dames; UC Berkeley, United States

Long-term preservation of biological tissue is a research goal amongst biomedical researchers and bioengineers for its potential impacts such as improving efficacy of organ transplants, a problem for which incremental advances correlate to thousands of lives saved each year. In particular, there is a concentrated research push towards achieving long-term organ storage via bulk vitrification of tissues, in which tissues are rapidly cooled while suppressing ice formation. Low-temperature storage of tissues in an amorphous phase prevents ischemic cell death and enables virtually limitless storage times. Among the barriers to this goal is the lack of a non-invasive diagnostic method to determine the phase of solid biological samples. Current quantitative techniques, including X-ray diffraction and direct measurement of cell death, are time- and cost-intensive and damaging to samples. Otherwise, imprecise measures such as visual examination for cracking are used. An optimal technique for probing phase in vitreous biological systems would be non-destructive to cells, distributable for research and clinical applications, and resolvable for times and sizes used in vitrification protocols.

To achieve this, we implement the 3ω method as an *in situ* thermal method to determine phases of representative samples, made possible by the high dependance of thermal conductivity on crystal structure. To demonstrate this, solutions of water and cryoprotective agents (CPAs) are used as representative thermal systems on a temperature-controlled cryogenic stage with electrical and optical feedthroughs. By manipulating CPA concentration and cooling rate, the sample can be selectively solidified into a vitrified (amorphous) or crystalline state. This solid phase is stable and allows for exploration of a variety of potential characterization methods, including a modified 3ω method for thermal conductivity. Today, we demonstrate the viability of an alternative scheme in which a 'buried substrate' is measured allows for simplified experimentation and fabrication, which was preferred for dissemination of the technique.

A parallel study utilizes the refractive properties of crystals as an indication of phase. Ordinary ice (ice I_h) has a hexagonal crystal structure which exhibits birefringence. This causes the double refraction of incident polar excitations. As amorphous solid water, or a vitreous organ, is isotropic and therefore not birefringent, polarized light macroscopy can be used as an independent metric for the phase of representative samples. Here, we demonstrate the use of optical techniques as a means for phase identification in representative systems and explore the potential of polarized acoustics as a high-speed, volumetric probe for crystal symmetries in opaque systems.

3:00 PM SF03.09.06
Thermal Transport in Ga_2O_3 Polymorph Heterostructures Azat Abdullaev[1], Kairolla Sekerbayev[1], Alexander Azarov[2], Zhandos Utegulov[1] and Andrej Kuznetsov[2]; [1]Nazarbayev University, Kazakhstan; [2]University of Oslo, Norway

Gallium oxide (Ga_2O_3) is a very promising material that belongs to the novel class of ultra-wide bandgap semiconductors exhibiting such unique features as very high electric field breakdown, acceptable electron mobility, low-cost fabrication process, etc. However, there is a fundamental limitation of Ga_2O_3 attributed to its low thermal conductivity [1]. Therefore, effective thermal energy management is crucial for the further development of Ga_2O_3 technology. Up to now, most of the studies on Ga_2O_3 were focused on its conventional monoclinic β-phase due to its high stability, but thermal management is not limited just to this phase and there is a strong interest to explore properties of other phases [2]. The second most studied structure is corundum α-Ga_2O_3, but it is a metastable phase that converts to monoclinic β-phase at high temperatures (~650°C) [3]. Most recently it was demonstrated that ion implantation can result in the formation of highly oriented new Ga_2O_3 polymorph on the top of β-phase having sharp polymorph interfaces. This new phase was identified as orthorhombic κ-Ga_2O_3 [4] or defective cubic spinel γ-Ga_2O_3 [5]. Moreover, there is a strong demand to study the properties of phase-transformed interfaces, particularly thermal transport as it has a great impact on device performance. To the best of our knowledge, there is also no information from the literature neither on the thermal properties of κ- or γ-Ga_2O_3, nor on interfacial thermal conductance across phase-transformed interfaces, nor on phonon transport in ion beam-modified Ga_2O_3 materials.
In this work, we study the phonon thermal transport in [010] oriented β-Ga_2O_3 irradiated by 500 keV, 1 MeV, and 1.7 MeV Ga ions to a fluence of 6×10^{15} ions/cm^2. X-ray diffraction and Rutherford backscattering spectrometry techniques reveal a radiation-induced phase transformation in the implanted region. Heat transport measurements were performed using a femtosecond laser-based frequency-modulated time-domain thermoreflectance (TDTR). By controlling the penetration depth of the thermal waves using different modulation rates, we could spatially probe two different regions: first was several hundred nanometer-thick new phase and damaged β-phase. The thickness of the new phase was estimated to be in excellent agreement with the Rutherford backscattering technique, therefore demonstrating the capability of TDTR to spatially isolate the conductivities of individual phases. To validate the experimental results, the density functional theory was implemented to predict the thermal conductivity of the emerging κ-phase.
This work was supported by Nazarbayev University collaborative research program (CRP) grant 11022021CRP1504. M-ERA.NET GOFIB project (RCN project number 337627) is also acknowledged for financial support.

3:30 PM *SF03.10.01
First-Principles Studies of Thermal Conductivity in $AlGaO_3$ Alloys Chris G. Van de Walle; University of California, Santa Barbara, United States

Gallium oxide (Ga_2O_3) has promising applications in high-power and high-frequency electronics due to its wide band gap and excellent electronic transport properties. However, practical device applications are hampered by its low thermal conductivity. Devices also require forming heterojunctions with the wider-bandgap aluminum gallium oxide. We investigate the lattice thermal conductivity of monoclinic Ga_2O_3 and of the $AlGaO_3$ alloys using the phonon Boltzmann transport equation, with the harmonic and third-order anharmonic force constants calculated from density functional theory. Interestingly, we find that 50/50 alloys of Ga_2O_3 with Al_2O_3 can form a low-energy ordered structure [1]. We find that the thermal conductivity of this ordered $AlGaO_3$ is raised by more than 70% compared to Ga_2O_3 [2]. The enhancement is ascribed to (1) increased group velocities and (2) reduced anharmonic scattering rates due to the reduced weighted phase space. The findings offer an avenue towards improved heat dissipation from Ga_2O_3 devices.

The Phonon Quantum of Thermal Conductance—What Are We Calculating and What Are We Measuring? Carlos Polanco[1,2], Ambroise van Roekeghem[1,2] and Natalio Mingo[1,2]; [1]CEA, France; [2]Université Grenoble Alpes, France

Two decades after the first reported measurements and calculations of the thermal conductance quantum in suspended nanostructures[1], reconciling experiments and theory remains elusive[2]. Through calculations of phonon transport in micrometer-sized three-dimensional structures, we show that part of the disagreement between theory and experiment stems from a misconception of thermal transport at small scales and low temperatures, and a possible inadequacy of the experimental geometrical designs. After clarifying the meaning of temperature in the wave ballistic regime, we show that the spatial placement and dimensions of thermometers, heaters, and supporting micro-beams in the suspended structures, can noticeably affect the thermal conductance's measured values. In addition, diffusive transport assumptions made in the data analysis may result in measured values that considerably

differ from the actual thermal conductance of the structure.

Ionic Thermoelectric Materials with Giant Thermopower and Figure of Merit Jianyong Ouyang; National University of Singapore, Singapore

Thermoelectric materials are significant for sustainable development because they can be used to directly convert heat into electricity and there is abundant waste heat on earth. The conventional thermoelectric materials are inorganic or orgnaic conductors and semiconductors. However, their thermopower due to the Seebeck effect is low, and their thermoelectric properties are not good enough for large scale application. Recently, ionic thermoelectric materials emerged as the next-generation thermoelectric materials mainly due to their high thermopower. The thermopower of ionic conductors can be higher than electronic conductors/semiconductors by 1-2 orders in magnitude. Here, I will present various methods to improve the thermpower and ionic conductivity of ionic conductors. The thermopower can be higher than 40 mV/K, and the figure of merit (ZTi) can be greater than 6 at room temperature.

4:45 PM SF03.10.04
Effect of Sb-Doping on the thermoelectric Performance of CuInTe$_2$ Sabrine Hachmioune[1,2,2], Seán R. Kavanagh[1,3], Maheswar Repaka[2], Zhai Wenhao[2], Kedar Hippalgaonkar[2,4], Michael Sullivan[2] and David O. Scanlon[1]; [1]UCL, United Kingdom; [2]Agency for Science, Technology and Research, Singapore; [3]Imperial College London, United Kingdom; [4]Nanyang Technological University, Singapore

CuInTe$_2$ is a material of interest for thermoelectric power generation and photovoltaic energy harvesting. We present a detailed experiment-theory study of all intrinsic defect species, followed by extrinsic doping by antimony (Sb), to investigate the optimal conditions for performance. Hybrid-density functional theory (DFT) with spin-orbit coupling (SOC) was used to accurately model the electronic behaviour of CuInTe$_2$. Antimony was the chosen dopant as experimental studies observed an improvement in the power factor and transport properties required for a desirable thermoelectric figure of merit (ZT).[1]
The formation of energies of Cu$_{1-x}$Sb$_x$InTe$_2$, CuIn$_{1-x}$Sb$_x$Te$_2$ and CuInTe$_{2-x}$Sb$_x$ systems were calculated to determine the lowest energy defective composition, employing the ShakeNBreak approach to identify the ground-state defect structures.[2] In addition, a ternary competing phase was included to give new insights on the true phase space of the system.
The effect of Sb-doping on the transport properties of CuInTe$_2$ was then calculated by applying the momentum relaxation time as implemented by the AMSET[3] code. Combining the theoretical and experimental results, we rationalise the effect of Sb-doping on the power factor and electrical thermal conductivity, yielding insights and design principles that can be applied to optimise performance in this and other emerging thermoelectric materials.

5:00 PM SF03.10.05
Effect of Antiferromagnetic Order on Thermal Conductivity of NiO from 125 to 700 K Qiyang Sun[1], Songrui Hou[1], Bin Wei[2], Yaokun Su[1], Victor H. Ortiz[1], Bo Sun[3], Jiao Lin[4], Hillary Smith[5], Sergey Danilkin[6], Douglas L. Abernathy[4], Richard B. Wilson[1] and Chen Li[1]; [1]University of California, Riverside, China; [2]Henan Polytechnic University, China; [3]Tsinghua University, China; [4]Oak Ridge National Laboratory, United States; [5]Swarthmore College, United States; [6]Australian Nuclear Science and Technology Organisation, Australia

Thermal transport in magnetic insulators is governed by lattice dynamics, spin dynamics, and the interactions between these two systems. Thermal transport mechanisms of how phonons carry heat are well understood. However, how phonon-magnon interactions affect conduction is not well established. In this work, we use time domain thermoreflectance to measure the thermal conductivity of NiO between 125 and 700 K. Nickle oxide (NiO) is an antiferromagnetic material with Néel temperature being 523 K. We observe that the thermal conductivity (Λ) of NiO has an anomalous $T^{-1.5}$ temperature dependence between 200 and 500 K, and a more normal dependence above 550 K. To understand the origins of the anomalous temperature dependence below 500 K, we measured the phonon and magnon dispersion relations at 10, 300, 550, 640 K by inelastic neutron scattering. We observe NiO loses its long-range spin order at temperatures above its Néel temperature. And we observe no evidence of phonon softening near the Néel temperature that could explain the anomalous dependence of Λ. Therefore, we credit the temperature dependence to phonon scattering caused by spin-disorder. As spin-disorder increases near the Néel temperature, phonon lifetimes decrease. The effect of spin-disorder saturates at the Néel temperature of 523 K. To support this hypothesis, we performed first-principles calculations of Λ vs. T between 200 and 500 K that include the effects of phonon-phonon and phonon-defect scattering. Our study improves understanding of how spin-disorder in magnetic materials effects phonon lifetimes and conduction.

SESSION SF03.11: Thermal Transport of Nanostructures and Interfaces
Session Chairs: Renkun Chen and Lucas Lindsay
Thursday Morning, April 13, 2023

8:00 AM *SF03.11.01
Increasing Thermal Conductivity in Assemblies of Colloidal Nanocrystals and Magic-Sized Clusters Robert Y. Wang; Arizona State University, United States

Colloidal nanocrystal assemblies are actively been explored for a variety of electronic and optical applications, and are already being commercially-used in LED displays. However, these materials also have low thermal conductivities (0.1 - 0.5 W m^{-1} K^{-1}), which will lead to heat dissipation challenges as they become used in an increasing number of applications. The low thermal conductivity in these materials stems from organic ligands that cover the surface of these nanocrystals. These organic ligands result in weak van der Waals interactions between adjacent nanocrystals that in turn rate-limit thermal transport. In this talk, I discuss my group's ongoing work to improve thermal transport in these materials. More specifically, I present three different methods for improving thermal conductivity: (i) crosslinking the organic ligands between adjacent nanocrystals, (ii) increasing nanocrystal order via superlattice formation, and (iii) improving size dispersion through the use of magic-sized clusters. We show that each approach can lead to ~3-fold improvements in thermal conductivity. To complement these thermal transport measurements we also perform materials characterization, mechanical measurements, and modeling on these materials.

8:30 AM SF03.11.02
High-Performance and Flexible Thermal Interfaces Based on Self-Assembled Boron Arsenide Ying Cui, Zihao Qin, Huan Wu, Man Li and Yongjie Hu; University of California, Los Angeles, United States

Thermal management is the most critical technology challenge for modern electronics. Recent key materials innovation focuses on developing advanced thermal interface of electronic packaging for achieving efficient heat dissipation. Here, for the first time we report a record-high performance thermal interface beyond the current state of the art, based on self-assembled manufacturing of cubic boron arsenide. The self-assembly of BAs exhibits highly desirable characteristics of high thermal conductivity up to 21 W/mK and excellent elastic compliance similar to that of soft biological tissues down to 100 kPa through the rational design of BAs microcrystals in polymer composite. In addition, the s-BAs demonstrates high flexibility and preserves the high conductivity over at least 500 bending cycles, opening up new application opportunities for flexible thermal cooling. Moreover, we demonstrated device integration with power LEDs and measured a superior cooling performance of BAs beyond the current state of the art, by up to 45 °C reduction in the hot spot temperature. Together, this study demonstrates scalable manufacturing of a new generation of energy-efficient and flexible thermal interface that holds great promise for advanced thermal management of future integrated circuits and emerging applications such as wearable electronics and soft robotics.

8:45 AM SF03.11.03
Twin Boundaries in Bi2Te3—Their Impact and Importance in Thermal Transport Aoife K. Lucid[1], Javier F. Troncoso[2], Jorge Kohanoff[2], Stephen B. Fahy[1] and Ivana Savic[1]; [1]Tyndall National Institute, Ireland; [2]Queen\'s University Belfast, United Kingdom

Highly efficient, room-temperature thermoelectric materials are key to the future of environmental energy harvesting, solid-state cooling, and the powering of the Internet of Things, among many other applications. In pursuit of such materials, the impact of nanostructure engineering on thermal transport is a factor which must be carefully considered. Nanostructured thermoelectric materials are generally highly polycrystalline, meaning extended defects such as interfaces, are prevalent. Advancing beyond the current state-of-the-art room-temperature thermoelectrics requires an atomistic-level understanding of the impact of interfaces on thermal transport in currently utilised materials, such as Bi2Te3. Ideally, interfacial properties could be linked to thermal transport, allowing targeted engineering of interfaces and leading to optimised thermoelectric materials. These insights can also be extended to new and emerging materials.

In this work, we employ reverse non-equilibrium molecular dynamics simulations (rNEMD)[1] with a recently developed classical two-body interatomic potential[2], to examine the effect of specific interfacial structures, in this case, twin boundaries, on thermal transport in Bi2Te3. The quintuple layer structure of Bi2Te3, separated by van der Waals gaps, lends itself readily to the formation of interfaces, e.g. basal plane twin boundaries[3]. The interfacial thermal resistance (Kapitza resistance) and interfacial structures are compared across a number of twin boundaries. Density-functional theory (DFT) optimised twin boundary structures and formation energies are also compared to existing interatomic potentials. Additionally, we will examine the impact and importance of finite-length effects in rNEMD simulations of interfaces as these are frequently overlooked or not discussed. We will also explore the limitations of existing classical interatomic potentials (for interfacial simulations) and consider the development of machine-learned interatomic potentials for Bi2Te3.

9:00 AM SF03.11.04
Phonon-Influenced Transport Characteristics of Superionic ThO_2 Yuqing Huang, Anant Raj and Jacob Eapen; North Carolina State University, United States

Fluorites, which belong to the class of superionic materials, exhibit a second order phase transition at a critical temperature below the melting point. Thoria (ThO_2), which is a promising oxide nuclear fuel, portrays superionic behavior at high temperatures, particularly in accident conditions. Phonon properties such as dispersion and lifetimes are crucial to understanding the thermal response of nuclear fuel under such conditions. However, the interplay between the phonon properties and anion transport in the superionic state remains as a fundamental knowledge gap. In this work, molecular dynamics simulations are performed with ThO_2 at high temperatures using the BPNN-SCAN potential [*Sci. Rep.* 12(1) (2022)]. First, the temperatures corresponding to the onset of the superionic state and the second order phase transition are determined. Then, the oxygen ion transport, which occurs through correlated hopping in the superionic state, is quantified. Lastly, the excited phonon modes and interactions are correlated to anion hopping and glass-like dynamics in the superionic state. Our work highlights how phonon dynamics influences anion transport in ThO_2 at high temperatures.

9:15 AM SF03.11.05
Low Temperature Enhancement of *Z* in Silicon "Nanoblade" Micro-Thermoelectric Coolers Mark Lee[1], Ruchika Dhawan[1,2] and Hal Edwards[2]; [1]The University of Texas at Dallas, United States; [2]Texas Instruments, United States

To improve thermal management in Si integrated circuits (ICs), micro-thermoelectric coolers (µTECs) compatible with ICs are being investigated. Most research on µTEC technology concentrates on materials having high TE factor $Z = (\alpha^2\sigma)/\kappa$, where α, σ, and κ are the thermopower, electrical conductivity, and thermal conductivity. The focus on high Z materials is because the maximum temperature reduction achievable is $\Delta T_{max} = (T_{source} - T_{sink}) = -\tfrac{1}{2}Z(T_{source})^2$, where T_{source} and T_{sink} are the temperatures of the heat source and sink. However, high Z materials can be expensive, often contain toxic or rare elements, and may be incompatible with IC processing. Si is not usually considered a viable TE material because its high phonon contribution to κ makes its $Z \sim 1\%$ of modern high Z materials.
Doped Si nanowires (SiNWs) can have Z values competitive with state-of-the-art high Z materials while being compatible with IC processing. It is believed this enhancement in Z is due to the cross-sectional dimensions of SiNWs being smaller than the phonon mean-free-path (mfp), increasing phonon surface scattering and reducing κ. However, over the past decade µTE devices incorporating SiNWs or other kinds of Si nanostructures have mostly failed to demonstrate substantial enhancements in performance that should result from higher Z.
We report on prototype µTECs using $Si_{0.97}Ge_{0.03}$ as the TE material, made on an industrial Si IC process line. The TE elements were structured by standard lithographic etching into "nanoblades" 80 nm wide by 350 nm tall by 750 nm long. By comparison, the phonon mfp near 300 K is ~ 200 nm. For T_{source} = 300 K, using bulk material parameter values the ideal $\Delta T_{max} \approx -1.5$ K, while our measured $\Delta T_{max} = -0.3$ K. The reduction from ideal value is due to parasitic series resistances. Near 300 K the inferred Z value of the nanoblades is indistinguishable from bulk material.
However, at T_{sink} = 150 K, ΔT_{max} remains nearly constant. That is, these µTECs can still reduce T_{source} by around –0.3 K below T_{sink} , and measurable

cooling of T_{source} persists to $T_{\text{sink}} \sim 100$ K. If the values of all material and device parameters were temperature independent, then we expect $\Delta T_{\max}(150\ \text{K})/\Delta T_{\max}(300\ \text{K}) = ¼$. The fact that the measured ratio is actually close to unity cannot be attributed to decreases in parasitic resistances; these tend to increase at lower temperature which should make $\Delta T_{\max}(150\ \text{K})/\Delta T_{\max}(300\ \text{K}) < ¼$.
We then infer that the nanoblades' $Z(150\ \text{K})/Z(300\ \text{K}) > 4$ to compensate for the temperature decrease. However, using bulk material properties indicates $Z(150\ \text{K})/Z(300\ \text{K})$ should be < 1. This implies a low temperature increase in Z unrelated to bulk behavior. We believe the likely cause is an increase in the phonon mfp with decreasing temperature; the mfp is estimated to be ~ 3x longer at 150 K compared to 300 K. Thus at 300 K a nanoblade is smaller than the phonon mfp in width only, whereas at 150 K it becomes smaller in both width and height. This makes phonon heat transport effectively one-dimensional, which could significantly reduce the phonon contribution to κ and enhance the nanoblade Z. Full experimental results and comparisons to theoretical analyses of low dimensional phonon transport on Z will be presented.

Thermal Transport in Flowing Granular Media Renkun Chen; University of California, San Diego, United States

Granular media such as ceramic particles have been used as heat transfer media in heat exchangers for solar-thermal energy capturing and storage systems. However, thermal transport processes in flowing granular media are still not fully understood. Particularly, it is still not clear whether and how the thermal conductivity of the particles in the near-wall region could be impacted by the particle -wall interaction when the particles are flowing. While numerous models exist, there is a lack of a suitable experimental technique to directly probe the thermal transport processes of flowing granular media. In this work, we report the instrumentation development of high-temperature thermal conductivity measurement of flowing ceramic particles within a confined channel. We extend an existing technique called modulated photothermal radiometry (MPR) to high temperature measurements (up to 700 deg. C). MPR is a non-contact technique where the surface of the sample is heated by an intensity-modulated laser and it utilizes the intrinsic thermal emission from the specimens for thermometry, which is favorable for the measurement at high temperature in harsh environment. The high-temperature MPR setup is validated by measuring bulk, thin coatings, and liquids with known thermal conductivity. We then develop the technique for measuring both stationary and flowing ceramic particles. The results on the stationary particles are in good agreement with those obtained from a transient hot wire (THW) technique. The measured effective thermal conductivity of the flowing particles, however, show considerable reduction in thermal conductivity compared to the stationary ones. Further analysis of the frequency dependent data shows that this reduction in thermal conductivity is originated from the particle-wall thermal resistance. The measurement results are coupled with modeling based on the discrete element method (DEM) to understand thermal transport in both the bulk and near-wall regions of flowing particles.

High Speed Thermal Imaging of Melt Pools Reveals Underlying Thermophysics in Additive Manufacturing Processes Jonathan A. Malen, Alexander Myers and Guadalupe Quirarte; Carnegie Mellon University, United States

At its heart, additive manufacturing (AM) of metals is a heat transfer problem that depends on many nano and microscale thermophysical processes. Laser powder bed fusion, the most popular AM process uses a moving heat source (e.g. laser or an electron beam) to sinter metal powder together in predefined patterns, to build parts layer by layer. Temperature fields control the stability of the melt pool and common defect structures in laser powder bed fusion (L-PBF) parts. Experimental measurements of the melt pool temperature using conventional infrared imaging techniques or pyrometry lack the temporal and spatial resolution needed to determine melt pool temperature profiles. We have developed an alternative experimental method to measure melt pool and surrounding temperatures using a high-speed color camera (>50,000 frames per second). This method creates real-time thermal imaging AM tool leveraging the principle of two-color (a.k.a. dual-wavelength) pyrometry, where each pixel acts as a two-color pyrometer. Relative to conventional thermal imaging approaches, two-color pyrometry is advantageous because it is less sensitive to melt pool emissivity, plume transmissivity, and the camera's view factor. Our initial two-color experiments were performed using a Photron AX200 high speed color camera where the temperature given by the ratio of the red to green pixel values was validated against the NIST blackbody source.
Temperatures from melt pools of Ti-6Al-4V, Inconel, and 316L-SS were taken as a function of laser power and scan velocity offer new information about the thermophysical processes occurring in the melt pool. Our high resolution temperature images are amongst the first taken of the melt pool and suggest that temperatures peak between 3500-4000 K in these materials. These temperatures, which are directly under the laser, can surpass the metal's vaporization temperature causing the vaporization of material into a metal vapor plume. The mass loss due to vaporization, which is modified by the accommodation coefficient, results in a downward pressure on the melt pool, inducing convective flows towards the back of the melt pool. In addition, a vapor depression is formed such that the laser reflects internally, increasing the effective absorptivity for higher energy density processing conditions. Surface tension gradients can also induce convective currents in melt pools, known as Marangoni convection. Temperature-dependent specific heat, thermal conductivity, and density also impact the melt pool and surrounding temperatures. Computational fluid dynamics packages such as FLOW-3D incorporate these melt pool physics but require several input parameters that are uncharacterized. Surface temperatures measured with our high-speed two-color thermal imaging system are a starting point to fit uncharacterized parameters and validate these complex multi-physics models.

Ultrafast Ultraviolet Transient Grating—Tabletop Access to Nanoscale Thermal Transport in High-Bandgap Materials Joshua Knobloch, Brendan McBennett, Emma Nelson, Albert Beardo, Henry Kapteyn and Margaret Murnane; STROBE, JILA, University of Colorado Boulder, United States

Nanostructuring on length scales comparable to the fundamental length scales of phonons in materials such as silicon can provide control over thermal transport, making it possible to engineer thermal properties [1]. Finding effective thermal management strategies is critical for a host of applications, as temperature often determines the speed and efficiency, *e.g.* the clock-speed of modern processors is limited due to a heat buildup [2]. However, as devices become increasingly complex, thermal management solutions are elusive due to a lack of predictive models that span from micro-to-nano-to-atomic scale lengths. To advance our understanding of nanoscale heat flow, more precise measurements of the thermal properties of general, complex, nanostructured, and high-bandgap materials are needed, which can be used to validate predictive theories.
Specifically, recent research has shown that transient thermal grating experiments can reveal non-diffusive thermal transport [3], as well as exotic phonon behaviors such as second sound [4]. However, due to the fundamental diffraction limit of visible light, such visible-laser-based techniques cannot access the nanoscale length scales (<0.5 μm) relevant to advanced devices. Moreover, visible lasers cannot directly excite high-bandgap materials such as ceramic

materials for advanced battery applications, or diamond for quantum systems applications. Our recent work has demonstrated that tabletop, coherent short-wavelength laser-like beams can provide unique insight into the thermal transport properties of nanosystems—uncovering surprising new behaviors. These include exploring and explaining new behaviors for the cooling of periodic nanostructured heaters where close-packed hot spots cool faster than widely-spaced ones [5-7], validating novel theories using a hydrodynamic-like transport equation to predict phonon flow in general semiconductors [7], and a universal scaling of nanoscale heat flow in highly-confined geometries [8].

Here, we combine the versatility of tabletop transient thermal grating experiments with the sensitivity and precision of short-wavelength light by demonstrating a deep-ultraviolet (UV) transient grating metrology using ultrafast UV lasers with wavelengths <200 nm and with 100s of femtosecond pulse durations. We first upconvert ultrafast, infrared pulses to the deep-UV using nonlinear crystals [9], and then split and recombine the pulses to create a transient, sinusoidal interference pattern [10] of deep-UV light on the sample. The relaxation of the resulting sinusoidal thermal excitation is then observed using an ultrafast probe beam with wavelengths from the visible to UV. The short-wavelength of the light allows us to probe transport distances on the 100s of nanometer scale in both visibly-transparent and opaque materials. We then use this technique to observe non-diffusive nanoscale thermal transport in diamond on scale lengths less than dominant phonon mean free paths. We use microscopic theories and mesoscopic models to benchmark our results. This work demonstrates that tabletop sources of ultrafast, deep-UV light can reveal new insight into phonon transport at its intrinsic scales in a general set of materials allowing for the development and validation of advanced theories and for nondestructive, noncontact characterization of thermal properties of energy and quantum materials.

Developing Next Generation Building Envelope Insulation Emily F. Thomas[1,2] and Peter Holliman[1]; [1]Swansea University, United Kingdom; [2]TATA Steel, United Kingdom

In 2020, an average of 67% of the total household energy consumption within the EU was used for space heating in buildings.[1] Thermal insulation is crucial to improving the thermal efficiency of buildings by reducing the heat lost through the building envelope to the outside environment.[2] Organic based materials such as polyisocyanurate (PIR) foams are the current industry leading thermal insulation material for buildings due to their low density (< 45 kgm^{-3}), suitable structural properties, and low thermal conductivity (0.024 Wm^{-1}K^{-1}). But, despite these advantageous properties, PIR is classified as combustible, with a fire rating class of B-s2 according to the European fire classification system.[3] The Grenfell Tower disaster in London in 2017 demonstrated a fire propagating in a building envelope through combustible insulation.[4] Following this fire, the UK government banned combustible materials from the exterior of buildings taller than 18m.[5] According to the European fire classification, all new insulation materials must now be classed as A1, non-combustible or A2-s1, a limited combustible material (i.e. must self-extinguish < 10 s after ignition).[6] Stone wool an inorganic thermal insulation material with excellent fire resistance (A1 rating) but, a density up to 180 kgm^{-3} which is not ideal for building insulation.[7] Therefore, the study of low-density inorganic materials is a new concept to improve the fire ratings.

This work studies adding expanded perlite (EP) and powdered aerogel into PIR foam system. Both EP and aerogel provide a low-density cellular structure with a high surface area, and a low thermal conductivity, along with heat resistance and the necessary structural properties. EP and aerogel have previously been used as insulating materials in seldom, making them ideal materials to add to the existing PIR system.[8][9]

The experiments focused on three foam formulations, a low weight addition of either EP, aerogel or a 50/50 mix of EP and aerogel, to explore the feasibility of adding solid-state materials into a liquid-based material. All foams exhibit low thermal conductivity, an average at 0.021 Wm^{-1}K^{-1}, densities below 45 kgm^{-3}, but slightly higher compression values versus PIR. Foams were also studied using two different heat sources for visual and quantitative data. First, a radiant heat furnace was ramped from ambient to 600°C with samples (25x35x20mm) removed every 50°C. Mass and dimensions were recorded at each step to quantify mass loss and expansion/shrinkage. At 600°C, masses remaining were PIR (4%), EP (15%), aerogel (12%) and 50/50 mixture (5%), respectively. Secondly, a propane flame placed below the foam to study thermal heat transfer throughout the foam by thermography with data calibrated for foam emissivity to plot temperature against time. The data suggest that inorganic particles absorb and scatter heat (IR light) causing an average decrease in temperature across the foam, when compared with pure PIR.

High-Performance Modeling of First-Principles Electron and Phonon Transport Using Phoebe Jennifer Coulter[1], Andrea Cepellotti[1], Anders Johansson[1] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch LLC, United States

The theoretical prediction of electrical and thermal transport properties relies on an accurate description of the electrons, phonons, and their interactions must be considered to accurately predict transport behavior. While first-principles methods based on density functional theory can describe these material-specific quasiparticle properties, using this information to calculate transport coefficients can be computationally demanding. To address this challenge, we developed Phoebe (https://mir-group.github.io/phoebe/), which includes the effects of electron-phonon and phonon-phonon interactions to predict the transport properties of materials by solving the Boltzmann transport equation (BTE) using a full scattering matrix formalism. In this talk, I will report on ongoing new features of Phoebe, including the addition of magnetotransport calculations as well as new tutorials and updated performance benchmarks.

Tunable Thermal Conductance of Termination-Engineered MXenes through Intercalation M Cynthia Hipwell and Aditya Kuchibhotla; Texas A&M University, United States

First discovered in 2011, selective etching of transition metal carbides and nitrides with general formula $M_{n+1}AX_n$ in Hydrofluoric acid (HF) or HF-forming etchants results in a new class of layered two-dimensional (2D) materials called MXenes ($M_{n+1}X_nT_z$, where T is termination group, such as –O, -F, PH, -Cl). First principle thermal conductivity calculations of monolayer MXenes have demonstrated an order of magnitude change in thermal conductivity by changing surface termination from -F to -O due to increased phonon scattering rate and reduced phonon mean free path. While extensive research on unique electrical, electrochemical, and mechanical properties of MXenes has been reported, no experimental investigations exist characterizing thermal transport performance of a stack of MXene nanosheets or large area free-standing multi-layer MXene sheets. Here I will present our current research endeavors in advancing the application of MXenes in thermal management. Combining elemental analysis tools such as XRD with AFM for chemical and structural characterization and Time-Domain Thermoreflectance (TDTR) for thermal conductance measurements, we explore the correlation between surface functionalization and thermal transport. I will also describe our efforts beyond surface functionalization to further control the thermal transport through MXenes via electrochemical intercalation. Our findings lay the groundwork for advancing the engineering thermal transport through MXenes, both actively or passively, having wide reaching impact in energy harvesting, conformal/wearable electronics, electromagnetic interference shielding, and thermal management.

Thermal Conductivity Enhancement Through Kinetically Arrested Dispersion—Breaking Dispersion Barriers of Highly Conductive Carbon Allotropes in Aqueous Solutions Lucas L. Cullari[1], Istvan Furo[2], Gennady Ziskind[1] and Oren Regev[1]; [1]Ben-Gurion University of the Negev, Israel; [2]KTH Royal Institute of Technology, Sweden

Carbon-based nanomaterials such as graphene are usually produced industrially as powder-like materials. Harnessing the incredible potential of these nanocarbons (e.g., high electrical and thermal conductivities) in many applications (e.g., conductive inks and heat transfer fluids) requires their dispersion. However, when the highly hydrophobic graphene sheets are dispersed in water, they tend to aggregate and precipitate due to strong van-der-Waals attraction. Surface treatment of graphene (via surfactant adsorption or chemical modification) results in a low concentration of dispersed graphene (<0.2wt%) of relatively small lateral size (<0.5µm), or in high defect density, both are detrimental for thermal management applications. In this work, we disperse graphene in water by adding fibrous clay mineral - sepiolite - a negatively charged particle, which kinetically arrests the system. The “trapped” graphene cannot re-aggregate and precipitate. The trapping mechanism makes it possible to disperse high graphene concentration (1wt%) with high lateral size (>5µm). This approach applies to all three dimensionalities of carbon, that is, 1D-carbon nanotubes, 2D-graphene and 3D-graphite. The thermal conductivity (TC) of liquids, an essential parameter in heat dissipation applications, could be enhanced by 31% via loading graphene as a filler material both in water, and in commercial cooling liquids such as water-ethylene glycol mixtures. The proposed dispersion approach is filler independent, and could be employed in enhancing composite properties both in liquid and solid states for thermal managment applications of electronics.

Characterizing Highly-Confined Heat Flow, Elastic Properties and Porosity in a Semiconductor Metalattice Emma Nelson[1], Brendan McBennett[1], Albert Beardo Ricol[1], Charles Bevis[1], Sadegh Yazdi[2], Begoña Abad Mayor[1], Travis Frazer[1], Jorge Hernández-Charpak[1], Amitava Adak[1], Yuka Esashi[1], Hiu Y. Cheng[3,3], Alex J. Grede[3,3], Pratibha Mahale[3], Nabila Nova[3,3], Noel Giebink[3,3], Thomas Mallouk[3], John Badding[3,3], Baowen Li[4,2], Henry Kapteyn[1], Margaret Murnane[1] and Joshua Knobloch[1]; [1]University of Colorado, Boulder, United States; [2]University of Colorado Boulder, United States; [3]The Pennsylvania State University, United States; [4]Southern University of Science and Technology, China

Nanostructured semiconductors can exhibit thermal properties unachievable in bulk systems due to the increased influence of surfaces and interfaces. The ability to understand and fully characterize the thermal, elastic, and structural properties of these nanostructured semiconductor materials is important for developing new materials with tunable properties for applications in next-generation nanoelectronics and energy efficient devices. Managing thermal transport in nanoscale materials is critical for optimizing the performance of computer chips—however, when the critical dimensions have the same length scales as the average phonon mean free paths, traditional theories of heat flow break down. Moreover, first principles models of nanoscale thermal transport are too computationally challenging for 3D nanostructured geometries, while mechanistic approaches make overly simplistic assumptions about the nature of phonon-boundary interactions.

Here, we probe the elastic and thermal properties of a 3D nanostructured silicon metalattice, which consists of an interconnected network of nanoscale pores that dramatically alter the material properties compared to bulk crystalline silicon. We impulsively heat nickel grating transducers that are fabricated on the 3D silicon metalattice sample using an infrared pump laser pulse. This launches acoustic waves and heat into the metalattice, which we probe using diffraction from an extreme ultraviolet (EUV) probe pulse. This technique has high spatial and temporal resolution, since the ~30nm EUV light has a wavelength much shorter than that of visible light, with a pulse duration of ~10fs.

By using metallic gratings of varying linewidths and periodicities, we launch surface acoustic waves in the metalattice with wavelengths equal to the grating periodicity. These surface acoustic waves are detected by the probe as changes in the reflectivity and the surface displacement of the sample. We compare the experimental data to finite element models of the 3D silicon metalattice to nondestructively extract porosity and Young’s modulus. Also, by varying the period of the metallic grating we can vary the acoustic wave penetration depth, allowing us to characterize the 3D silicon metalattice film thickness and substrate elastic properties. To validate our extracted porosity value and the metalattice geometry models, we compare to 3D electron tomography reconstructions of the sample geometry [1].

Using the extracted porosity and elastic properties, we model heat flow in the metalattice using finite element methods and fit an apparent thermal conductivity two orders of magnitude below bulk silicon. We model the heat flow dynamics using a Fourier-like relation with an apparent conductivity indicating two key conclusions: the size of the heat source does not significantly affect the heat flow as the metalattice geometry dominates, and the transport is diffusive-like in highly-confined situations where ballistic transport is traditionally expected. We compare our results to other highly-confined nanostructured systems by separating the thermal conduction into a permeability component, which captures the geometry of the system, and a viscosity component related to the intrinsic phonon properties. This treatment reveals a universal trend in the permeability which can be used to predict the thermal conductivity in general nanostructured silicon systems—from nanomeshes, to metalattices, to porous nanowires and nanowire networks.

2:00 PM *SF03.13.03
Nanoscale Imaging of Phonon Dynamics Emergent from Single Defect and Interface by Electron Microscopy Xiaoqing Pan; University of California, Irvine, United States

Crystal defects and interfaces affect the thermal and heat-transport properties of materials by scattering phonons and modifying phonon spectra. Spatially resolved vibrational mapping of nanostructures and defects is indispensable to the development and understanding of thermal nanodevices, modulation of thermal transport and novel nanostructured thermoelectric materials. Through the engineering of complex structures, such as alloys, nanostructures and superlattice interfaces, one can significantly alter the propagation of phonons and suppress material thermal conductivity while maintaining electrical conductivity. There have been no correlative experiments that spatially track the modulation of phonon properties in and around individual defects and nanostructures due to spatial resolution limitations of conventional optical phonon detection techniques. In this talk, I will show that the vibrational spectra of a single defect or interface can be imaged by space- and angle-resolved vibrational electron energy-loss spectroscopy in a transmission electron microscope. It reveals a red shift of several meV in the energy of acoustic vibration modes near a single stacking fault in cubic silicon carbide, together with substantial changes in their intensity. These changes are confined to within a few nanometers of the stacking fault.[1] In a two-dimensional lateral heterostructure, new phonon modes at 27.9 and 41.1 meV are observed at the interface between monolayer thick MoS_2 and WSe_2 [2]. At a Si-Ge interface, localized interfacial phonon modes at ~48 meV.[3] Simulations show that these interfacial phonon modes contribute to the total thermal interface conductance. By tracking the variation of the Si optical mode in a phonon map from a single SiGe quantum dot, the nanoscale modification of the composition-induced red shift is observed.[4] We also developed a technique to differentially map phonon momenta, providing direct evidence that the interplay between diffuse and specular reflection largely depends on the detailed atomistic structure. Our work unveils the non-equilibrium phonon dynamics at nanoscale interfaces and can be used to study actual nanodevices and aid in the understanding of heat dissipation near nanoscale hotspots, which is crucial for future high-performance nanoelectronics.

SESSION SF03.14: Thermal Materials with Defects and Disorders
Session Chairs: Elif Ertekin and Ivana Savic
Thursday Afternoon, April 13, 2023
Marriott Marquis, B2 Level, Golden Gate A

3:30 PM *SF03.14.01
Describing the Vibrational and Thermal Properties of "In-Between" Materials Exhibiting Dynamical Disorder—Not Quite a Crystal, Not Quite a Glass Elif Ertekin; University of Illinois at Urbana-Champaign, United States

Certain materials live in configurational phase spaces that accommodate multiple degrees of freedom and host many energetically nearly-degenerate disordered configurations, with facile hopping between them. For example, in hybrid materials like perovskite methylammonium lead iodide ($MAPbI_3$), a high-symmetry lattice is decorated by low-symmetry molecular building blocks. In ion conducting materials such as the halide lithium ion conductor Li3YCl6 an ordered anion sublattice coexists with a cation sublattice that accommodates disorder in the distribution of Li, Y cations and vacancies. While such materials are often associated with "glass-like" thermal conductivity, describing the vibrational modes and thermal transport properties of such materials remains challenging. While the periodicity of conventional crystals enables the excitation of phonons -- propagating vibrational waves that carry heat, by contrast in glasses the lack of periodicity results in more localized and less wavelike vibrational modes most typically described by the theory of Allen/Feldman. In this presentation, we will highlight our recent investigations of vibrational transport in materials exhibitting dynamical disorder. Using MAPbI3 and Li3YCl6 as examples, we explore the application and limitations of both the phononic and glassy description, as well as recently developed two-channel models, to materials that lie in between crystalline and glassy. Using molecular dynamics, spectral energy density analysis, first-principles determination of higher order force constants, and Allen/Feldman theory we describe the vibrational properties of both the ordered prototype as well as of explicitly disordered versions of each material. A microscopic framework linking anharmonicity and soft bonding arising from chemistry, to the breakdown of the wavelike picture, to the presence of dynamical disorder is presented.

4:00 PM SF03.14.02
Stereochemical Modulation of Lone-Pair Electrons and Its Impact on Lattice Thermal Conductivity Hanhwi Jang[1], Michael Toriyama[2], G. J. Snyder[2], Yeon Sik Jung[1] and Min-Wook Oh[3]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Northwestern University, United States; [3]Hanbat National University, Korea (the Republic of)

Crystalline solids containing lone-pair electrons (LPEs) are of fundamental interest because the existence of LPEs makes physical properties (e.g., mechanical, optical, electrical, and thermal properties) of materials distinct from conventional materials. Among them, thermal properties have gathered significant attention from thermoelectric researchers because of the intrinsically low lattice thermal conductivity of LPE-containing solids, which is crucial for achieving high thermoelectric conversion efficiency. Conventional thermoelectric materials were intentionally doped with several impurities to suppress a propagation of phonons and reduce the lattice thermal conductivity. However, an intrinsically low lattice thermal conductivity of LPE-containing materials provided a room for optimizing electrical properties within a limited solubility of dopants, leading to a success in discovery of high-performance thermoelectric materials such as $AgSbTe_2$.
ABX_2-type compounds (A=Cu, Ag, B=Sb, Bi, X=S, Se, Te) are one of the typical LPE-containing materials, where s-orbital electrons of B-site cations

remain unpaired. These LPEs are known to exhibit strong lattice anharmonicity, which leads to the intrinsically minimal lattice thermal conductivity at room temperature. However, a clear demonstration of the effect of LPEs on the lattice thermal conductivity has not been reported. For example, it is not obvious whether the lattice thermal conductivity increases or decreases when some LPEs are eliminated from the lattice. Identifying the consequence of aforementioned question is important in that some dopants may reduce the concentration of LPEs due to their bonding characteristics.
Here, we experimentally demonstrate a rise of the lattice thermal conductivity with doping in Cd-doped $AgSbSnSe_3$, which is contradictory to the result expected from a conventional phonon scattering theory. We found that despite of an increased point defects scattering, more LPEs become stereochemically inactive with increasing Cd concentration, and this makes the lattice more harmonic. Systematic pair distribution function analysis by powder X-ray diffraction measurements reveal that the off-centering of cations is reduced and the crystal structure changes symmetrically with Cd doping. Density functional theory calculations support that these “harmonic” environment does not allow LPEs to suppress the phonon propagation, and ironically leads to higher lattice thermal conductivities with a doping. This study corroborates an importance of preserving LPE configurations in ABX_2-type compounds for maintaining intrinsically low thermal conductivity when designing thermal-glass materials.

4:15 PM SF03.14.03
Resolution Limits of Frequency Domain Thermoreflectance for Interconnect Damage in Heterogeneously Integrated Microsystems Wyatt Hodges, Amun Jarzembski, Brenden Herkenhoff, Ben Treweek, Anthony McDonald, Matt Jordan, Tim Walsh and G. W. Pickrell; Sandia National Laboratories, United States

In both industrial and consumer electronics, there is demand for increased computational power with a smaller physical footprint. Heterogeneously Integrated (HI) microsystems, using combinations of application-specific chiplets, have emerged as a way to deliver increased performance in smaller areas. HI architectures are typically constructed using metal microbumps to connect the set of chiplets. Damage to the microbumps can be detrimental to overall microsystem performance. These interconnects can be easily harmed during manufacturing processes or use, but damage identification in the metal interconnects is challenging for existing measurement techniques because the interconnects lie beneath the surface of the chiplets. Electron microscopy techniques offer detailed pictures of damage, but require cross sectioning of the HI device to interrogate the relevant interconnects. Other techniques such as acoustic microscopy or ultrasound are less destructive, but require extremely high frequencies (GHz) to image small features, and offer more limited data on interconnect failure.

To offer more detailed assessment of HI interconnect state of health, this talk demonstrates use of Frequency Domain Thermoreflectance (FDTR) to assess these subsurface geometries. The typical implementation of FDTR is a two-laser pump-probe setup which interrogates the sample of interest in the frequency domain. A metal transducer layer is patterned onto a sample to convert the incident pump laser into heat, which diffuses into the sample. Measured changes in reflected probe signal are proportional to the temperature rise on the sample surface in response to the heating from the pump beam. Typically, an analytical heat transfer model assuming radial symmetry is used to fit for thermal properties of the sample based on the phase difference between the reflected signal and pump beam assuming radial symmetry of the sample.

To demonstrate FDTR capability to assess HI microsystem interconnect state of health a thermal finite element analysis (FEA) model is validated and used in Sandia’s structural dynamics FEA code (Sierra/SD). The FEA model frees the analysis from relying on radially symmetric geometries, and shows that FDTR can be leveraged to sense buried rectilinear features. This model is used to calculate expected phase deviation due to a damaged interconnect, and is additionally used to examine the relationship between depth and resolvable feature size. FDTR is shown to be viable for sensing HI features through silicon layer thicknesses of over 100 microns. These model predictions are compared to FDTR imaging data collected on mock HI microsystems, and effects of experimental noise floor are examined.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

Impact of Static and Dynamic Disorder on Thermal Conductivity of Sodium Superoxide (NaO_2) Hariharan Ramasubramanian[1], Cheng Shao[2] and Alan McGaughey[1]; [1]Carnegie Mellon University, United States; [2]Shandong Institute of Advanced Technology, China

The pyrite phase of sodium superoxide, NaO_2, is studied using molecular dynamics simulations to understand the influence of static and dynamic disorder on its thermal conductivity at temperatures between 50 and 500 K. NaO_2 is a discharge product in sodium-air batteries that can be recharged at lower overpotentials than the expected peroxide. Understanding NaO_2 vibrational structure and thermal transport will enable specification of working conditions that favor its production.
In the pyrite structure, the Na^+ and O^-_2 ions' centers of mass form a simple cubic lattice. Three distinct structural regimes are observed over the studied temperature range based on the rotational autocorrelation function (RACF) of the O^-_2 ions. At lower temperatures, the O^-_2 ions take on an ordered configuration, with orientations aligned along the four cube diagonals, and librate at their lattice sites. In this regime, the RACF is fit to a linear combination of exponential and damped cosine functions to extract the librational frequencies and decay rates. As the temperature increases, the system enters a transition regime exhibiting static disorder, where the O^-_2 ions alternate between librating and rotating to one of the other cube diagonal orientations. At higher temperatures, the O^-_2 ions rotate freely. The RACF quickly decays to zero following a single exponential decay, whose time constant decreases with increasing temperature.
Thermal conductivity is then calculated using the Green-Kubo method to study the impact of static and dynamic disorder across the three structural regimes. The calculations include contributions from both translational and rotational heat fluxes. At low temperatures, where the O^-_2 ions librate and the system is fully ordered, the thermal conductivity shows a crystal-like temperature dependence (i.e., it decreases with increasing temperature). It reaches a value of 5.3 ± 0.2 W/m-K at a temperature of 50 K. At higher temperatures, where the O^-_2 ions freely rotate and the system is dynamically disordered, thermal conductivity increases with increasing temperature similar to a disordered material, reaching a maximum value of 4 ± 0.2 W/m-K. The thermal conductivity reaches its minimum value of 1.4 ± 0.1W/m-K at a temperature of 150 K in the transition regime, where the material is statically disordered. This robust approach is transferable to other crystals that contain molecules with rotational degrees of freedom and can quantify the contributions of molecular rotations to thermal conductivity.

Persistent Hot Carrier Diffusion in Boron Arsenide Single Crystals Imaged by Ultrafast Electron Microscopy Usama Choudhry[1], Fengjiao Pan[2], Xing He[2], Basamat Shaheen[1], Taeyong Kim[1,3], Ryan Gnabasik[1], Geethal Amila Gamage[2], Haoran Sun[2], Alex Ackerman[1], Ding-Shyue Yang[2], Zhifeng Ren[2] and Bolin Liao[1]; [1]University of California, Santa Barbara, United States; [2]University of Houston, United States; [3]Seoul National University, Korea (the Republic of)

Cubic boron arsenide (BAs) is promising for microelectronics thermal management because of its high thermal conductivity. Recently, its potential as an optoelectronic material is also being explored. However, it remains challenging to measure its photocarrier transport properties because of small sizes of available high-quality crystals. Here, we use scanning ultrafast electron microscopy (SUEM) to directly visualize the diffusion of photocarriers in BAs single crystals. SUEM integrates the temporal resolution of femtosecond lasers with the spatial resolution of scanning electron microscopes (SEMs). The change in local secondary electron (SE) yield as a result of the optical excitation is measured and used to form contrast images. Given the shallow escape length of SEs (a few nanometers), SUEM is highly sensitive to surface charge dynamics and has been used to study photocarrier diffusion. We observed ambipolar diffusion at low optical fluence with persistent hot carrier dynamics for above 200 ps, which can likely be attributed to the large frequency gap between acoustic and optical phonons, the same feature that is responsible for the high thermal conductivity. At higher optical fluence, we observed spontaneous electron-hole separation. Our results show BAs is an attractive optoelectronic material combining high thermal conductivity and excellent photocarrier transport properties. Our study also demonstrates the capability of SUEM to probe photocarrier transport in emerging materials.

The work conducted at the University of California, Santa Barbara, is based on research supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under award DE-SC0019244 (for the development of SUEM) and by the U.S. Army Research Office under award W911NF-19-1-0060 (for studying photocarrier dynamics in emerging materials). The growth of high-quality BAs crystals at the University of Houston was supported by the U.S. Office of Naval Research under Multidisciplinary University Research Initiative grant N00014-16-1-2436. Thermal Conductivity of BAs under Pressure Richard B. Wilson[1], Songrui Hou[1], Chen Li[1], Fengjiao Pan[2], Zhifeng Ren[2] and Bo Sun[3]; [1]University of California, Riverside, United States; [2]University of Houston, United States; [3]Tsinghua University, China

BAs has a thermal conductivity (Λ) 10x higher than Si despite similar crystal structure, elastic constants, and density. Its unusually high thermal conductivity is explained by first-principles theory to be a result of its special phonon dispersion relation [1], which limits three phonon scattering rates. To better understand the relationship between BAs' vibrational structure and three- and four-phonon scattering rates, we report experimental measurements of its thermal conductivity vs. pressure, Λ vs. P. Thermal conductivity vs. pressure is measured by time-domain thermoreflectance with a diamond anvil cell. Compression of BAs leads to significant changes in phonon dispersion. An increase in the frequency gap between acoustic and optic phonons should suppress four-phonon scattering and increase phonon thermal conductivity. Alternatively, a decrease in acoustic bunching should increase three-phonon scattering rates and decrease thermal conductivity. Therefore, measurements of $d\Lambda/dP$ provide an experimental measure of the relative importance of three- vs. four-phonon scattering rates. We observe of ~1200 W m^{-1} K^{-1} between 0 and 30 GPa [2]. From 30 to 60 GPa, decreases monotonically to ~600 W m^{-1} K^{-1}. Brillouin scattering measurements show that the speed of sound increases monotonically across this pressure range. Therefore, the decrease in thermal conductivity at high pressures implies large changes in the average phonon lifetime. Our results corroborate first-principles predictions for how three- and four-phonon scattering rates depend on vibrational structure, and expand fundamental knowledge of phonon-physics in high thermal conductivity materials.

Ultrahigh Heat-Generation Power in Ferrite Nanoparticles by Magnetization Resonance Yongsub Kim, Jae-Hyeok Lee and Sang-Koog Kim; Seoul National University, Korea (the Republic of)

Magnetic nanoparticles are increasing interesting due to their unique magnetic properties such as superparamagnetism and particle-size-dependent magnetization dynamics [1-2]. These novel properties make magnetic nanoparticles very attractive for bio-applications including hyperthermia and MRI contrast agents. Nonetheless, their applications are quite limited by their toxicity to human beings and low heating power based on conventional Néel-Brownian relaxation and hysteresis-loss mechanisms.
Here, we found a new magneto-thermal modality entailing resonantly excited magnetization dynamics followed by consequent dissipation [3-5]. We experimentally observed extraordinary high powers of heat generation using MnF_2O_4 nanoparticles: an initial temperature-increment rate of more than 670 K/s over as short a duration as 0.1 sec, with a low AC-field strength of 17 Oe. The observed high-power local heating can be applied not only for magnetic hyperthermia but also for metal ablations via a rapid melting process. Our present work provides a better understanding of the relationship between the fundamental spin dynamics of nanoparticles and their technologically useful application for rapid local heating toward a high target temperature.

Low-Temperature Thermal Characteristics of Graphene Composites—Applications in Thermal Management of Quantum Technologies Zahra Ebrahimnatajmalekshah[1], Youming Xu[1], Jonas Brown[1], Jivtesh Garg[2], Xi Chen[1], Fariborz Kargar[1] and Alexander A. Balandin[1]; [1]University of California, Riverside, United States; [2]The University of Oklahoma, United States

Interfacing electrically the cryogenic superconducting quantum technologies with room-temperature semiconductor electronics requires efficient thermal insulating materials. It is important to insulate cryogenic environments efficiently and reliably while allowing for electrical connectivity. Composites consisting of epoxy with graphene and few-layer graphene fillers show significantly increased thermal conductivity as compared to the base epoxy when measured near and above room temperature [1-2]. We have previously demonstrated graphene composites with thermal conductivity reaching ~15 W/mK at room temperature [3-4]. For comparison, the thermal conductivity of pristine epoxy is ~0.2 W/mK. The thermal characteristics of graphene composites at cryogenic temperature can be strikingly different from those near room temperature. At such temperatures, the added graphene fillers can act more as scattering centers rather than heat-conducting inclusions. We established that at temperatures above 11 K the thermal conductivity increases when increasing the loading of few-layer graphene. However, at temperatures less than 11 K there is a noticeable change – the thermal conductivity of graphene composites becomes lower than that of epoxy. The effective out-of-plane thermal conductivity of few-layer graphene is responsible for the behavior in the composite with graphene loading below 20 wt. %. At the graphene loading above ~20 wt. %, the trend changes again owing to the onset of thermal percolation. Our somewhat unexpected experimental findings suggest that the epoxy composites with the low loading of graphene and few-layer graphene can act as efficient thermally insulating materials at sufficiently low temperatures. These results indicate the potential of graphene composites for applications in the thermal management of cryogenic technologies.

Hygrothermal and Viscoelastic Properties of Polyurea Elastomeric Foam Mark Smeets[1], Behrad Koohbor[2] and George Youssef[1]; [1]San Diego State University, United States; [2]Rowan University, United States

The emergence of elastomeric foams for impact mitigation applications, including sports protective gear, hinges on their superior mechanical behavior as a function of various operating, environmental, and loading conditions. For example, polyurea elastomeric foams have shown exceptional potential as helmet liners, protective body pads, and shoe insole materials. It is hypothesized that polyurea foams inherit the superior environmental and mechanical behaviors of their solid constituents, *i.e.*, polyurea. This research aims to broadly investigate the hygrothermal and viscoelastic behaviors of elastomeric polyurea foams, assessing their response to moisture with different pH levels, temperatures, and mechanical loading rate. The experimental approach used in this study consist of three sets of measurements. First, the heat flow rate of in-house fabricated polyurea foam plugs is measured using differential scanning calorimetry (DSC) at temperatures ranging from -120C to 400C. The DSC thermograms are analyzed to extract the glass transition temperature, crystallization temperature, apparent melting/softening temperature, and enthalpy and latent heat. Second, foam plugs are submerged in deionized and saline water for extended periods, 2 and 4 weeks, before pyrolyzed using a thermogravimetric analyzer (TGA) from room temperature up to 700C. The TGA thermograms elucidate the hygrothermal and decomposition behavior of polyurea foams as a function of the submersion solution. Finally, the time-dependent mechanical response of polyurea foams is quantified using a dynamic mechanical analyzer (DMA) at frequencies ranging from 1 to 5 Hz, congruent with biomechanical loading scenarios at temperatures ranging from -100C to 100C, covering a broad range of loading conditions. The DMA results relate the viscoelastic properties to the stochastic microstructure of the foam. The outcomes of these investigations extend the applicability of elastomeric polyurea foams to a broad range of civilian and military applications while substantiating the process-structure-property interrelationship of stochastic elastomeric foams.

Atomistic Calculations of Irradiation Damage in Tungsten Improved with Temperature-Dependent Electron-Phonon Coupling Byeongchan Lee and Younggak Shin; Kyung Hee University, Korea (the Republic of)

Plasma-facing components (PFCs) in fusion reactors are exposed to extreme heat flux, making thermal management of PFCs critical to protect the entire reactor. More important, PFCs experience neutron irradiation and undergo severe microstructural damages. In the absence of true fusion environment, however, test and design of PFCs substantially depends on simulations; neutronics, magnetohydrodynamics, and atomistic calculations to name a few.

Atomistic calculations using primary knock-on atoms (PKAs) are of particular importance as the detailed information on the microstructural degradation during irradiation is readily available. To that end, it is crucial to implement a virtual environment as well as a virtual/atomistic specimen compatible or at least comparable with the true environment, and our focus is specifically on the thermal conductivity: how extreme energy density delivered locally via PKAs is dissipated through the material, and what the impact of computational settings would be on conduction.

In this talk, tungsten is studied from atomistic calculations as it is one of the candidate materials for PFCs thanks to its high melting temperature and thermal conductivity. Specifically, a two-temperature model (2TM) handling the background electron-thermal contribution associated with electron-phonon coupling is used for a quantitative improvement in the conductivity prediction. Without 2TM, the thermal conductivity only from phonons is predicted to be less than 20% of the experimental measurements. Surprisingly, the electron-phonon coupling coefficient increases over 5 times with increasing electron temperature, and the thermal conductivity at high temperature is decreased down to nearly a half of the room-temperature value. Given that an irradiation cascade results in an extreme temperature gradient, generating a range of local conditions with different thermal conductivities, it is necessary to incorporate the temperature-dependent electron-phonon coupling coefficients into atomistic calculations.

We report the results of variable electron-phonon coupling effects in irradiated damages, and also discuss the effects of defects on the thermal conductivity as damage progresses. We briefly discuss how we can predict the upper and lower bounds of the irradiated damage in terms of thermodynamic as well as numerical settings.

Thermal and Transport Properties of Novel Metal Oxychalcogenides for Energy Recovery Joe Willis, Katarina Brlec and David O. Scanlon; University College London, United Kingdom

It is estimated that up to half of global energy input is lost to thermal processes.[1] Harvesting this waste heat and converting it into consumable, electrical energy is a viable route towards cleaner energy, and is made possible through the use of thermoelectric materials and the Seebeck effect. Historically, thermoelectrics contain heavy, toxic metals such as Pb, and are unsuitable for use in everyday society. The discovery of non-toxic, earth-abundant thermoelectrics is therefore highly desirable, enabling widespread improvements in energy efficiency and potential climate change mitigation.
Following the recent proposal of the mixed anion system $Y_2Ti_2O_5S_2$ as an n-type thermoelectric,[2] we investigate the thermal and transport properties of a

family of related $Ln_2M_2O_5Ch_2$ oxychalcogenides (Ln = Sc, Y, La, M = Ti, Zr, Hf and Ch = S, Se, Te) for energy recovery applications. We use AMSET,[3] a package for calculating scattering rates from first principles, to assess mobility, power factor and carrier lifetimes. These results will allow us to determine the effects of simultaneous cation and anion substitution on the electronic properties of this family of materials, and to identify promising candidates for the calculation of lattice thermal conductivity and figure of merit (ZT).

A Substitute Contact Layer to N-Type Nanocrystalline Diamond Surfaces Using Hafnium Evangeline Amonoo, Vishal Jha, Franz Koeck, Gabriel Munro-Ludders, Robert J. Nemanich, Trevor Thornton and Terry Alford; Arizona State University, United States

For the first time, gold, platinum, and hafnium nanofilms were grown on nanocrystalline diamond to serve as electrical contact layers. Hall effect measurements confirmed n-type conduction behavior of the nanocrystalline diamond material and hafnium was observed to form a conductive carbide after annealing at temperatures above 800 °C. After electrical measurements, a specific contact resistance in the range of 10^{-2} $\Omega.cm^2$ and a sheet resistance in the range of 6300 Ω/sq was attained.

5:00 PM SF03.15.12
Multiscale Modeling of Boltzmann Transport Equation to Study Unsteady Thermal Transport Using FEM Kunwar Abhikeern; Indian Institute of Technology Bombay, India

The **thermoelectric (TE) materials** could complement the renewable energy extraction from sources like solar energy and it can also act as an alternative to heat engines while harvesting waste heat from several electrical devices like computers. The **figure of merit *ZT*** is responsible for the thermal efficiency of TE materials which can be increased by decreasing the lattice thermal conductivity of the materials. It has been found that *ZT* is enhanced in nanostructured grains with small misorientations. It has also been observed that nanocomposites such as optimally doped Bi_2Te_3 and its solid solution with Sb_2Te_3, Bi_2Se_3 and silica powder can enhance *ZT*. These grains and nanoinclusions are of nanometer to micrometer sizes for which first principle calculations and molecular dynamics based calculations become computationally too expensive to even attempt. Therefore, not only there is a need to **understand thermal transport across interfaces**, **grain boundaries** and **naoninclusions** using known methods, but a **mutiscale modeling of Boltzmann Transport Equation (BTE)** will also help **understand thermal and electrical transport** across all these defects and composites involving several scales. We aim to **develop a multiscale framework** in which the **phonon** information coming from **molecular dynamics/DFT** simulations will be **coupled** with Finite Element Methods (**FEM**) **for solving BTE** which has advantages such as constructing a well defined boundary solution to be used to study thermal transport across the grain boundaries or phase and interface boundaries for nanoinclusions. This will be cross verified by the experiments involving nano-composites of $Bi_x\ Sb_{\{2-x\}}Te_3$. The finite volume scheme is already in use but the current work uses FEM whose accuracy could be improved by mesh refinement or by increasing the order of interpolation functions.

5:00 PM SF03.15.13
Printing 3D Cuboid Thermoelectrics Using Commercially Available Inorganic Binders Geraint Howells[1,2,3], Matthew Burton[1,4], Matthew Carnie[1,4], Shahin Mehraban[1,5] and Nicholas Lavery[1,5]; [1]Swansea University, United Kingdom; [2]Coated, United Kingdom; [3]Tata Steel UK, United Kingdom; [4]SPECIFIC, United Kingdom; [5]Materials Advanced Characterisation Centre (MACH1), United Kingdom

Rising concerns of global warming and its subsequent effects mean that energy production must move away from traditional fossil fuels to cleaner green solutions. Thermoelectric materials recycle waste heat and turn it into useful electrical energy, by utilising the Seebeck effect (a movement of charge carriers from the hot, high energy state to the cold, low energy state). Thermoelectric generators (TEGs) consist of p-type and n-type legs, combined electrically in series and thermally in parallel. Thermoelectric performance is characterized by the dimensionless figure of merit value, ZT ($ZT = \sigma S^2T/\kappa$), consisting of the Seebeck coefficient (S) electrical conductivity (σ), thermal conductivity (κ), and the absolute temperature (T).[1] Traditionally, thermoelectric materials have been dominated by tellurium based compounds, bismuth telluride and lead telluride for low and medium temperatures, respectively. These materials, however, are toxic, and tellurium itself is relatively earth scarce, with an abundance like platinum (1 $\mu g\ Kg^{-1}$).[2] To alleviate the problems surrounding these materials, new compounds must be researched. Tin selenide (SnSe) has been shown to exhibit a record high figure of merit, ZT number of 3.1 in 2021, due to its ultralow thermal conductivity and high Seebeck coefficient.[3] Manufacturing methods of making SnSe based thermoelectrics include Bridgman crystal growth and spark plasma sintering, which take a long time and are energy intensive.[3,4] As a result, there is a need to look at new manufacturing techniques for thermoelectric materials.
This work, consequently, looks at the feasibility of printing SnSe produced via ball milling constituent elements. Printing dramatically lowers the embodied energy of manufacturing, has a high production output, and lowers the cost to make thermoelectric materials.[5] Typical thermoelectric printing techniques such as screen printing or inkjet printing produce inherently thin samples (thickness <1mm) which are undesirable for efficient TEGs (>5mm). This work successfully demonstrates a method of psudo-3D printing SnSe powders using varying inorganic, industrially established binders forming samples of any desired thickness. Printing was followed by a short curing step of 1 hour in an argon atmosphere at 873 K. These results were repeatable, rapid, scalable and samples were shown to have sufficient dimensions (approximately 1 cm^2 by 2 cm) for TEG use. The materials characterisation methods of x-ray powder diffraction and energy dispersive X-ray spectroscopy displayed that the printed materials were SnSe. X-ray photoelectron spectroscopy was also employed to analyse surface chemistry of the samples. Characterization of thermoelectric performance was done on a ULVAC ZEM3 system and showed a peak power factor of 127.9 $\mu W\ m^{-1}\ K^{-1}$ at 850 K. The samples also showed no sign of thermal degradation, even after five thermal cycles up to 850 K. The peak ZT observed was 0.3 at 823 K, higher than most printed thermoelectric materials within the literature.[5] Proof of concept p-type only TEGs were produced from the samples, which produced 467 µW at 789 K, which is the highest of any printed SnSe based TEG to date.[6]

5:00 PM SF03.15.15
Investigation of the Thermal Conductivities of Single Nickel Nanowires Wei-Tsu Peng[1], Jiun-Hung Yi[2], Kuan-Ju Yu[1], Tien-Kan Chung[1] and Ming-Chang Lu[2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]National Taiwan University, Taiwan

Magnetoresistive random-access memory (MRAM) is an emerging memory device technology with the advantages of consuming less power, fast reading and writing, and being a non-volatile memory. Therefore, it has the promising potential to replace dynamic random-access memory (DRAM) and static random-access memory (SRAM) devices. MRAM stores the data in the magnetic domains, and operates by changing the resistance of a magnetic tunnel junction (MTJ). The resistance change in an MTJ is usually accomplished by applying a spin current to switch the magnetization of the MTJ. The operation of an MRAM involves coupling a magnetic field and electron transport; in the meantime, Joule heating is also induced by the applied spin current.
Given that Ni is the most common material in MRAM devices; therefore, this study investigates the effect of magnetic field on heat transfer and current transport in single Ni nanowires (NiNWs). The NiNWs were fabricated by electroplating Ni into a porous anodic aluminum oxide (AAO) template. The Halbach magnets were employed to apply the external magnetic fields with different magnitudes and orientations on the NiNWs. The X-ray diffraction (XRD), transmission electron microscopy (TEM), selected-area electron diffraction (SAED), energy-dispersive x-ray spectroscopy (EDS), and superconducting quantum interference device (SQUID) were conducted for the characterization of the NiNWs. It was found that the NiNWs were polycrystalline with a face-center cubic (FCC) crystal structure and a grain size of approximately 21 nm. The SQUID revealed that the magnetization of the NiNW array increased with an increasing magnetic field and was saturated at approximately 3 kOe.
The measurement results showed that the orientation of magnetic fields had little influence on the thermal conductivities (*k*s) and electrical resistivities of the NiNWs. On the other hand, the *k*s of the NiNW were reduced significantly by the applied magnetic field, whereas their electrical resistivities were almost unaffected. These results indicate that the magnetic field has a relatively profound influence on magnon transport compared with electron transport. In addition, the magnon-contributed k at a magnetic field was retrieved from the difference between the *k* at a zero magnetic field and at the applied magnetic field. It was found the magnon-contributed *k* accounted for 20%–30% of the total *k* at room temperature.
In addition, a theoretical model based on the Boltzmann transport equation was developed for the magnon thermal conductivity. Four scattering mechanisms, including boundary scattering, defect scattering, magnon-magnon scattering, and magnon-phonon scattering, were considered in the model. The theoretical modeling revealed that magnon-defect and magnon-boundary scatterings played the most critical roles in magnon transport compared to the magnon-magnon and magnon phonon scatterings.

5:00 PM SF03.15.16
Thermal, Electrical and Mechanical Characterizations of Aligned Copper Nanowires Array Long Zhu, Weixiao Gao and Fei Ren; Temple University, United States

High performance and reliable thermal interface and electrical contact materials are in great demand for high power density electromechanical devices in semiconductor industry. Vertically aligned Cu nanowire (NWs) arrays exhibit remarkable thermal, electrical conductivity and mechanical compliance, and have been used in a variety of applications, such as liquid-vapor phase-change heat transfer enhancement, selective electrochemical sensor, enhanced field emission, thermal interface materials (TIMs), lithium-ion battery, etc. In this study, double sided Cu NWs array on Cu substrate were prepared via template assisted electrodeposition and used as TIMs and electrical contact material for electrical interconnection. The thermal and electrical transport properties of the double-sided Cu NWs array were systematically investigated.
In addition to their functional properties, the reliability of the devices depends on the robust bonding between the metal structures to the underneath substrates. Quantitively evaluating the mechanical properties and the bonding strength between the metal structures and substrates can provide guidance for the design, fabrication, and failure analysis of the devices. Here, nanoindentation and nanoscratch tests were performed on Cu NWs to investigate the mechanical properties and bonding strength of Cu NWs to the Cu substrate, respectively.

5:00 PM SF03.15.17
Silicon-Based TEM Grids for the Complete Thermoelectrical Characterization of Individual Nanowires Jose Manuel Sojo Gordillo[1,2], Carolina Duque Sierra[2], Nerea Alayo[2], Marc Salleras[3], Yashpreet Kaur[1], Saeko Tachikawa[1], Nicolas Forrer[1], Luis Fonseca[3], Ilaria Zardo[1], Alex Morata[2] and Albert Tarancón[2,4]; [1]University of Basel, Swaziland; [2]Catalonian Institute for Energy Research (IREC), Spain; [3]Institute of Microelectronics of Barcelona, IMB-CNM (CSIC), Spain; [4]Catalan Institution for Research and Advanced Studies (ICREA), Spain

Currently employed materials in Thermoelectric Generators (TEGs) such as bismuth telluride or lead telluride are scarce, expensive, toxic, and environmentally harmful, relegating this technology to specific niches. However, in recent years, the thermoelectrics paradigm has changed mainly due to the introduction of low-dimensional materials. This miniaturization enabled tailoring some properties of materials, such as reducing thermal conductivity by phonon scattering. Consequently, materials previously discarded due to a large bulk thermal conductivity have gained significant interest. Semiconductor nanowires (NWs) – in particular Si and SiGe NWs – have demonstrated fascinating properties with applications in a wide range of fields, including energy and information technologies. Despite this interest, a proper evaluation of the compositional, morphological, and thermoelectrical properties in such nanostructures still represents a great challenge.

Typically, the study of individual integrated NWs following the bottom-up approach faces two main issues. The first one is the need for catalyst nanoparticle precursor deposition to grow them, usually performed by colloidal solution depositions. The randomness of this process dramatically hinders the precise allocation of the desired NW into the employed test microdevices. The second challenge relates to the different architectures of test microdevices devoted to measuring one nanomaterial property. These challenges often result in the use of different NW to measure each of the studied properties, being one of the primary sources of error in the characterization of NWs.

This work presents the conceptual design, simulation, fabrication, and testing process of a micro-machined device for the complete evaluation of a single bottom-up integrated NW. In the exhibited design, the NWs can grow between multiple pairs of breakable cantilevers. This approach allows the user to select the most suitable sample among the available in the chip after the random deposition of the catalyst precursor and discard the rest. The design also incorporates though micro-trenches. This feature, added to the nominal device diameter of 3 mm, enables the use of Transmission Electron Microscopy for detailed morphology analysis and compositional characterization techniques such as EELS or EDX. In the same architecture, electrical collectors and isolated heaters are available at both ends of the trenches for thermoelectrical measurements of the NW. Moreover, through micro-Raman measurements, thermal conductivity evaluation is improved thanks to the lack of substrate below the NW and the electrical and thermal access to the NW for in-operando analysis. Finally, the fabrication process is designed without using anisotropic etching processes, allowing the chip to be fabricated in any crystallographic direction needed.

The device presented here shows remarkable utility in the challenging thermoelectrical characterization of integrated nanostructures and in the development of multiple devices such as thermoelectric generators.

Dynamically Stable Cubic-Phase MAPbI$_3$ Structure and Its Phonon Particle-/Wave-Nature Jin Yang[1], Ankit Jain[2] and Wee-Liat Ong[1,1]; [1]Zhejiang University, China; [2]IIT Bombay, India

Hybrid halide perovskites, with their favorable carrier recombination time and ultrashort phonon mean-free paths, are potential candidates for numerous energy conversion applications like photovoltaics and thermoelectrics. The origin of the ultralow thermal conductivity in the prototypical methylammonium lead triiodide (MAPbI$_3$) is of intense research interest for improving its energy conversion performance.[1] So far, such an understanding remains elusive in the MAPbI$_3$ above room temperatures (c-MAPbI$_3$) despite numerous efforts due to the unstable modes in its phonon dispersion. [2]

Using molecular dynamics and the Wigner-transformed Boltzmann transport equation,[3] we report the discovery of several c-MAPbI$_3$ local energy minimum structures.[4] These stable structures are amenable to lattice dynamics-based calculations to produce totally positive phonon dispersions. Our results reveal a coherence-channel-dominated thermal transport mechanism in the c-MAPbI$_3$ crystals. Interestingly, an inter-conversion between the population- and coherence-channel occurs when the c-MAPbI$_3$ changes across these energetically equivalent structures at the same temperature. Such an effect is yet to be observed in simple atomic crystals. Our work also shows that existing thermal transport intuitions based on the phonon gas model can be misleading in such hybrid crystals. Further, the dominance of the non-traditional coherence-channel of phonons can affect the interpretation of other phonon-mediated processes in MAPbI$_3$ and other hybrid perovskites.

Aluminum Nitride Microstructures by UV Laser Processing for Two Phase Heat Transfer Applications Muhammad Shattique[1], Roman Giglio[1], Ercan M. Dede[2], Mehdi R. Asheghi[3], Kenneth E. Goodson[3] and James W. Palko[1]; [1]University of California, Merced, United States; [2]Toyota Research Institute of North America, United States; [3]Stanford University, United States

With the increase of power electronics applications, the demand for higher heat flux cooling is increasing. The high thermal conductivity and electrical resistivity of AlN make it an effective substrate material in power electronics applications. Here we present nano second pulsed UV laser processing approaches under ambient atmospheres for the production of AlN microstructures for two-phase heat transfer applications. Scanning electron microscopy reveals that laser micromachining enables creation of high surface area micro pin fin type arrays in a single processing step compared to the complex processing protocols employed in traditional micromachining. The surface roughness of these laser machined micropillars is measured to be ~6 μm. The micropillar structures and high surface roughness enables capillary wicking and superior wetting of applicable working fluids. We observe that the laser exposure of the AlN surface causes metallization of AlN to Al. Conductivity measurement of the machined substrate reveals the sheet resistance to be 2.5-4 Ω/square with a corresponding thickness of the resulting aluminum layer deduced to be 6-8 nm. XPS analysis confirms the AlN Al transformation with the N signal disappearing from the laser micromachined surface. The laser machined pin fin arrays have been characterized for heat transfer performance and exhibit a critical heat flux of 145 W/cm^2 with a superheat of 20°C. We analyze the resulting performance in terms of structural and surface property modification imparted by the laser processing approach. Facile processing of AlN holds significant promise to further the use of two phase heat transfer applications at large scale.

Innovative Swaging-Drawing ATF Tube of Thermal Stability Evaluation by LOCA Situation for PWR Unho Lee, Ji Hyeok Choi, Jisu Na, Jeong Hye Jo and Young Soo Yoon; Gachon University, Korea (the Republic of)

After Eu-taxonomy in 2022, PWR (Pressurized Water Reactor) is scheduled to be treated with verification technology applied with ATF (Accident tolerant fuels) technology until 2028. Among nuclear power plant materials, nuclear fuel tubes must have resistance to accident situations as well as pressurized and high-temperature environments. In order to delay the accident of Zr-alloy tube in LOCA (loss-of-coolant accident) situation, research on surface coating and composition change is in progress. However, since Zr-alloy is used as the base material, it is very difficult to provide dramatic changes to overcome the nuclear accident. This Korean research team shows excellent thermal stability in the LOCA simulation situation for the swaging-drawing technology, which is the core technology to which the ATF technology is applied. In addition, SS-Zr-SS tube (SS316L/Zr-alloy/SS316L) exactly match the specifications of commercial Zr-alloy tubes for nuclear fuel and has the advantage of being a room temperature and mass production process. A swaging-drawing of an ultra-thin SS tube of about 70 micrometers was performed inside and outside, and thermal stability evaluation was performed in the LOCA simulation situation at 1,200°C. Oxidation was inhibited by the formation of Zr-nitride in the interfacial environment of SS and Zr. In theory, it was also confirmed that there was no decrease in the power generation output of a Fe-based alloy having a high neutron absorption cross-sectional area. In conclusion, the innovative swaging-drawing triple tube is expected to be an ATF application technology candidate for PWR, which has not only thermal stability but also accident resistance in the LOCA simulation situation.

Tuning Polymer Thermal Conductivity by Molecular Alignment Yoko Tomo[1,2] and Zhenan Bao[2]; [1]Kyushu University, Japan; [2]Stanford University, United States

Polymer is a widely used material in industrial and personal applications due to its low cost, high formability, lightweight and chemical stability. Its ultralow electrical conductivity is also an important feature. In many electronic devices, polymers are used as electrical insulators in the form of interfacial materials and flexible substrates. However, the low thermal conductivity is a disadvantage for thermal management because it hinders the thermal dissipation in electrically-heating devices and causes a significantly high-temperature rise. A molecular dynamics simulation study showed that single polymer chains could have as high thermal conductivity as metals. Recent experimental research also reported high thermal conductivity polymers up to

104 $Wm^{-1}K^{-1}$ by drawing polymer fibers or films. However, this high thermal conductivity is usually fixed once the polymer elongated because the polymer structures are irreversible. In this work, we measured the in-plane thermal conductivity of shape memory polymer using home-developed sensors. We discovered that the thermal conductivity was enhanced by drawing films because it induced molecular structure alignment. Moreover, the thermal conductivity decreased when the films became at the original length. Our results showed that the thermal conductivity of shape memory polymer is tunable by molecular alignment and also suggested that shape memory polymer could be prospective materials for a thermal switch.

SESSION SF03.16: Thermal Transport at Interfaces and Surfaces

8:00 AM SF03.16.01
A Bio-Inspired Artificial Butterfly Wing-Like Membrane for Thermal and Optical Management Yeongju Jung, Seongmin Jeong and Seung Hwan Ko; Seoul National University, Korea (the Republic of)

Natural species often introduce novel functionalities or offer viable solutions for the current technologies as the species evolved through genetic mutations over time to adapt to the specific environment. Similarly, a large number of butterfly species in the warmer climate have evolved to attain interesting properties on their wing scales which exhibit dual functionalities of optical property (structural coloration) and thermal management (radiative cooling). The Archaeoprepona demophoon dorsal wing scale exemplifies such functionalities due to its nanostructure that is characterized by the periodic ridge grating and random nano pore matrix. Despite the fascinating properties that can be translated into practical thermal and optical management applications, there has been no report that reconstructed the physical nanostructure of the butterfly wing scale, although several studies have investigated the origin of functionalities.
Inspired by the fascinating characteristics that the natural species exhibit, we introduce the bio-inspired artificial membrane that artificially reconstructs the wing scale nanostructure of Archaeoprepona demophoon to replicate the thermal and optical management functionalities. To replicate the optical property (iridescent structural coloration) of the butterfly species, PDMS ridge grating structure was fabricated by laser interference lithography. The ridge structure is able to generate of the large color gamut that is capable of expressing 91.8 % of sRGB. For the thermal management property (radiative cooling), the hierarchical PVDF-HFP nano pore membrane was fabricated using SiO_2 nanoparticle etching process. PVDF-HFP nanoporous membrane demonstrates desirable optical properties for radiative cooling: reflectivity = 0.99 (in the range from ultraviolet to visible) and emissivity = 0.95 (in the range of atmospheric window). In this study, we fabricated the artificial bioinspired butterfly wings for thermal and optical management to translate dual functionalities of the butterfly wing into real-world applications. The membrane exhibited the effective radiative cooling with maximum temperature reduction of 8.45 °C. We expect that this study will not only provide the experimental platform that clarifies the optical structure-functionality correlation of the Archaeoprepona demophoon wing scale but it would also share useful insights into the current optics and heat-transfer technologies.

Longitudinal Sound Speed and Thermal Properties of Atomic Layer Deposition-Grown Amorphous AlN/Al2O3 Multilayers with Varying Oxygen Composition Md Shafkat Bin Hoque[1], Ian Brummel[1], Eric R. Hoglund[1], Jaymes Dionne[2], Kiumars Aryana[1], John Tomko[1], John T. Gaskins[1], Daniel Hirt[1], Sean W. Smith[3], Thomas Beechem[4], James M. Howe[1], Ashutosh Giri[2], Jon Ihlefeld[1] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]University of Rhode Island, United States; [3]Radiant Technologies, United States; [4]Purdue University, United States

Dielectric AMLs are currently being used in a wide array of applications such as optical coatings, nanoelectronic, energy harvesting, and recovery devices. The relatively low thermal conductivity of AMLs makes it particularly challenging to effectively dissipate the waste heat generated during these applications. The problem is further compounded in AMLs with high interface densities as the non-negligible role of the interfaces leads to additional thermal conductivity reductions. Thus, it is of vital interest to find pathways of modulating interface density of AMLs without sacrificing thermal conductivity. Here, we report on the sound speed and thermal conductivity of a series of amorphous AlN/Al_2O_3 multilayers grown via plasma enhanced atomic layer deposition. To introduce compositional disorder in the AMLs, the oxygen content of the multilayers is systematically varied as function of interface density. The longitudinal sound speed of the AMLs is solely dictated by the composition. The thermal conductivity, on the other hand, is dictated by both composition and interface density. The oxygen content and interfaces act to increase and decrease the thermal conductivity, respectively. Due to such competing influences of the two parameters, the thermal conductivity of the AMLs remains nearly constant as a function of interface density.

8:30 AM SF03.16.03
Synthesis of Nanostructured Mott insulator La_2CuO_4 and Its Magnon Thermal Transport Properties Shucheng Guo[1], Hongze Li[2], Shuchen Li[1], Jianshi Zhou[2] and Xi Chen[1]; [1]University of California, Riverside, United States; [2]The University of Texas at Austin, United States

The Mott insulator La_2CuO_4, which crystalizes in a two-dimensional layered structure with strong antiferromagnetic coupling, is a promising material for thermal management applications due to its large magnon thermal conductivity. Although bulk La_2CuO_4 crystals have been synthesized and studied extensively, there have been few reports on the synthesis of the nanostructures and studying their magnon thermal transport properties . Here, we study the synthesis of La_2CuO_4 nanostructures and measure their thermal transport properties. Nanorods and nanoparticles of La_2CuO_4 have been prepared by a wet chemical method. The growth mechanism of these nanostructures has been investigated by electron microscopy and energy dispersive X-ray spectroscopy studies. Moreover, nanostructured bulk samples were prepared by consolidating as-synthesized powders. The role of grain size and shape on magnon thermal transport was determined by the thermal conductivity measurements. These results provide useful insights into the development of magnetic nanomaterials for spin caloritronic and thermal management applications.

Interfacial Thermal Resistance from Non-Equilibrium Phonons and Electrons Jinchen Han and Sangyeop Lee; University of Pittsburgh, United States

Large interfacial thermal resistance challenges thermal management in nanostructured devices and opens opportunities for developing ultralow-thermal conductivity materials. However, interfacial thermal transport remains poorly understood due to complex physics and limited methodologies. For example, the complex interplay between the interfacial scattering and intrinsic phonon-phonon and electron-phonon scattering in nano-to-microscale has not been comprehensively studied. Methods that have been widely used in the past include the Landauer's formalism ignoring the intrinsic scattering of phonons and molecular dynamics simulation having a much smaller length scale than the typical mean free paths of phonons. To explore the role of intrinsic scattering of phonons on the interfacial thermal resistance at microscale, we solve the Boltzmann transport equation in both reciprocal and real spaces using a Monte Carlo method with *ab initio* inputs.

Our simulation indicates a significant non-equilibrium of phonon distribution near the interface due to the interfacial scattering in Si-Ge and III-V semiconductor interfaces. The process in which intrinsic phonon scattering attempts to relax the non-equilibrium distribution to a local equilibrium distribution generates a large amount of entropy according to the Boltzmann's H-theorem and leads to excessive thermal resistance. The non-equilibrium effect is observed to contribute more thermal resistance than the interfacial scattering itself in many interfaces. The III-V compound semiconductor interfaces were comprehensively studied to search for general rules of non-equilibrium resistance between two constituent materials. We further involve the electron-phonon scattering in the metal side of the Al-Si interface to investigate its effect on metal-semiconductor interfacial thermal transport. Our study brings a new insight into the significant role of intrinsic phonon-phonon scattering and electron-phonon scattering on interfacial thermal resistance above the atomistic scale.

9:00 AM SF03.16.05
Impacts of Various Interfacial Nanostructures on Spectral Phonon Thermal Boundary Conductance Rui Xie, Janak Tiwari and Tianli Feng; University of Utah, United States

Nanoengineering of interfaces has become an effective way to tune the thermal boundary conductance (TBC) of heterostructures. However, the same nanostructure design can have opposite impacts on TBCs for different systems. To provide a clue toward a unified explanation, in this work, we directly and explicitly reveal the impacts of nanostructures on mode-dependent phonon TBC contributions. We study four representative types of nanostructures, i.e., (1) an intermediate layer, (2) interfacial interlaced teeth, (3) interfacial atomic mixing, and (4) interfacial atomic defects on two example heterostructures: 28Si/Ge and 6Si/Ge, which have moderate and large phonon frequency mismatches, respectively. We find that most of these nanostructures reduce the TBC of 28Si/Ge while increasing the TBC of 6Si/Ge. Each nanostructure is found to have two competing impacts on an interface—one tends to increase TBC while the other tends to decrease TBC. For example, adding an intermediate layer provides a phonon bridging effect, which tends to increase both elastic and inelastic phonon transmission, but it adds one more interface and, thus, more phonon reflection. As a result, an interlayer decreases the TBC of the 28Si/Ge interface by decreasing the inelastic transmission while increasing both elastic and inelastic transmissions of the 6Si/Ge interface. Other nanostructures with atomic disorder can increase transmission by increasing the contact area but can also decrease transmission by phonon-disorder backscattering. This work unveils the fundamental thermal transport physics across interfaces with nanostructures and sheds light on future interface nanoengineering for electronic devices such as high-power transistors, photodiodes, and supercomputing architectures.

9:15 AM SF03.16.06
The Significant Effect of Intrinsic Defects on the Performance of Novel Lightweight Thermoelectric, MgB_4 Sabrine Hachmioune[1,2,2], Alex M. Ganose[3] and David O. Scanlon[1]; [1]UCL, United Kingdom; [2]Agency for Science, Technology and Research, Singapore; [3]Imperial College London, United Kingdom

Thermoelectric materials are being explored as an avenue for alternative power generation. They are typically composed of heavy elements such as Bi, Pb and Te, and are used for large-scale applications. By contrast, this work explores a promising lightweight thermoelectric, MgB_4, with the potential to power wearable electronics, mobile phones, and sensors.[1] We use hybrid-density functional theory (DFT), AMSET[2] and Phono3py[3] to explore the thermal and carrier transport properties of MgB_4, followed by a full defect study to understand its doping limits.

MgB_4 has never been studied before as a thermoelectric material and this work reports ZT's greater than 1, above 900 K under n-type doping, with reduced ZT's under similar p-type doping. The material exhibits an average lattice thermal conductivity of 4.20 $Wm^{-1}K^{-1}$ at 900 K, that reduces upon nano-structuring. The defect study reveals the key role of the intrinsic defects and ionic charge compensation in the dopability and achievable thermoelectric performance of this system.

9:30 AM SF03.16.08
Orientation Effects on Near-Field Radiative Heat Transfer Between Complex-Shaped SiO_2 Particles Lindsay Walter and Mathieu Francoeur; The University of Utah, United States

Near-field radiative heat transfer between micro/nanoscale dielectric particles is often characterized by shape-dependent, localized surface phonon-polariton resonances. These localized resonances are of interest because they typically dominate near-field radiative heat transfer and may be modified through alteration of particle geometry to shift the spectrum of heat transfer. In addition to geometry effects, a few theoretical studies have predicted that the orientation of particles may be used as a method for tuning the heat flux by as much as two orders of magnitude, opening the possibility of developing particle-based thermal switches (R. Incardone *et al*., *Europhys. Lett*. **106**, 41001, 2014; M. Nikbakht, *J. Appl. Phys*. **116**, 094307, 2014). These previous studies on particle orientation, however, have been limited to a small range of geometries encompassing spheroidal point dipoles, gold cylinders (A. W. Rodriguez *et al*., *Phys. Rev. B* **88**, 054305, 2013), and graphene dimers (F. V. Ramirez *et al*., *Phys. Rev. B* **96**, 165427, 2017). The work presented here is not restricted to the point dipole approximation and goes beyond these previous studies to address the knowledge gap concerning orientation effects on near-field radiative heat transfer between more complex-shaped particles. Specifically, we model systems of two 50-nm-radius SiO_2 superellipsoid particles of variable concavity and orientation (L. P. Walter and M. Francoeur, *Appl. Phys. Lett.* **121**, in press, 2022). The analysis is conducted using the discrete system Green's function (DSGF) method for radiative heat transfer (L. P. Walter *et al*., arXiv:2204.05399, 2022). The DSGF method is a volume integral approach for solving the equations of fluctuational electrodynamics where particles are discretized into cubic subvolumes. In this way, all electromagnetic interactions are accounted for throughout the volume of each particle, and location-dependent power dissipation is resolved. The key results of this work are: (1) the range in the total conductance of the complex-shaped superellipsoid particles over variable orientation is significantly less than that predicted from spheroidal dipole models; (2) orientation effects are strongly correlated with the minimum vacuum gap distance between particles; and (3) the center-of-mass separation distance at which orientation effects on near-field radiative heat transfer are negligible is related to the particle topology. The results and insight from this work are important for engineering effective thermal management in real-world particle devices that may contain a variety of complex particle shapes and orientations, such as Mie-resonance-based metamaterials.

SESSION SF03.17: Nanoscale Microscopy
Session Chairs: Irena Knezevic and Andrea Pickel
Friday Morning, April 14, 2023
Marriott Marquis, B2 Level, Golden Gate A

10:30 AM SF03.17.01
Combining Ratiometric Thermometry and Super-Resolution Imaging of Upconverting Nanoparticles Ziyang Ye and Andrea Pickel; University of Rochester, United States

Modern electronic, data storage, and energy conversion devices increasingly combine nanoscale dimensions with challenging operating conditions, including extreme temperatures, high pressures, large electromagnetic fields, and harsh chemical environments. In tandem, thermal properties play an outsize role in determining the overall performance of these technologies. Engineering improved performance thus requires the ability to visualize heat flow using non- invasive thermometry techniques with nanoscale spatial resolution. Conventional far-field optical techniques enable non-contact measurements, but such approaches fundamentally lack the spatial resolution required to resolve nanoscale temperature heterogeneities. Upconverting nanoparticles (UCNPs) are popular luminescent thermometers with Boltzmann-distributed emission intensity that facilitates thermometry via temperature-dependent spectral peak intensity ratios, an approach known as "ratiometric" thermometry. UCNP coatings have been applied for temperature mapping with diffraction limited spatial resolution. Additionally, single-UCNP measurements have been used to circumvent the diffraction limit, but this approach only allows for single-point nanothermometry. Recently, heavily (~10%) Tm-doped UCNPs were shown to enable a super-resolution imaging method called stimulated emission depletion (STED) that has been widely used in biological imaging to circumvent the optical diffraction limit. Compared with other common STED imaging probes, UCNPs require much lower STED laser powers. Separately, this same UCNP composition, but with a much lower Tm concentration of ~1%, has been used for diffraction-limited ratiometric thermometry, suggesting the possibility of adapting STED imaging for far-field optical temperature mapping with sub-diffraction limited spatial resolution.

Here, we demonstrate that individual heavily Tm-doped UCNPs can be applied both for ratiometric thermometry and STED imaging. We measure temperature-dependent emission spectra of individual UCNPs as function of temperature, and we identify several temperature-dependent peak intensity ratios. While the temperature dependence deviates from the Boltzmann-distributed emission intensity that has been observed for lightly Tm-doped UCNPs, these ratios show sensitive, repeatable temperature dependence with good particle-to-particle uniformity. Using a custom-built STED imaging and spectroscopy system, we successfully demonstrate single-UCNP spectroscopic depletion for the first time, a key requirement for ratiometric STED nanothermometry. We also show that the sub-diffraction limited imaging resolution of our system is maintained from room temperature up to 400 K. Using an interfacial self-assembly method, we demonstrate the ability to create uniform UCNP monolayers spanning regions many microns wide, which can subsequently be placed on a sample surface. We then scan the surface of a monolayer-coated substrate that is heated to different uniform temperatures and successfully generate uniform temperature maps by recording temperature-dependent ratios at each pixel. These results indicate that temperature-dependent STED imaging of heavily Tm-doped UCNP monolayers has excellent potential to facilitate optical super-resolution thermometry of structures with nanoscale temperature heterogeneities in the near future.

10:45 AM SF03.17.02
Probing Performance Improvements in Thermophotovoltaic Energy Conversion at Nanoscale Gaps Rohith Mittapally[1,2], Byungjun Lee[1], Ju Won Lim[1], Linxiao Zhu[3], Stephen R. Forrest[1], Pramod Sangi Reddy[1] and Edgar Meyhofer[1]; [1]University of Michigan, United States; [2]Massachusetts Institute of Technology, United States; [3]The Pennsylvania State University, United States

Thermophotovoltaic systems enable the direct conversion of heat into useful electrical power. A typical TPV system consists of a hot emitter facing a cold photovoltaic cell (PV), where the emitted electromagnetic radiation generates electron-hole pairs in the PV cell. When such an emitter and a PV cell are separated by gaps larger than the thermal wavelength—said to be in the far field of each other— a blackbody limit bounds the power output density. Theoretical studies in the last decade predict that large enhancements in power output beyond the blackbody limit are possible by reducing the gaps to nanometric distances, i.e., by placing them in the near-field (NF) of each other. Experimental validation and precise characterization of this phenomenon have been challenging because accurately positioning a hot body at nanometric distances from a PV while quantifying the heat flux to the PV cell is demanding. Here, we will first describe how we experimentally establish an NF-TPV system's temperature- and gap-dependent performance and demonstrate a ~40-fold enhancement in power output in the NF compared to the far field[1]. Next, we report experimental techniques that allowed us to maintain a hot silicon emitter (at 1300 K) at gaps as small as 100 nm away from an InGaAs-based PV cell at 300 K. Aided by the development of doped silicon emitters that could be heated to temperatures as high as 1300 K and high-quality InGaAs PV cells equipped with a back surface reflector, our NF-TPV system supports a record-high power density output of 0.5 W/cm^2 at an efficiency of 6.7% [2]. Further, we will discuss our theoretical model based on a combination of fluctuational electrodynamics and PV cell modeling, which agrees with the measurements at different temperatures and gap sizes. We will conclude the talk by discussing ideas of how to (further) improve the performance of NF-TPV systems.

11:00 AM SF03.17.03
Quantitative Temperature Measurement of Self-Heating in Non-Linear Devices Using Scanning Thermal Microscopy Nele Harnack, Pengyan Wen, Olivier Maher, Siegfried Karg and Bernd Gotsmann; IBM Research Europe - Zurich, Switzerland

Self-heating in electronic devices relates to rich and unexplored transport physics of heat and charge. Phenomena range from hot spots causing device failure [1], to exploiting self-heating as a new platform for computing by utilizing electro-thermal processes [2]. Imaging and understanding thermal transport and thermal processes at the nanoscale enables thermal management and new ways of computing, making it highly relevant in today's integrated microelectronic devices.

Scanning Thermal Microscopy (SThM) has become a valuable method to investigate device states and failure mechanisms due to its high spacial and temperature resolution. However, quantitative SThM thermometry is so far mostly limited to devices with linear current-voltage characteristics [3]. We have extended the method to investigate non-linear devices, broadening the application range to include many of the functional device types used in today's microelectronics. For instance, devices for logic or sensing involve complex interfaces that may lead to energy barriers and energy filtering.
In this method, the non-linear device under study is driven to an elevated temperature with a periodic and constant part using an applied oscillating and offset voltage. The applied amplitude allows the simultaneous estimation of temperature and thermal resistance, while the applied offset is used to set the

device state. These lead to an oscillating and constant temperature rise in the heated sensing element, which are detected through resistance changes via a Wheatstone-bridge and lock-in amplifier.

The constant temperature rise in the device can then be inferred using

$\Delta T_{DC} = T_{sensor,0} * \Delta V_{AC,n\omega} / (\Delta V_{AC,n\omega} - \beta_n * \Delta V_{DC})$ (1)

Where $T_{sensor,0}$ is the heater temperature out of contact with the device, ΔV are the heater's constant and oscillating voltage rise measured over the Wheatstone-bridge and n refers to the harmonic under investigation. The newly introduced non-linearity factor β_n accounts for the changing device resistance and is estimated numerically from its I-V characteristics. Our new technique was verified mapping the temperature of exemplary linear (ohmic) and non-linear (memristive and logical) devices.

In conclusion, the method developed here can be used to investigate non-linear devices and materials, including volatile and non-volatile phase-change materials. The combination of an AC voltage with a DC bias allows the separate investigation of different voltage-dependent device states. The method will therefore be crucial to understand dynamics in operating devices and to shine light on reliability issues and break-down mechanisms.

Comparing Near-Field Thermal Radiation Between Different Materials Including III-V Semiconductors Mathieu Thomas[1], Christophe Lucchesi[1], Julien Legendre[1], Natasha Gruginskie[2], Rodolphe Vaillon[3] and Pierre-Olivier Chapuis[1]; [1]CNRS-CETHIL, France; [2]Radboud University, Netherlands; [3]CNRS IES, France

When the distance between objects decreases below the characteristic wavelength of thermal radiation (few micrometers in the 300-1000 K range), the radiative heat exchanged between these objects is increased beyond the blackbody limit imposed by Planck's law in the far field. This increase of thermal radiation, which takes place in the near field, can reach several orders of magnitude. Explained by the additional contribution of evanescent waves to the radiative transfer, this phenomenon, which is now well documented theoretically and experimentally, can be of interest for thermal-energy harvesting. For instance, thermophotovoltaics (TPV) can take advantage of this enhancement of the radiative heat flux in order to increase the electrical output power density when the emitter is brought closer to the cell [1]. A further improvement of such a device is to place a light–emitting diode (LED) on the heated emitter side, which allows controlling the emission spectrum; such device is termed thermophotonic (TPX).

Some of us have demonstrated recently that Stefan-Boltzmann's law is modified in the near field [2] and that the temperature dependence of near-field radiative heat transfer varies with the material considered. Here, we analyse the near-field radiative heat transfer between a heated emitter and different types of samples of interest for energy harvesting. For TPV and TPX devices, III-V semiconductors such as InSb, GaAs, InGaP or AlGaAs are key materials. We report on the experiments, which consist in executing several approaches of a heated micrometric spherical emitter close to the flat studied sample in order to obtain the near-field radiative conductance as a function of distance. Since the increase in the radiative flux depends dramatically on distance, we also report on our recent efforts to determine the flux more accurately in the last 50 nm before contact by means of combined analysis of laser deflection, fiber interferometry and resistive thermometry.

***Ab Initio* Simulation of Swift Heavy Ion-Driven Damage on Nanoscale Thermal Transport in ZnO** Kairolla Sekerbayev[1], Azat Abdullaev[1], Bekdaulet Shukirgaliyev[1], S. Mehdi V. Allaei[2], Yanwei Wang[1,3] and Zhandos Utegulov[1]; [1]Nazarbayev University, Kazakhstan; [2]University of Tehran, Iran (the Islamic Republic of); [3]National Laboratory Astana, Kazakhstan

Swift heavy ion (SHI) irradiation of non-metallic materials is a promising approach to engineering their thermal transport properties at the nanometer scale. SHI damage can be imparted into host semiconducting and insulating solid lattices in the form of cylindrical ion tracks or near-surface point defects[1]. However, there is a lack of clear understanding of the effect of SHI damage on nanoscale thermal transport in irradiated solids.

In this work, we analyze the *SHI-induced damage* to wide-bandgap semiconducting ZnO single crystal by a hybrid simulation technique combining *ab initio* Monte-Carlo Time-Resolved Electron Kinetics (TREKIS) and molecular dynamics (MD), which is free from fitting parameters[2]. In this approach, the evolution of electron dynamics of host Zn and O atoms is simulated following the initial impact of Bi ion on the ZnO lattice within the first 100 fs. The radial energy density distributed by ion to the lattice is obtained from TREKIS, the output of which is used to set the initial velocities for the classical MD model in the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) code[3] to predict the 3D damage pattern to the initial zinc oxide hexagonal lattice during its relaxation on a time scale from 100 fs to hundreds of ps. Four different Zn-O interatomic potentials (IAPs) are considered in MD simulations. IAP determines both the ion-induced defect formation and the subsequent thermal conductivity (k) calculations. This TREKIS-MD method is compared with randomly distributed atomic displacements in the crystal formed by the Atomsk software[4].

Then the phonon thermal conductivity of the ion-damaged subsurface region of the ZnO lattice along the (0001) direction obtained from TREKIS-MD is calculated with equilibrium molecular dynamics (EMD) and is compared with the results from the Boltzmann transport equation relaxation time approximation (BTE-RTA), semi-analytical Klemens-Callaway and Rayleigh effective medium approximation models. The k of pristine ZnO obtained by BTE-RTA matches that found by EMD. The difference between the TREKIS-MD and randomly introduced point defects model is seen at high ion doses due to overlapped impinging ions. The *random defects model* fails at high ion doses and predicts further k decrease. On the contrary, the TREKIS-MD model demonstrates k saturation observed experimentally but overestimates the saturated k value. The convergence between TREKIS-MD and spatially-controlled time-domain thermoreflectance measurements of k can be tailored by the appropriate selection of the IAP. The described computational approach opens up an avenue for the design of thermal nanomaterials by controlling the radiation damage via monitoring the electronic excitation by SHIs and subsequent electron-lattice phonon relaxation.

This work was funded by Nazarbayev University collaborative research program (CRP) grant 11022021CRP1504.

Dynamics of Long-Wavelength Phonons Near Boundaries and Interfaces in Nanomaterials Irena Knezevic; University of Wisconsin-Madison, United States

Long-wavelength phonons undergo infrequent phonon-phonon scattering and thus tend to propagate ballistically over long distances in single-crystalline, high-quality bulk materials, thereby making a major contribution to thermal conductivity in these systems. The dynamics of long-wavelength phonons and their interaction with boundaries and interfaces can be accurately modeled within the elastic-continuum limit. I will present recent work, combining experiment and theory, that shows phenomena such as the incoherent-to-coherent transition in thermal transport in III-V superlattices and the changes in the power-law dependence of phonon lifetime on frequency for rough nanowires and membranes with varying correlation types. The work illustrates the complexity of phonon interaction with disorder, and the utility and flexibility of numerical techniques such as the finite-difference time-domain (FDTD) method for elucidating the dynamics of phonons in nanomaterials.

Enhanced Near-Field Radiative Heat Transfer Between Planar Membranes Thinner Than the Vacuum Gap Spacing—Experiment Lei Tang[1], Livia Correa[2], Mathieu Francoeur[2] and Chris Dames[1]; [1]UC Berkeley, United States; [2]The University of Utah, United States

Several experiments have demonstrated that near-field radiative heat transfer (NFRHT) between two flat surfaces can exceed Planck’s blackbody limit (e.g., Song et al., *Nature Nanotechnology* 11, 509-514, 2016; DeSutter et al., *Nature Nanotechnology* 14, 751-755, 2019; Tang et al., *ACS Photonics* 7, 1304-1311, 2020). Recent simulations based on the discrete system Green’s function (DSGF) method (Walter et al., arXiv:2204.05399, 2022) used for modeling NFRHT in arbitrary 3D geometries suggest that the radiative heat transfer coefficient can be further enhanced when the two surfaces facing laterally are thinner than their separation gap. To date there has been no experimental work in this regime, which here we address by measuring NFRHT between the edges of two planar silicon carbide (SiC) membranes thinner than their vacuum gap spacing. More specifically we measured the NFRHT between a series of suspended microdevices consisting of pairs of coplanar SiC membranes with thickness and gap spacing respectively smaller than 100 nm and 500 nm. The measured radiative heat transfer coefficients are large and exceed predictions for two infinite surfaces at the same gap. For instance, at a fixed separation gap of an estimated ~ 100 nm, the measured near-room-temperature radiative heat transfer coefficient for 50-nm-thick SiC membranes is 470 W/m^2-K, which is around 3.1 times larger than calculations for two infinite surfaces of SiC at the same gap, ~ 30 times larger than the far-field results of Thompson et al. for 270-nm-thick SiN membranes (*Nature* 561, 216-221, 2018), and ~ 320 times higher than predicted from a classical blackbody heat transfer calculation for the same geometry. The measurements also agree reasonably well with simulations using the DSGF method. These findings may help inform various applications such as energy conversion, radiative cooling, and thermal rectification.

Thermal Conductivity of GaAs-GaP Superlattices Nanowires Chaitanya Arya[1], Johannes Trautvetter[1], Yashpreet Kaur[1], Valentina Zannier[2], Omer Arif[2], Riccardo Rurali[3], Lucia Sorba[2] and Ilaria Zardo[1]; [1]Universität Basel, Switzerland; [2]NEST, Istituto Nanoscienze-CNR and Scuola Normale Superiore, Italy; [3]Institut de Ciencia de Materials de Barcelona (ICMAB−CSIC), Spain

In the last decades, continuous efforts have been made to understand and control phonons with great potential for numerous technological applications [1]. The objective of this work is to investigate phonons interference and different phonon transport regimes, which is crucial for phonons manipulation. Nanowires are promising candidates for studying phonons interference effects because they offer unique possibilities in terms of heterostructuring and also enable the growth of high-quality nanowire junctions. In this respect, a superlattice (a lattice made by different materials periodically alternated) can be used to investigate the behavior of phonons scattered from interfaces. Phonons scattered from single interfaces lose their phase information, leading to diffusive thermal transport. However, scattered phonons can interfere before losing their phase information resulting in a modified phonon dispersion and thermal conductivity in case of periodic repetition of interfaces with a lengthscale comparable to the phonon mean free path [2,3].
In this work, we are investigating the phonon interference effect in superlattice (SL) nanowires through thermal conductivity measurements. Thermal conductivity of SL nanowires is measured using thermal bridge method using a microdevice which consists of two SiNx suspended platforms with platinum coils that act as a heater and sensor. These platforms aresupported by 0.5mm long suspended SiNx beams, onto which gold lines are deposited, to ensure thermal isolation [4]. The nanowire is suspended between the two platforms using a micromanipulator. To measure the thermal conductance, the temperature is raised on one platform while the change in temperature on the second platform is measured as a function of heating power. To assess the temperature, the resistance of meanders is measured by four-point probe technique and the heat flux across the nanowire is calculated by measuring the power dissipated in the meanders [5].

The thermal conductivity of GaAs-GaP superlattice nanowires is measured for various SL periods from 4.8 to 23.3 nm. The nanowire sample consists of a GaAs-GaP superlattice embedded between two GaP segments. It is observed that the thermal conductivity decreases with decreasing period length and there is a minimum around the period of 8 nm, afterwards the thermal conductivity increases for smaller periods. The minimum in thermal conductivity occurs at the transition between particle-like and wave-like behavior of phonons. In the incoherent regime (i.e. particle-like behavior), the thermal conductivity decreases due to scattering from the increasing number of interfaces. When the period length is comparable to the phonons coherence length in the system, phonons scattered from the interfaces start to interfere consequently increasing the thermal conductivity. This work is a promising step toward using SL nanowires as a powerful platform for exploiting coherent phonons in thermal applications.

Architecture-Induced Control of the Heat Front Propagation in Ni/Al Reactive Multilayers Nensi Toncich, Fabian Schwarz and Ralph Spolenak; ETH Zürich, Switzerland

Reactive multilayers are metastable heterogeneous nanostructures consisting of the stacking of several layered thin films that have a strong tendency toward mixing. The constituents are characterized by a large negative enthalpy of mixing and a high adiabatic reaction temperature. Upon ignition, the alternating metal thin films react in a highly exothermic reaction front that propagates through the entire system in a self-sustaining manner. Taking advantage of their nanometer size, on-demand ignition, high temperatures reached, and many other features, these materials find application as intrinsic heat sources in many fields, such as thermal batteries, joining, thin-film healing, and in the microelectronics industry. Depending on the application, different propagation velocities and temperatures are required, and for this reason, many investigations on the control of the reaction behavior have been conducted in recent decades [1]. However, to expand their scope and enable these materials to perform in more specific applications, further studies need to be carried out. In our work, we analyze the thermal management of Ni/Al reactive multilayers through architecture design. To this end, molecular dynamics simulations [2] and experimental studies were performed on the effect of the presence of a premixed layer between the two reactants, the presence of interface roughness, and the stoichiometric variation on the heat front propagation velocity and the temperature reached. Molecular dynamics simulations demonstrated a direct correlation between the premixed layer thickness and the heat front propagation velocity. An increase in the premixed layer thickness leads to a decrease in the heat front propagation velocity. The same trend, with a decrease in the combustion temperature, was observed experimentally. A second simulation showed that the introduction of an interface roughness speeds up the heat front propagation. Contrary to modeling predictions, experimentally the reaction behavior appears to be unaffected to variations in roughness. Finally, a stoichiometric variation showed a change in the reaction front behavior in both simulation and experiment. For the experimental study, Ni/Al multilayers were deposited via magnetron sputtering, and the reaction was triggered by a low-power pulse. High-speed IR imaging was performed on the samples as well as structural and compositional characterization.

2:00 PM SF03.18.04
Thermal Conductivity and Application of Boron Nitride Nanosheets Qiran Cai[1], Hongbo Jiang[1], Srikanth Mateti[1], Elton J. Santos[2], Luhua Li[1] and Ying Chen[1]; [1]Deakin University, Australia; [2]The University of Edinburgh, United Kingdom

Heat dissipation becomes increasingly critical, especially in miniaturised modern devices, and boron nitride (BN) nanosheets are considered as a promising material for heat dissipation because of high thermal conductivity yet electrical insulation. Here, we firstly report the intrinsic thermal conductivity of atomically thin BN, and the density functional theory calculation reveals the thickness and isotope effects on the heat transport *(1-2)*. To improve the dispersibility of BN nanosheets for the fabrication of advanced composites, we develop a simple, yet efficient mechanochemical exfoliation technique to prepare functionalised BN nanosheets with excellent dispersibility in water and organic solvents *(3)*. Using the high-quality BN nanosheet dispersion as a precursor, BN spheres with high, isotropic thermal conductivity are fabricated, which can isotropically enhance the thermal conductivity of poly(vinyl alcohol) by ~3700%, and address the challenge that BN reinforced polymer offers a highly anisotropic thermal conductivity *(4)*. This study provides not only the important insight into the heat transport and phonon scattering mechanism, but also a practical route to fabricate BN-enhanced thermal interface materials with high isotropic thermal conductivity and promising materials that are valuable for heat dissipation in new-era advanced electronics and related applications.

2:15 PM SF03.18.06
A Data-Driven Exploration of Structure-Property Relationships of Thermal Transport in Metal-Organic Frameworks Meiirbek Islamov[1], Hasan Babaei[2], Jeffrey Long[2,3], Alan McGaughey[4], Diego Gómez-Gualdrón[5] and Christopher E. Wilmer[1]; [1]University of Pittsburgh, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Carnegie Mellon University, United States; [5]Colorado School of Mines, United States

Metal-Organic Frameworks (MOFs) are a class of nanoporous materials that have been heralded as revolutionary materials for gas adsorption applications. However, the usefulness of MOFs depends on how quickly they can dissipate the enormous amount of heat generated during the exothermic adsorption process. Despite its importance, thermal energy management in MOFs has been frequently neglected, which resulted in a limited understanding of the structure-thermal transport relationships in MOFs. To shed a data-driven perspective into these relationships, we performed the first large-scale computational screening of 10,194 hypothetical MOFs for thermal conductivity using classical molecular dynamics (MD) simulations and the equilibrium Green-Kubo method. We found that high thermal conductivity is favored by small pores, high density, and four-connected metal nodes. Moreover, we discovered six hypothetical MOFs that exhibit very high thermal conductivity. Interestingly, these six MOFs have in common square planar metal nodes that are each connected to four perpendicular organic linkers, indicating that topology may be particularly important for heat conduction in MOFs.

Computational Analysis of Plastic Crystals as Solid-Solid Phase-Change Materials—Insight into the Molecular Mechanism of Thermal Energy Storage Atta Muhammad[1,2], Eliodoro Chiavazzo[1] and Matteo Fasano[1]; [1]Politecnico di Torino, Italy; [2]Mehran University of Engineering and Technology, SZAB Campus, Pakistan

Plastic crystals are promising candidates for solid-solid phase-change materials (PCMs) in thermal energy storage components and systems. The peculiar feature is the fact that they remain solid throughout the phase transition temperature range, thus reducing the need for containment and possible additivation [1]. Plastic crystals are organic molecular crystals that display solid-solid phase transitions at temperatures ranging from 310 K to 463 K with relatively large latent heat (over 100 J/g-K). Plastic crystals transform from a low-symmetry crystal structure to a high-symmetry one at a set temperature while absorbing a significant amount of heat (and vice versa).
In this work, we perform theoretical investigations based on classical molecular dynamics (MD) simulations to obtain new physical insights into plastic crystals as PCMs and provide useful information for the rational design of new solid-solid PCMs [2]. We calculate the latent heat, density, number of hydrogen bonds, the energy of hydrogen bonds, radial distribution function, specific heat capacity, and thermal conductivity of three polyalcohols (Pentaerythritol, Pentaglycerine, and Neopentylglycol). MD simulations are also performed to elucidate the relationship between the thermophysical

characteristics of polyalcohols and their crystalline structures at the atomic level. These plastic crystals are selected because relevant thermophysical properties have been reported being phase transition temperature and latent heat for pentaerythritol much higher than those for pentaglycerine and neopentylglycol. Our MD simulation results quantitively reproduce the properties of polyalcohols obtained in recent experiments for the first time [3]. Based on the analysis, we find that their latent heat originates mainly from the decrease in the number and strength of intermolecular hydrogen bonds upon solid-solid phase transition. Furthermore, we also examine the origin of the difference in latent heat between these three polyalcohols.
Overall, this work reveals the molecular mechanism of thermal energy storage of solid-solid PCMs and provides valuable insights for the development of new materials with high latent heat without the need for encapsulation, with a prospected impact in the development of a new class of thermal energy storage systems based on solid-solid PCMs [4].

3:30 PM SF03.19.02
Study of Carrier and Thermal Transport in Semiconductors Using Frequency Domain Thermoreflectance Qichen Song[1] and Samuel Huberman[2]; [1]Harvard University, United States; [2]McGill University, Canada

Frequency domain thermoreflectance (FDTR) is a versatile and powerful characterization technique to study thermal transport in materials. A metallic transducer is often coated on top of the sample to convert laser irradiation into lattice heating. However, the additional layer complicates the heat transfer analysis, and it is thus tempting to conduct the FDTR without the transducer layer. To properly interpret the transducerless FDTR, the non-thermal processes after photon absorption must be modeled. Here, we solved the coupled carrier and heat diffusion equations, which capture the physical processes including ambipolar diffusion, electron-phonon coupling and carrier recombination. Our transducerless FDTR measurements in Si, Ge and GaAs corroborate our model and reveal that the contribution of carrier transport to the signal varies with the dopant concentration. Our study offers insights in understanding the energy dissipation processes in semiconductor devices.

3:45 PM SF03.19.03
Tunability of Thermal Conductivity in Porous 2D-Covalent Organic Frameworks Emma Tiernan[1], Zoheb Hirani[2], John Tomko[1], Lidia Kuo[2], Nathan Bradshaw[2], Nicholas Williams[2], David Burke[2], Austin Evans[3], Mark C. Hersam[2], Patrick E. Hopkins[1] and William Dichtel[2]; [1]University of Virginia, United States; [2]Northwestern University, United States; [3]Columbia University, United States

Covalent organic frameworks (COFs) are a unique class of porous material, in which chemists can easily modulate multiple properties of the COFs by varying the nodes and linkers that make up the framework. The interchangeability of these organic building blocks allows for the structures to have a multitude of applications such as gas separation, catalysis, sensing, electronic devices, energy storage, and more. Conversely, the ability to implement COFs in these applications was limited due to the COFs polycrystalline powder form. In recent years, there has been a large effort to grow 2D COF thin films, which resulted in films with thermal conductivities of 1.0 W m^{-1} K^{-1}. In this presentation, we will use both time-domain thermoreflectance (TDTR) and steady state thermoreflectance (SSTR) to measure thermal and mechanical properties of a variety of COF thin films, including boronate-ester and imine-linked 2D COFs. TDTR and SSTR are non-contact, laser-based, pump-probe measurement techniques, which relate the change in reflectivity of the sample surface, to the thermal conductivities of the COF films below. We will discuss the effects of film thickness, connectivity, and pore functionality on the thermal properties of COF thin films.

4:00 PM SF03.19.04
Near-Field Thermal Radiation vs Near-Field Electroluminescence—Conditions for a Nanothermophotonic Refrigerator Thomas Châtelet, Julien Legendre, Pierre-Olivier Chapuis and Olivier Merchiers; Univ Lyon, CNRS, INSA-Lyon, Université Claude Bernard Lyon 1, CETHIL UMR5008, France

Fluid-based refrigerating devices are known to be noisy, involve polluting refrigerants and cannot be miniaturized easily, so solid-state coolers are especially promising to replace them. Peltier thermoelectric coolers are well-established devices that are smaller, vibration-free heat pumps, but they suffer from low efficiency at room temperature and are difficult to miniaturize further without reducing the temperature difference between the hot and cold sides. Light-emitting diodes (LED), which are also thermodynamic machines, are another category of solid-state coolers [1]. Under particular conditions, LEDs are expected to emit larger radiative power than the supplied electrical power, by pumping heat from their crystalline lattice, resulting in a cooling of the LED and its contacting environment: this effect is called electroluminescent cooling [2]. Since this effect is small, two improvements have been suggested. First, harvesting the radiation emitted by the LED by converting it into electricity in a photovoltaic (PV) cell and sending it back to the LED allows reducing the need for external powering and therefore increases the coefficient of performance of the device. Such combined device is termed thermophotonic (TPX) [1, 3]. Second, the emitted radiation can be enhanced by placing the PV cell in close proximity of the PV cell, in order to allow additional (evanescent) photons to tunnel through the separation gap: the device works then in the near field [4].
A key issue in such device is that the warmer PV cell can also radiate thermally towards the LED, reducing the net power transferred by the LED towards its surrounding. The issue is particularly significant when the two components are in the near field. By means of accurate nanoscale radiative computation

(fluctuational electrodynamics) and detailed balance, we investigate the effect of internal quantum efficiency, temperature, and vacuum gap distance on the potential performances of near-field TPX refrigerators made of GaAs-based materials. In a second step, the drift-diffusion equations are solved to analyse the charge carrier behaviour in a more realistic TPX system [4]. Finally, we analyse how surface roughness impacts the light extraction efficiency and the radiative heat transport in the device.

4:15 PM SF03.19.05
Heat Transfer by Nonequilibrium Electrons in Nanoscale Metal Thin Films and Bilayers Xinping Shi and Richard Wilson; University of California, Riverside, United States

Photoexcitation of a metal drives electrons into a high energy nonequilibrium state. Relaxation of the excited electrons back to equilibrium is often treated with a two-temperature model framework. In the two-temperature model, nonthermal effects are ignored, and transport is assumed to be diffusive. Alternatively, nonequilibrium electron dynamics can be modelled with the Boltzmann transport equation [1]. The Boltzmann transport equation predicts different energy relaxation time-scales and predicts different energy transport length-scales than the two-temperature model. Clear criteria for when the two-temperature model vs. Boltzmann transport equation apply have not been experimentally established. In this talk, we report experimental measurements of nonequilibrium energy dynamics in Al, Cu, Ag, and Au. Our goal is to understand how electron-phonon interaction strengths effect the applicability of two-temperature model vs. Boltzmann transport equation. Measurements of Al, Cu, Ag, and Au are a good test for this because these four metals have systematically different electron-phonon interaction strengths due to differences in atomic mass. We perform a series of time domain thermoreflectance measurements on Al, Cu, Ag, and Au wedge thin-films and Al/Fe, Cu/Pt, Ag/Pt and Au/Pt wedge bilayers. The wedge samples have thicknesses that vary between 0 and 500 nm as a function of position. By performing measurements at different sample locations with different thicknesses, we can accurately measure how far nonequilibrium electrons carry heat before thermalizing with phonons in different material systems. We perform experiments both in a standard front/front and a front/back laser flash geometry. Our experiments show that, while the energy dynamics in Au after photoexcitation are nonthermal, heat transport by nonequilibrium electrons is almost entirely diffusive. We establish simple heuristics that describe how nonequilibrium processes effect energy dynamics in metal heterostructures on time-scales from 10 fs to 10 ns. Our work provides benchmark knowledge about nonequilibrium electron dynamics that will aid applications in nanoscale thermal engineering, photocatalysis, and spintronics.

Thermal, Mechanical and Electronic Tunability in Polymerized Fullerene Structures Jaymes Dionne, Muhammad Akif Rahman and Ashutosh Giri; University of Rhode Island, United States

Recently, polymerized fullerene crystals have been synthesized through the intercalation of alkaline earth metals, avoiding the costly fabrication process involving high pressure conditions. In this study, we show that this polymerization and the introduction of intermolecular bonds between fullerene molecules offers tunable control over their mechanical, thermal, and electronic properties. The superatomic crystals polymerize in tetragonal and rhombohedral phases, or T- and R-phase, respectively, where the molecules are arranged in uniquely layered sheets, similar to that of graphene and its' bulk structure graphite. By utilizing molecular dynamics (MD) simulations and density functional theory (DFT) calculations to investigate the thermal, mechanical, and electronic properties of these phases of polymerized fullerene crystals, we find a drastic enhancement of the thermal conductivity in the in-plane direction when compared to the nonbonded FCC fullerite structure. Moreover. we find that the intercalation of magnesium atoms results in a higher thermal conductivity at room temperature compared to the pristine polymerized structure, which we attribute to the competing mechanisms of temperature-independent impurity scattering and temperature-dependent Umklapp scattering.
In terms of the mechanical properties when compared to other condensed carbon phases, the polymerized fullerenes are relatively more flexible, with a Young's modulus of 110-170 GPa, and are comparatively softer with a bulk modulus of 38.5 GPa. Moreover, the R-phase structure is more flexible than the T-phase structure thus providing an avenue for tunability in their mechanical properties. For both structures, we visualize the von Mises strain distributions and discover that the bulk of the strain is localized in sp^2 carbon atoms near the sp^3 carbon atoms forming the intermolecular bonds, rather than the sp^3 carbon atoms themselves.
For their electronic properties, we find a strain dependent band gap for which the electronic band gap reduces from 0.54 to 0.31 eV under a 4% applied strain. By visualizing the electronic localization function, we attribute this reduction in band gap to increased overlap of covalently bonded atoms forming the intermolecular bonds. As these phases of polymerized fullerenes have the potential to be used as next-generation battery materials, these results highlight their mechanical and electronic similarities to current battery electrodes, as well as the opportunity to potentially improve their heat transfer properties for better thermal management of battery systems.

SESSION SF03.20: Emerging Thermal Materials—From Nanoscale Heat Transport, Devices and Applications, to Theories I

Fundamental Study on Phonon Engineering Nuo Yang; Huazhong Univ of S&T, China

Recently, with the rapid development of smart society, our demand for new functional materials and hardware is urgent. Thermal functional materials play an important role in thermal management, energy storage and energy conversion. Phonons are lattice vibrational waves, which are the main energy carriers in dielectric solids. After electronic engineering and photonic engineering, the research progress of phonon engineering has attracted much attention. Phonon engineering is the discipline of designing and controlling phonon transport and conversion by using phonon devices with micro/nano structure,

which plays a leading role in the design of thermal functional materials. The research objects of phonon engineering include lattice wave quantum transport, thermoelectric conversion, phonon devices and so on. The progress of nanotechnology has also promoted the development of phonon engineering, so there is an urgent need to understand the mechanism of phonon regulation and transport.
Professor Nuo YANG and the Nano Heat Group [1] focus on the fundamental and applied research of heat transfer, thermal control and energy conversion in micro/nano- and multi- scale [2-5]. The report will introduce the research progress of the Nano Heat Group in the following aspects: nanoscale heat conduction, thermal control, thermal interface conduction, hotspot, size effect, etc.

Synergistic Experimental and Computational Research on New Multinary Chalcogenides with Earth Abundant Constituents George S. Nolas and Lilia Woods; Univ of South Florida, United States

Multinary metal chalcogenides are known to form in a variety of structure types and exhibit varying properties depending on composition, crystal structure, chemical bonding, and processing conditions. Nevertheless, providing new avenues for discovery allows for pathways towards the design of new materials, and processing techniques, with targeted properties for specific applications of interest. One such approach is by cation substitution methods, where one can “build” a variety of materials with different chemical formulas while maintaining the valence electron count. Moreover, knowledge of the thermal properties is essential for any application of interest, particularly for thermoelectric, thermophotovoltaic, thermos-acoustic and thermal barrier materials, where low thermal conductivity is obtained when specific features, such as weak bonding, coordination preferences, lone pair electrons, large number of atoms per unit cell, nanoscale effects and strong anharmonicity, are realized. Motivated by these considerations and our continued interest in the effect of complex structure and disorder on the thermal properties of multinary chalcogenides, we investigated the thermal and electronic properties of several new chalcogenides employing cationic substitution. We expand on the techniques we’ve previously employed in investigating Kesterites and Stannites, and will present our most recent work on the structure-property relationships of materials with Adamantine, Sphalerite and Aikinite crystal structures. An intrinsically low thermal conductivity is typical in these materials, and a result of lattice anharmonicity as well as the particular bonding and, in some cases, defects these materials possess. Our research provides a better understanding of the fundamental properties of these materials, with an eye towards determining their suitability for use in thermoelectric applications.

Near-Field Radiative Enhancements—Benefits and Drawbacks for Thermophotonic Energy Harvesting Julien Legendre and Pierre-Olivier Chapuis; CNRS-CETHIL, France

Thermophotonics (TPX) [1] is a technology close to thermophotovoltaics (TPV), where a heated light-emitting diode (LED) is used as the active emitter. Interestingly, an LED is physically similar to a TPV cell, but used in the opposite fashion, i.e. it emits light from electrical power. With such a device, the emission profile can be tuned: initially in the infrared range, it can be shifted by means of electroluminescence to a spectral range matching better the gap of efficient TPV cells. With the development of LEDs and the increase of their achievable quantum efficiency, TPX has come out as an attractive concept for both energy harvesting and refrigeration [2]. One advantage is that the emitter temperature can stay moderate, close to few hundreds of degrees Celsius, in contrast to usual TPV emitters. The many studies on near-field (NF) thermal radiation and their application into efficient NF-TPV devices [3] highlight the possibility to extend the concept to near-field thermophotonics (NF-TPX), where enhanced energy conversion is due to both electrical control and wave tunneling.

In order to model accurately the device and deduce the electrical power output, we couple a radiative transfer solver based on fluctuational electrodynamics - a framework allowing to deal with thermal and nonthermal (electroluminescent) emission within the medium - with a drift-diffusion equations (DDE) solver used for both the LED and the cell [4,5]. This reveals that an electrical power density as high as 2.2 W/cm^2 (~7 mW/cm^{2}K) can be obtained from the NF-TPX device by using realistic AlGaAs PIN homojunctions with the emitter at 300°C. Through a thorough analysis of this device, we point out that such high power can only be achieved in the near-field regime, which is mandatory to extract any power [5]. However, going to the near field also largely increases thermal radiation due to below-bandgap energy surface plasmon/phonon polaritons, which potentially gives rise to large temperature deviation in both LED and cell components and thus induce a significant performance drop. A thermal study performed on TPX devices shows that for a given thermal management system, there is an optimal separation distance that results from a trade-off between increased above-bandgap power transmission and worsened thermal management.

2:30 PM SF03.20.05
Chemically Induced Tuning of Interfacial Thermal Resistance in Porous Silicon/Hexadecane Nanocomposite Oksana Makukha[1], Vladimir Lysenko[2] and Ali Belarouci[1]; [1]Institute of Nanotechnology of Lyon, France; [2]Light-Matter Institute, France

During the last decade, the rapid evolution of elaboration methods for new nanomaterials and nano-architectured devices and systems requires deep understanding and technological mastering of fundamental mechanisms responsible for heat transport at the nanoscale [1]. A specific scientific interest is focused on thermal phenomena taking place across multiphase nanoscale interfaces, such as liquid-solid interfaces. The presence of liquids confined in nanopores of a solid-state material strongly affects heat transfer at the nanoscale as well as the global thermal properties of the liquid-solid nanocomposites. In a porous crystalline matrix with large specific surface areas up to 600-800 m^2/g (such as porous silicon, for example) containing a liquid confined in the nanopore network, one should absolutely consider heat transfer phenomena through the solid-liquid interfaces described in terms of interfacial thermal resistances. Surface chemistry modification of the nanoporous solid skeleton may lead to significant changes in thermal resistance. The thermal mismatch at the interface can be reduced by appropriate surface functionalization, whose thermal properties, hydrophilicity, and wettability characteristics match better those of the surrounding liquid [2].
There are numerous approaches for the chemical functionalization of Si surfaces. The most common methods rely on: (i) formation of Si–C

(hydrosilylation, carbonization, etc.) or (ii) Si–O bonds (e.g., silanization). A wide range of existing chemical functionalities allows tuning surface properties according to a specific application. In particular, an outstanding versatility of silanization enables to vary wetting properties in a wide range, from hydrophilic to super-hydrophobic. At the same time, monolayer and crosslinked multilayers are achievable, grafted either to the whole surface or with some patterns. Among the strongest advantages of silanization are mild conditions of the reaction permitting deposition of molecules with active or sensitive functional groups, such as –SH, –CN, –COOH, –COH, –C(O)C, –NH2, etc.
In the current work, the photo-induced temperature growth estimated from micro-Raman measurements was correlated with the steady-state heat transport finite element modeling (FEM) to estimate thermal conductivity values of porous silicon/hexadecane nanocomposite. To illustrate the impact of surface chemistry at silicon/hexadecane interface on the corresponding interfacial thermal resistance, silanization with alkyl and amino silanes was performed. In order to prevent any significant changes of porous silicon morphology, soft wet chemical oxidation was carried out. Contribution of the formed oxide and grafted silanes to the heat conduction in the porous silicon/hexadecane nanocomposites were studied.

4:00 PM SF03.21.02
Testing and Modeling of an *In Situ* Shear Exfoliated 2D Nanocomposite Coating Casing Material for the Suppression of Li-Ion Battery Fires in Electric Vehicles Md Ashiqur Rahman[1], MD Abdur Rahman Bin Abdus Salam[1], Humaun Kabir[2], Elmmer Vera Alvarado[1], Tousif Sadman[3], Rajib Mahamud[4], Kibria K. Roman[5], Mohammad Nahid[6] and Ali Ashraf[1]; [1]University of Texas Rio Grande Valley, United States; [2]Chittagong University of Engineering and Technology, Bangladesh; [3]Bangladesh University of Engineering & Technology, Bangladesh; [4]Idaho State University, United States; [5]The State University of New York at Canton, United States; [6]FCA Fiat Chrysler Automobiles, United States

The requirements of high energy density Li-ion battery along with its flammable electrolyte in electric and hybrid electric vehicles makes it susceptible to abusive operating conditions leading to thermal runaway, gas venting, fires, and explosions. Though there are external cooling and in-situ measures (e.g., coating of cathode with inert materials) for the prevention of thermal runaway, initiation of thermal runaway in one cell can easily propagate to adjacent cells, the entire pack assembly, and the vehicle. The commercial application generally focuses on water mist for the suppression of fire, the effectiveness of which depends on the types of fire encountered or the particular event scenarios. In this study, a 2D nanocomposite coating material, a mixture of dragon skin® (flame-resistant silicone elastomer from Smooth on, Inc.) and hexagonal boron nitride (DS/hBN), was applied on the traditional polycarbonate casing material to study its effect on flame retardancy. Dragon skin polymer precursor (dragon skin part A) and curing agent (dragon skin part B) with 5% low-cost layered hBN were mixed separately in a Hauschild planetary mixer to get homogenous mixing (at 2500 rpm for 2 minutes). A micro batch mixer was used to simultaneously exfoliate hBN nanosheets from bulk layered hBN raw materials and disperse these nanolayers into both dragon skin polymer precursor and curing agent separately (at 100 rpm for 10 minutes). Dragon skin polymer precursor and curing agent with exfoliated hBN were mixed in a 1:1 weight ratio to coat the polycarbonate and dried for 24 hours. Scanning electron microscopy (SEM) images confirmed the uniform dispersibility of these nanosheets. Standard 'UL94 Flammability Test' protocol was followed to measure the flame retardancy of the prepared sample. Here, Tests were conducted in both the horizontal and vertical testing arrangement specified in the standard. Besides, for the control experiment, another sample containing a coating of only dragon skin (DS) was prepared and tested. In the horizontal test, uncoated polycarbonate was found to burn extensively (labeled as "Failed"), whereas DS-coated and DS/hBN-coated polycarbonate slowed the burning rate by 33 mm/min and 9 mm/min, respectively. The burning rate of DS-coated and DS/hBN-coated samples is lower than 75 mm/min, so these can be categorized as "HB". In the vertical test, after the initial flame exposure, the flame was extinguished within 5 sec and 15 sec for the DS/hBN-coated and the DS-coated sample, respectively. During the burning, no dripping was observed for the DS/hBN-coated sample, whereas the DS-coated sample showed severe dripping and crack propagation in the coating layer. Moreover, during the vertical test of the DS-coated sample, the fire spread quickly and reached the clamp before extinguishment. So, DS-coated and DS/hBN-coated sample was rated as 'Failed' and 'V-1', respectively. These promising findings show the potential hBN nanosheets-based nanocomposites prepared from low-cost materials by in-situ shear exfoliation, which can form three-dimensional networks to rapidly disperse heat and build an efficient char layer for insulating the exposed polymer and forming a thermal barrier. Additionally, A multiphysics model is developed and applied to study the effect of butane fire on a traditional casing material and the 2D nanocomposite-coated material.

4:15 PM SF03.21.03
Subnanometer-Scale Visualization of Interaction Forces at Self-Assembled Molecules/Water Interfaces with 3D-AFM Moe Ogasawara, Masayuki Morimoto and Hitoshi Asakawa; Kanazawa University, Japan

The formation of self-assembled structures with organic building blocks on solid materials through a bottom-up process has been studied by many researchers. Three-dimensional (3D) self-assembled structures are promising for functional devices such as separation and storage. Molecular recognition utilizing nanospaces in self-assembled structures is an important research topic for their applications. However, understanding the recognition mechanism, for example, how the nanospace in a host structure interacts with the guest molecule, is still challenging. One of the main obstacles is a lack of analytical methods for investigating interaction forces acting in 3D nanospaces. 3D scanning atomic force microscopy (3D-AFM) has been developed as a "structural measurement" technique that allows us to visualize the spatial distributions of hydration and surface fluctuating structures in the nanospaces at the solid/liquid interfaces. Tip scanning of conventional AFMs is only in the XY direction, whereas the tip is scanned in the Z direction in addition to the XY direction in the 3D-AFM imaging. The Z + XY tip scanning makes it possible to obtain 3D force distribution images. Combining the 3D-AFM with a frequency-shift detection method, the interaction forces acting on the tip are detectable at the pico-Newton (pN) level. Based on the principle and performance, we believe that the 3D-AFM technique can be applied as an analytical tool for not only "structural measurement " but also "interaction force measurement."
In this study, we demonstrated the direct visualization of the interaction forces in 3D nanospaces at self-assembled molecules/water interfaces with the 3D-AFM technique. Two types of tetrakis4-ethynylphenylmethane (TEPM) derivatives with oligo(ethyleneglycol) (EG$_n$) chain (EG$_2$-TEPM, EG$_4$-TEPM) were used as the building blocks. The TEPM derivatives form self-assembled monolayers on graphite. In the monolayers, there are hydrophobic pockets

(diameter: approx. 1.7 nm) surrounded by the aromatic structure of the TEPM derivatives. The interaction forces in hydrophobic pockets were measured by the 3D-AFM in water. As a result, characteristic localized attractive interaction was visualized only at the EG_2-TEPM monolayer/water interface, and analysis of the 3D-AFM images suggests that the attractive interactions originate from hydrophobic pockets. The number of hydrogen bond networks of water in the hydrophobic pockets of EG_2-TEPM monolayer is small compared to bulk water, resulting in the low density of water molecules. The attractive interactions are likely caused by the low density of water molecules in the hydrophobic pockets. Our results demonstrate that the 3D-AFM technique has the capability of visualizing the characteristic interaction forces at the single molecule level, suggesting future contributions to the elucidation of the molecular recognition mechanisms.

4:20 PM SF03.21.04
Thermal Properties and Phase Transformation Behavior of YSZ Co-Doped by Rare Earth Oxides (La2O3, Gd2O3, Yb2O3) Tserendorj Khadaa, Junseong Kim, Janghyeok Pyeon, Hyeryang Choi, Bong-Gu Kim, Byungil Yang, Yeon-Gil Jung and SeungCheol Yang; Changwon National University, Korea (the Republic of)

Thermal barrier coating (TBC) materials were used to the application at high operating temperature component of gas turbine engines. Recently, 6-8 wt.% yttria-stabilized zirconia (8YSZ) has been widely used material for TBC. However, 8YSZ deteriorates at temperatures above 1200 °C due to their sintering phenomena and phase transition, which limiting its use as the TBC material for high temperature gas turbine. Co-doped YSZ powders containing rare earth oxides have recently been the subject of ongoing research. So, we recommend improved three types of YSZ compositions co-doped with La, Gd, and Yb. The YSZ co-doped with the compositions were prepared by ball milling and then made pellets and sintered. Then, we analyzed microstructure, thermal properties, mechanical properties and phase transformation behavior with various tools. The addition of La, Gd and Yb into YSZ effectively make thermal conductivity low and improve phase stability and mechanical properties of the YSZ which would improve the performances of thermal barrier coating. Therefore, we suggest that three types of compositions can be used instead of 8YSZ as materials for next-generation gas turbine engines.

4:25 PM SF03.15.07
Enhancement of Thermoelectric Performances by Aliovalent Bi and Sb Doping in SnTe-Based Material Wenxuan Wang[1], Chen Chen[2] and Yue Chen[1]; [1]The University of Hong Kong, Hong Kong; [2]Great Bay University, China

Thermoelectric materials are considered as a potential replacement of fossil fuels for their ability of directly converting heat to electricity. The Pb-free SnTe-based materials show high thermoelectric performances and attract much research attention. However, only few of the optimizations focused on the high carrier concentration attributed to the intrinsic Sn vacancies. In this work, we demonstrate that bismuth and antimony doping in an SnTe-based material, where Ge and Mn are added to manipulate the band structure, and self-compensation of Sn decrease the carrier concentration. The doping of bismuth and antimony further reduce the carrier concentration and contribute to the enhancement of Seebeck coefficient and thermoelectric performance. The highest dimensionless figure of merit (zT_{max}) reaches ~1.2 at 823 K, showing the influence of Sn vacancy compensation on thermoelectric performance.

4:30 PM SF03.13.02
Structural Evolution Mechanisms of Anticorrosion Coatings on Steel Using Raman Mapping Microscopy Jixi Zhang and Rodney Smith; University of Waterloo, Canada

Micron-scale coatings are widely used to protect steel plates from oxidation during hot stamping, which is a particularly important manufacturing protocol for the automotive industry. These coatings effectively protect the steel, but they also melt at the necessary temperatures for steel processing. The high-temperature liquids can then transfer to furnace components and damage the manufacturing line, incurring high costs through maintenance and production line downtime. Once melted, however, these coatings are also known as leech Fe from the steel to form intermetallic phases. This leeching leads to a change in composition, inducing a complex multi-step chain of reactions that ultimately yield a solid coating. The identity of these intermetallic phases and the series of phase evolutions have been studied extensively by electron microscopy and energy dispersive X-ray spectroscopy. We introduce Raman microscopic mapping as a simple, rapid, and complementary technique for phase transition analysis. Samples were prepared by heating a series of 22MnB5 steel coupons to set temperatures between 570 to 900°C to simulate the industrial hot stamping conditions. Raman microscopic mapping of cross-sections of each sample reveals the phase transitions with increasing temperatures. This analysis reveals a structural evolution mechanism slightly different than that suggested by electron microscopy. New insights gained through Raman microscopic mapping show that it is a powerful tool to identify the underlying chemical problems that lead to the destruction of industrial infrastructure, and to test the viability of strategies to overcome these problems.

SESSION SF04.01: Wave Phenomena in Architected Materials
Session Chairs: Michael Frazier and Carlos Portela
Tuesday Morning, April 11, 2023
Marriott Marquis, B2 Level, Golden Gate C3

10:30 AM *SF04.01.01
Extreme Wave Phenomena in Mechanical Metamaterials Andrea Alu; City University of New York, United States

In this talk I will discuss our recent progress in the area of mechanical architected metamaterials, showcasing extreme examples of wave manipulation of elastic waves. In addition to discussing the general opportunities stemming from architected materials for extreme wave manipulation, I will also present examples in which reconfigurability, wave interference and geometric transformations offer new opportunities for extreme and dynamic wave control, with a broad range of applications.

11:00 AM *SF04.01.02
Elastodyanmic Properties of Architected Metamaterials Yun Jing; The Pennsylvania State University, United States

While architected metamaterials have been well studied for their quasi-static properties, their elastodynamic properties have been largely unexplored. In this talk, I will give an overview of our recent theoretical and experimental works pertaining to how architected metamaterials interact with vibration. I will first introduce a class of metamaterials that achieve low-frequency band gaps with a volume fraction as low as 3% (mass density as low as 0.034 g/cm^3). The working of the proposed design hinges on a 3D trampoline-like mode behavior that gives rise to wide, omnidirectional, and low-frequency band gaps for elastic waves despite very low-mass densities. Such a 3D trampoline effect is derived from a network of overhanging nodal microarchitectures that act as locally resonating elements, which give rise to band gaps at low frequencies. I will then present results on architected metamaterials made of a periodic arrangement of octet truss units with alternating circular strut diameters. The octet truss endows the meta-structure with a high effective stiffness and a low effective density, while alternating the units with different struts radii enables the opening of a band gap for elastic waves. For both types of metamaterials, samples were 3D printed and experimentally validated using a shaker and accelerometer. Unidirectional compression test was also performed to characterize the mechanical properties of the octet truss lattice.

SESSION SF04.02: Advancement in Fabrication of Architected Materials
Session Chairs: Xiaoyue Ni and Xiaoxing Xia
Tuesday Afternoon, April 11, 2023
Marriott Marquis, B2 Level, Golden Gate C3

1:30 PM *SF04.02.01
Intelligentsia of Nano-Architected Hierarchical Materials Julia R. Greer[1], Seola Lee[1], Max A. Saccone[2], Widianto P. Moestopo[3] and Seneca Velling[1]; [1]California Institute of Technology, United States; [2]Stanford University, United States; [3]Lawrence Livermore National Laboratory, United States

Creation of reconfigurable and multi-functional materials can be achieved by incorporating architecture into material design. In our research,we design and fabricate three-dimensional (3D) nano-architected materials that can exhibit superior and often tunable thermal, photonic, electrochemical, biochemical, and mechanical properties at extremely low mass densities (lighter than aerogels), which renders them useful and enabling in many technological applications. Dominant properties of such meta-materials are driven by their multi-scale nature: from characteristic material microstructure (atoms) to individual constituents (nanometers) to structural components (microns) to overall architectures (millimeters and above).
Our research is focused on fabrication and synthesis of nano- and micro-architected materials using 3D lithography, nanofabrication, and additive manufacturing (AM) techniques, as well as on investigating their mechanical, biochemical, electromechanical, and thermal properties as a function of architecture, constituent materials, and microstructural detail. Additive manufacturing (AM) represents a set of processes that fabricate complex 3D structures using a layer-by-layer approach, with some advanced methods attaining nanometer resolution and the creation of unique, multifunctional materials and shapes derived from a *photoinitiation-based chemical reaction* of custom synthesized resins and thermal post-processing. A type of AM, vat polymerization, has allowed for using hydrogels as precursors, and exploiting novel material properties, especially those that arise at the nano-scale and do not occur in conventional materials. The focus of this talk is on additive manufacturing via vat polymerization and function-containing chemical synthesis to create 3D nano- and micro-architected metals, ceramics, multifunctional metal oxides (nano-photonics, photocatalytic, piezoelectric, etc.), and metal-containing polymer complexes, etc., as well as demonstrate their potential in some real-use biomedical, protective, and sensing applications. I will describe how the choice of architecture, material, and external stimulus can elicit stimulus-responsive, reconfigurable, and multifunctional response.

2:00 PM *SF04.02.02
3D and 4D Printing: High Performance and Stimuli-Responsive Polymer Materials Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

The advent of 3D printing has enabled prototypes and devices of high-performance polymeric materials which have appended functionality based on composition and macromolecular design. 3D printed polymers can be further classified into thermoplastics, thermosetsond elastomers based with their corresponding thermo-mechanical properties. However, using multi-materials and 4D printing allows the design of new materials and applications based on integrating conversion chemistry with the printing mode. This talk will demonstrate stimuli-responsive properties and 4D fabrication of multi-materials, including epoxy and benzoxazine thermosets and silicone elastomers with concept objects and elastomeric properties exhibiting stimuli-response. While most of the method focuses on DIW or viscous solution printing (VSP), other works using SLA, SLS, and FDM 3D Printing will also be revealed.

2:30 PM SF04.02.04
Universal Way to 'Glue' Capsules, Gels and Tissues in 3D Using Electric Fields Leah K. Borden[1,2] and Srinivasa R. Raghavan[1]; [1]University of

Maryland, United States; [2]Massachusetts Institute of Technology, United States

This work will demonstrate the use of an adhesion induced by an electric field, i.e., Electro-adhesion (EA) to connect a variety of soft materials into 3D structures. EA requires a cationic and an anionic material, but these can be of diverse origin. For example, these can include covalently crosslinked hydrogels made by polymerizing charged monomers as well as physical gels/capsules formed by the ionic crosslinking of biopolymers (e.g., alginate and chitosan). In addition, the anionic material could be electroadhered to naturally occurring soft materials such as animal and plant tissues [1].

Between each cationic/anionic pair, EA is induced rapidly (in ~ 10 s) by low voltages (~ 10 V DC) - and the adhesion is permanent after the field is turned off. This adhesion is strong enough to allow millimeter-scale capsules/gels to be assembled in 3D into robust structures such as capsule-capsule chains, capsule arrays on a base gel, and a 3D cube of capsules. EA-based assembly of spherical building blocks can be done more precisely, rapidly, and easily than by any alternative techniques. Moreover, the adhesion can be reversed (by switching the polarity of the field) - hence any errors during assembly can be undone and fixed.

EA can also be used for selective sorting of charged soft matter - for example, a 'finger robot' can selectively 'pick up' capsules of the opposite charge by EA and subsequently 'drop off' these structures by reversing the polarity. In this talk we will also explore various experimental results that shed light on the mechanism of EA. Overall, our work shows how electric fields can be used to connect soft matter without the need for an adhesive or glue.

Reversible Electroadhesion of Hydrogels to Animal Tissues for Suture-less Repair of Cuts or Tears.
Nature Communications, 12, 4419 (2021)

2:45 PM SF04.02.05
Additive Manufacturing of Micro-Architected Metals via Hydrogel Infusion Max Saccone[1,2], Rebecca A. Gallivan[3,2], Kai Narita[2], Daryl W. Yee[4,2] and Julia R. Greer[2]; [1]Stanford University, United States; [2]California Institute of Technology, United States; [3]ETH Zürich, Switzerland; [4]École Polytechnique Fédérale de Lausanne, Switzerland

Metal additive manufacturing (AM) has emerged as a uniquely powerful tool to produce complex and high-performance parts with applications from the aerospace to biomedical fields. Most existing metal AM techniques use heat to define part shape via thermally initiated melting or sintering. In contrast, we report an AM technique, coined hydrogel infusion additive manufacturing (HIAM), that produces metals and alloys with microscale resolution via vat photopolymerization (VP). To fabricate micro-architected metal structures, we infuse 3D-architected hydrogels with aqueous metal precursors, then calcine and reduce the infused hydrogel scaffolds to create miniaturized metal replicas. Unlike existing VP strategies, which incorporate target materials or precursors into the photoresin during printing, HIAM does not require re-optimization of resins and curing parameters for different materials, enabling quick iteration, compositional tuning, and the ability to fabricate multimaterials. We demonstrate HIAM of micro-architected metals such as copper, nickel, silver, cobalt, cupronickel alloys, high entropy alloys, and tungsten with critical dimensions of ~50 µm. Hydrogel scaffolds can be considered responsive architected materials—we demonstrate how a single architected gel can respond to a variety of chemical and thermal stimuli to transform into a vast array of metals, providing a pathway to create advanced micro-architected metals.

3:00 PM SF04.02.06
Metallized Ultraporus 3D Printed Lattices Nihan Sengokmen Ozsoz and Frederik Claeyssens; The University of Sheffield, United Kingdom

High internal phase emulsions (HIPEs) are potential stereolithography-based inks for producing innovative light-weight porous materials. However, the use of these resins has only been shown in bespoke stereolithography set-ups. From these studies, it can be learnt that stereolithography-based polyHIPE structures tend to be overcured due to their inherent light scattering nature, but that the inclusion of light absorbers can drastically increase the printing resolution. In this study, we focus on the inclusion of biocompatible light absorbers within the resin and the compatibility of those resins with commercial vat photopolymerization additive manufacturing (or stereolithography) set-ups. A surfactant (hypermer) stabilized water-in-oil emulsion based on ethylhexyl acrylate and isobornyl acrylate was used. For the light absorbers, both hydrophobic (beta-carotene) and hydrophilic (tartrazine) molecules were used, which dissolve in the organic phase and aqueous phase, respectively. It was found that using a combination of both beta-carotene and tartrazine provided the best stereolithography-based 3D printing resolution. Additionally, the emulsion was stable for the duration of the printing experiment and showed a polyHIPE pore structure with open surface porosity. The formulation of these HIPE-based resins permits them to be used in a wide range of applications since complex structures can be fabricated from HIPEs.
Architected truss structures with inherent porosity were 3D printed to be used as scaffolds for innovative applications. The mechanical properties of these structures have been improved four times by applying electroless nickel plating. This result showed that HIPEs could be used as scaffolds thanks to electroless metal deposition for innovative applications.

A Free-Standing Organogel That Spontaneously Degrades to a Thin Sol After a Set Time Faraz Burni and Srinivasa R. Raghavan; University of Maryland, United States

Many applications in the oilfield industry utilize a nonpolar organic solvent (i.e., an oil) to be gelled. The gel must be a shear-thinning fluid so that it can be pumped into an oil well. When the fluid reaches its destination in the oil-bearing formation, it must set into a gel. From a rheological perspective, this organogel must be sufficiently strong (high elastic modulus G' as well as yield stress) so that it can act as an effective plug to block the flow of fluid (oil or water). However, the gel-like nature (and thus the plugging ability) may become undesirable after a period of time (2 to 4 weeks). Thus, after this time, there is a need for the gel to be degraded or dissolved. Numerous 'degrading agents' have been examined by the oilfield industry for a given type of gel, but they all have their drawbacks. Here, we present a solution to this vexing problem by designing a *self-degrading molecular organogel*. We use a small-molecule gelator, dibenzylidende sorbitol (DBS), that self-assembles into nanoscale fibrils in oils like n-alkanes or mineral oil, thereby gelling the oils. DBS organogels are highly robust and exhibit G' above 10,000 Pa for just 2 wt% of added gelator – indeed the gels are free-standing, i.e., strong enough to manipulate between one's fingers or place vertically on a countertop. At the same time, we have found that certain acid moieties can be introduced into the DBS organogel and induce slow degradation. Thus, the same strong organogel degrades into a thin liquid over a period of time, which can be tuned to be hours to days to weeks. In other words, we can formulate the gel with an in-built clock that sets in the degradation time. This avoids the need for injecting a degrading agent into the oil well. Our approach could be a game-changer for the oilfield industry.

Knots are Not for Naught—Design, Properties and Topology of Hierarchical Intertwined Micro-Architected Materials Widianto P. Moestopo[1,2],

Sammy Shaker[2], Weiting Deng[2] and Julia R. Greer[2]; [1]Lawrence Livermore National Laboratory, United States; [2]California Institute of Technology, United States

Lightweight and tough engineered materials are often designed with three-dimensional (3D) hierarchy and interconnected structural members whose junctions are detrimental to their performance because they serve as stress concentrations for damage accumulation and lower mechanical resilience. We introduce a new class of architected materials, whose components are interwoven and contain no junctions, and incorporate micro-knots as building blocks within these hierarchical networks. Tensile experiments, which agree with an analytical model for overhand knots, reveal that knot topology allows a new regime of deformation capable of shape-retention, leading to ~92% increase in absorbed energy and up to ~107% increase in failure strain compared to woven structures. Our exploration unlocks knotting and frictional contact to create highly extensible low-density materials with tunable shape reconfiguration and energy absorption capabilities.

SESSION SF04.04: Mechanical Instability and Multi-Stability
Session Chairs: Michael Frazier and Carlos Portela

10:00 AM SF04.04.01
Multi-Planar Printing and Control of Liquid Crystal Elastomers Devin J. Roach[1], Jeremy Herman[1,2], Samuel C. Leguizamon[1], Erik Linde[1], Adam Cook[1], Timothy White[2] and Bryan Kaehr[1]; [1]Sandia National Laboratories, United States; [2]University of Colorado Boulder, United States

Liquid crystal elastomers (LCE) are an active material that can provide rapid, reversible, and programmable actuation. In recent years, the additive manufacturing (AM) of LCE has gained attention as a facile means to both fabricate and program the actuation response. Nonetheless, LCE printing patterns and subsequent actuation directions have been limited to planar structures or simple geometries. To overcome this, we propose a method for printing of LCE in a laponite support gel which enables multi-planar, complex LCE structures. Furthermore, the LCE printing process can be monitored using in-situ measurements to build a machine learning model which will inform print parameters and final actuation properties. Lastly, we will provide demonstrations of how using machine learned printing parameters on multi-planar geometries will enable unprecedented multi-dimensional actuation profiles.

10:15 AM SF04.04.02
Tailoring the Multistability of Reconfigurable 3D Magnetic Mesostructures Xueju Wang and Yi Li; University of Connecticut, United States

Three-dimensional (3D) mesostructures that can reversibly change their geometries and thereby their functionalities are promising for a wide range of applications such as deployable devices, soft robotics, etc. The multistability of such structures is critical for their applications but is challenging to manipulate due to the highly nonlinear deformations and complex configurations of the structures. In this talk, I will present a comprehensive experimental and computational study to tailor the multistable states of continuous 3D mesostructures and origami-inspired, buckled ferromagnetic structures as well as their reconfiguration paths. Using table/ribbon structures as an example, a design phase diagram is constructed as a function of the geometry, crease number, and compressive assembly strain. For example, in origami-inspired ribbon structures, as the crease number increases from 0 to 7, the number of distinct stable states first increases and then decreases. The multistability is also shown to be actively tuned by varying the strain from 0% to 40%. Furthermore, analyzing energy barriers for reconfiguration among the stable states reveals dynamic changes in reconfiguration paths with increasing strain. Guided by the studies above, diverse examples are designed and demonstrated, from programmable structure arrays to soft robots. These studies lay out the foundation for the rational design of functional, multistable structures.

10:30 AM *SF04.04.03
Ultra-Fast, Programmable and Electronics-Free Soft Robots Enabled by Snapping Metacaps Lishuai Jin[1], Yueying Yang[1], Bryan O. Torres Maldonado[1], Sebastian Lee[2], Nadia Figueroa[1], Robert Full[2] and Shu Yang[1]; [1]University of Pennsylvania, United States; [2]University of California, Berkeley, United States

Soft robots have a myriad of potentials because of their intrinsically compliant bodies, enabling safe interactions with humans and adaptability to unpredictable environments. However, most of them have limited actuation speeds, require complex control systems, and lack sensing capabilities. To address these challenges, here we geometrically design a class of metacaps whose rich nonlinear mechanical behaviors can be harnessed to create soft robots with unprecedented functionalities. Specifically, we demonstrate a sensor-less metacap gripper that can grasp objects in 3.75 ms upon physical contact and a pneumatically actuated gripper with tunable actuation behaviors that have little dependence on the rate of input. Both grippers can be readily integrated into a robotic platform for practical applications. Furthermore, we demonstrate that the metacap enables propelling of a swimming robot, exhibiting amplified swimming speed as well as untethered, electronics-free swimming with tunable speeds. Our metacaps provide new strategies to design the next generation soft robots that require high transient output energy and are capable of autonomous and electronics-free maneuvering.

11:00 AM SF04.04.04
Domain Wall Manipulation by Hierarchy in Multi-Stable Metamaterials Chongan Wang and Michael J. Frazier; University of California, San Diego, United States

The manipulation of domains is critical to emerging functionalities in multi-stable metamaterials; however, the available strategies for domain control -- especially, those applicable in two-dimensional environments -- are few and, often, limited in their ability to sculpt and stabilize the domain contours. Here, we analyze domain wall motion in hierarchical metamaterial architectures formed by intersecting chains of elastically-coupled multi-stable elements, which establish a tailorable, non-uniform energy landscape for producing the sought-after behavior. The intersections create an energy barrier that impedes (even halts) domain wall motion and, thus, are mechanisms of control of the same. In tailoring the hierarchical structure, an assortment of unusual and complex domain contours can be realized and stabilized. We highlight some applications facilitated by the hierarchical structure.

11:15 AM *SF04.04.05
Functional Architected Materials by Harnessing Structure Instabilities Lihua Jin; University of California, Los Angeles, United States

Architected materials are materials with micro-architectures, which give rise to unusual mechanical properties and functions that are difficult or impossible to achieve in homogeneous materials. In this work, new types of architected materials are developed to demonstrate energy absorption and spatiotemporal shape morphing by harnessing structure instabilities. Subjected to an axial compression, a wide hyperelastic column can discontinuously buckle, snapping from one stable equilibrium state to another, leading to energy dissipation, while upon unloading, it can completely recover its undeformed state. Making use of this property, we design an energy-absorbing architected material by stacking layers of wide hyperelastic columns, and fabricate it by multi-material 3D printing and sacrificial molding. Characterized by quasi-static and drop tests, the material shows the capability of energy dissipation and impact force mitigation in a reusable, self-recoverable, and rate-independent manner. In a second example, we achieve spatiotemporally programmable and reconfigurable metasurfaces with simple control by exploiting pseudobistability of viscoelastic shells, which are pneumatically actuated to a concave state, held for a certain period, and recover the initial convex state after a delay time when the load is removed. We computationally and experimentally show that the recovery time can be widely tuned by the geometry and material viscoelasticity of the shells. By assembling such shells with different recovery time into arrays, we build metasurfaces with pre-programmed spatiotemporal textural morphing under simple pneumatic actuation, and demonstrate temporal evolution of patterns, such as digit numbers and emoji, and spatiotemporal control of friction. Our work opens up new avenues in designing functional architected materials by harnessing structure instabilities.

SESSION SF04.05: Mechanical Intelligence by Design

Marriott Marquis, B2 Level, Golden Gate C3

1:30 PM *SF04.05.01
Reconfigurable Matter – From Wave Control to Mechano-Intelligence Kon-Well Wang; University of Michigan, United States

In recent years, the concept of reconfigurable matter developed based on nature-inspired modular architectures has been explored to create advanced engineering systems. For example, inspired by the observation that some of skeletal muscle's intriguing macroscale functionalities result from the assembly of nanoscale cross-bridge constituents with metastability, the idea of synthesizing metastructures from the integration of mechanical metastable modules has been pursued. In another example, inspired by the physics behind the plant nastic movements and the rich designs of origami folding, a class of metastructures is created building on the innovation of fluidic-origami modular elements. Overall, the modules are designed to be reconfigurable in their shape, mechanical properties, and stability features, so to produce synergistic and intriguing dynamic functionalities at the system level, such as programmable phononic bandgap control and nontraditional wave steering. More recently, with the rapid advances in high-performance intelligent systems, we are witnessing a prominent demand for the next generation of mechanical matter to have much more built-in intelligence and autonomy. An emerging direction is to pioneer and harness the metastructures' high dimensionality, multiply stability, and nonlinearity for mechano-intelligence via physical computing. That is, we aim to concurrently embed computing power and functional intelligence, such as observation, learning, memorizing, decision-making and execution, directly in the mechanical domain, advancing from conventional systems that solely rely on add-on digital computers to achieve intelligence. This presentation will highlight some of these advancements in harnessing reconfigurable matter for structural dynamics tailoring, from wave control to self-learning-self-tuning intelligence.

2:00 PM *SF04.05.02
Artificial Intelligent Architected Materials That Learn Their Properties Jonathan Hopkins; University of California, Los Angeles, United States

The objective of this work is to apply the concept of artificial neural networks (ANNs) to enable the creation of a new kind of architected material, called a mechanical neural-network (MNN) architected material, that can learn desired properties via a complex web of active flexible elements (AFEs) that constitute the materials' microstructure. These AFEs, which are joined together by rigid nodes, constitute an analogous physical embodiment of the mathematical weights that determine the values that are summed together by the neurons within traditional ANNs. By actively tuning the stiffness of these AFEs in a similar fashion to how weights are trained within ANNs, the new kind of architected material can learn desired mechanical properties and thus enable a variety of applications. Such applications include: (i) aircraft wings that can learn to optimally change their shape and stiffness at select locations as flight conditions change, (ii) aircraft exteriors that can learn to compensate for damage that may occur during combat or overuse by maintaining their designed properties regardless of defects or ware, and (iii) electrical, optical, or other components within aircraft that cannot be made of zero-thermal-expansion-coefficient materials but can learn to maintain their shape regardless of fluctuating temperatures.

2:30 PM SF04.05.03
Architected Mechanologics and Design Rules for Integrated Mechanical Computing Junghwan Byun[1,2,3], Aniket Pal[1], Seungjun Chung[2], Kyu-Jin Cho[3] and Metin Sitti[1]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

Mechanical computing is an unconventional domain of computation where computational operations are made solely by mechanical components and mechanisms. Recent studies in this direction harness built-in material responsiveness and structural intelligence to achieve seamless, monolithic integration between the computing process and input/output agents that can be directly coupled to surrounding environments. Specifically, digital abstractions of mechanical information (i.e., mechanical bits) have been realized by multistable configurations of mechanical elements that are able to change their shapes along with origami kinematics and/or nonlinear buckling dynamics of thin soft beams or shells. Pioneering studies have further demonstrated that architected design and engineered assembly of the multistable elements can accomplish stable transmission of elastic waves, mathematical computations, programmable metamaterials, and robotic mechanisms, all of which form the basis of mechanical computing. Despite these achievements, however, an understanding of mechanical computing has still been limited to the implementation of standalone computing units or mechanical transition waves lacking the rational design for deterministic computational functions.
In this work, we introduce a basic design principle of soft bistable beams with engineered potential energy profiles, and show how the strategic topological assembly of these engineered bistable elements can form into a monolithic computational platform in which nondispersive elastic solitary waves autonomously propagate with deterministic computational functions. Drawing inspiration from a mature design architecture of conventional electrical computing systems, we first postulate the design and functional requirements for integrated mechanical computing as follows: (i) stable transmission of mechanical signals without loss of information, (ii) a complete set of functional computing units with form factors matched with the transmission line, and (iii) lossless, computational cascades of mechanical signals through multiple computing units. The designs of transmission line units and mechanologics are physically implemented by topological assemblies of bistable building blocks into a unit square lattice frame. The resulting lattice-unit connection between fundamental mechanical components (i.e., transmission line units and mechanologics) allows us to investigate propagation behaviors of mechanical signals not only through a homogeneous elastic medium (transmission line), but also through a medium containing a computing unit with

structural heterogeneity. Based on an extensive set of experimental and numerical studies on the proposed mechanical system, we generalize a design rule for computational propagation of mechanical signals through networked computing units, and implement this decisive principle in realizing integrated mechanical computing. Proof-of-concept demonstrations of Mimosa plant-inspired soft machines show how the developed integrated mechanical computing can direct mechanical instructions across environmental inputs, computational operations and actuator modules in a seamless and monolithic form.

2:45 PM SF04.05.04
A Soft Shape-Morphing Surface with Embedded Shape Sensing Function Yuxin Pan[1], Yun Bai[1], Yuxuan Liu[2], Yong Zhu[2], Heling Wang[3] and Xiaoyue Ni[1,1]; [1]Duke University, United States; [2]North Carolina State University, United States; [3]Tsinghua University, China

Soft robotic materials that can autonomously morph into desired shapes can enhance human-robot interaction. Recent advances in soft electronics and data-driven inverse design strategies have allowed for the creation of rapidly reprogrammable shape-morphing soft matter. To control these surfaces accurately and robustly, a shape-sensing capability is necessary. Current shape sensing methods heavily rely on exteroception, which can compromise the accuracy, reliability, flexibility, and speed of shape reconstruction in a deployed environment. In this work, we introduce a shape-morphing surface that can sense its own shape. The soft surface is constructed from silicone-based membranes containing interconnected stretchable silver nanowire conductors. The conducting meshes serve as both electromagnetic actuation elements in the presence of a magnetic field for shape-morphing and a resistive strain sensor for shape-sensing. We investigate the mechanics and materials of the soft composites and flexible sensors for optimized surface design for complex shape-morphing. Combining a mechanical model, finite-element analysis (FEA), and a machine learning pipeline with high-throughput experimentation enabled by the robotic surface, we develop a theoretical framework to describe the relationships between the input control voltages and output shapes, as well as the relationship between the deformed shapes and output sensing voltages. Stereo-imaging provides a ground-truth surface reconstruction and validates the accuracy of the embedded sensing with a maximum error of 5%. With the sensing and actuation functions closely integrated at the material level, the robotic surface is able to perform real-time closed-loop shape morphing in various changing environments.

3:00 PM SF04.05.05
Shape Morphing Mechanical Metamaterials for Multifunctional Machines Michael D. Bartlett, Edward J. Barron III, Dohgyu Hwang, A B M Tahidul Haque and Ravi Tutika; Virginia Tech, United States

Biological organisms are rich with the ability to reconfigure their shape and properties to perform diverse tasks. These capabilities are inspiring emerging soft robots and intelligent matter that have the potential to display biological capabilities through material and physical intelligence. However, soft machines and intelligent matter struggle to achieve multiple complex configurations, quickly lock into shape to support loads, and go between multiple states reversibly. In this presentation we will introduce a multifunctional shape morphing mechanical metamaterial with reversible, rapid, and lockable polymorphic reconfigurability. We couple elastomeric kirigami with an unconventional reversible plasticity mechanism in metal alloys to rapidly (< 0.1 s) lock-in complex, load bearing shapes, with reversibility and self-healing through phase-change. Large deformations and complex morphologies are demonstrated where we show the ability to exhibit positive, zero, and negative Gaussian curvatures and conformally wrap complex surfaces. This approach overcomes trade-offs in deformability and load bearing capacity while eliminating power requirements to lock in shapes. This combination of properties is enabling for creating multifunctional soft robots. We demonstrate this material through integration with onboard control, motors, and power, to create a soft robotic morphing drone which autonomously transforms from a ground to air vehicle and an underwater morphing machine which can be reversibly deployed to collect cargo.

3:15 PM SF04.05.06
Effect of Form and Architecture on the Actuation Performance of Stimuli-Responsive Polymers Frank Gardea[1], Sevketcan Sarikaya[2], Bradley Lawrence[1], Todd Henry[1] and Mohammad Naraghi[2]; [1]DEVCOM Army Research Laboratory, United States; [2]Texas A&M University, United States

Soft actuators provide a promising alternative to conventional actuators by addressing the need for adaptability, flexibility, and tunability. Stimuli-responsive soft materials are viable candidates for actuation due to their ease of tunability of actuation performance by control of not only composition but by variation of architecture or form factor. Here, we report a study on the effect of architecture and form on the responsiveness and actuation performance of various soft materials. Specifically, the size dependence on rate of actuation, stroke, and strength of stimuli-responsive polymer fibers is presented. Additionally, a comparison between a coiled and aligned architecture of the fiber actuators is made with respect to actuation performance. Performance tunability is explored by varying architecture parameters, such as coil index and degree of twist. Polymers responsive to various stimuli (pH, humidity, temperature) are studied. Finally, the usability of these soft actuators is demonstrated by integrating them into viable structures. This work demonstrates the potential of soft polymer materials for use in responsive structures and how actuation performance can be enhanced and tuned by structural design.

3:30 PM BREAK

4:00 PM *SF04.05.07
Disordered Mechanical Metamaterials Stefano Zapperi[1,2]; [1]University of Milan, Italy; [2]Consiglio Nazionale delle Ricerche, Italy

Mechanical metamaterials, or architechted materials, are a class of artificial materials engineered to have exceptional mechanical properties that are difficult to find in conventional materials. Often inspired by biological systems, mechanical metamaterials are typically designed with an internal structure composed of multiple elements arranged in periodic patterns. The ordered geometries employed in mechanical metamaterials contrast with the disordered structures encountered in biological systems, formed through self-assembly in response to environmental pressures. In this talk, I will argue that there is a value in considering disorder in the design of mechanical metamaterials and discuss the emergence of novel features induced by disorder. I will then present a computational method for the automatic design of disordered mechanical metamaterial actuators that combines a reinforced Monte Carlo method with discrete element simulations. 3D printing of selected mechanical metamaterial actuators shows that the machine-generated structures can reach high efficiency, exceeding human-designed structures. I will also show that it is possible to design efficient actuators by training a deep neural network which is then able to predict the efficiency from the image of a structure and identify its functional regions.

4:30 PM SF04.05.08
Toward Elastically and Inelastically Isotropic Multiphase Interpenetrating Network Jehoon Moon, Suyoun Ma, Gisoo Lee and Hansohl Cho; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Heterogeneous or cellular materials architected on various crystal lattices have been extensively explored for a broad variety of engineering functionalities involving photonics, acoustics and mechanics with the recent advances in additive manufacturing and three-dimensional (3D) printing technologies. Long-range order in the heterogeneous materials architected on crystal lattices often culminates in undesirable, intrinsic anisotropy in elasticity and inelasticity in diverse mechanical loading scenarios. In this work, we propose a simple yet efficient design strategy to generate heterogeneous materials that exhibit nearly isotropic elasticity and inelasticity in extreme mechanical deformation events. Furthermore, we combine experiments and numerical simulations to explore how geometric connectivity (dispersed-particle vs. interpenetrating morphologies) throughout dissimilar domains influences shape recovery as well as energy dissipation in the disordered heterogeneous materials.

We design two types of disordered morphologies: dispersed-particle morphology and its interpenetrating counterpart. Representative volume element (RVE) for dispersed-particle morphology is generated by distributing a finite number of spheres in the unit cube. The centers of the spheres are randomly placed inside the unit cube. When placing the spheres, newly inserted spheres does not overlap the existing spheres under three-dimensional periodic boundary conditions (PBC)[1]. In order to generate an interpenetrating counterpart, we perform a Voronoi tessellation on the unit cube via the spatial random points seeded for the dispersed-particle morphology. We then perform rod-connecting the center point and the Voronoi neighbor points for each of the tessellated polyhedra in the RVE. Therefore, the RVE with interpenetrating morphology has randomly connected local microstructures throughout the tessellated polyhedral network.

We then fabricated prototypes for the RVEs of both disordered morphologies using a high-resolution, multi-material 3D printer. A plastomeric material exhibiting large flow stresses and hysteresis under cyclic loading conditions was used for the hard domains (particles or rod-connected network) while a hyperelastic, elastomeric material was used for the soft domains. We then conducted large strain mechanical tests on the 3D-printed prototypes under diverse cyclic loading scenarios. Altering the connectivity throughout the disordered network was found to impact significantly on key elastic and inelastic features including initial stiffness, flow stresses, energy dissipation and elastic-inelastic shape recovery in the two morphologies upon cyclic loading and unloading conditions. Furthermore, the 3D-printed prototypes with interpenetrating morphology exhibited more robust performance in resilience and energy dissipation under repeated loading and unloading cycles. Last, we examined anisotropy in both morphologies in experiments and numerical simulations, by which the universal anisotropy index[2] was calculated. Interestingly, though altering the connectivity from dispersed-particle to interpenetrating morphologies resulted in a slight increase in anisotropy, the universal anisotropy indices for both morphologies were found to be below 0.05 (nearly isotropic behavior). In addition to the elastic isotropy, our experimental data and numerical simulation results reveal that these disordered heterogeneous materials exhibit nearly isotropic behaviors in inelastic features involving energy dissipation and shape recovery in extreme deformation conditions.

4:45 PM SF04.05.09
A Novel Digital Manufacturing Strategy to Print Magnetically Responsive Soft Continuum Robots in a Sustainable Supporting Medium Jaemin Lee, Dmitrijs Kozminihs, Vittorio Francescon, Alistair Bacchetti, James Chandler, Pietro Valdastri and Russell Harris; University of Leeds, United Kingdom

In this talk, a breakthrough in the development of an aqueous solution-based printing medium that enables a novel direct-write method for printing microscale soft continuum robots composed of magnetic metamaterials will be described. The new cost-effective, biocompatible, sustainable printing medium offers exceptional rheological properties to keep the printed high-density magnetic tentacles securely floated in the medium and to maintain the cylindrical cross-section of the printed microscale continuum robots along the length; securing cylindrical cross-section in this scale has been a major bottleneck in additive manufacturing of soft continuum robots. With the utility in direct writing, the outstanding digital printing capability can now dramatically enhance multi-axis navigation capabilities to improve surgical efficacy during operation and reduce patient trauma,[1] making this technology more widely accessible. Simultaneously, the new development addresses major challenges such as a considerably limited polymer-based material catalog,[2] the high demands for complex chemistry to surround the printed objects in this type of medium-based printing[3, 4] and sophisticated modifications of composites to control the printing behavior.[5] The latest device performance investigation will also be presented, in conjunction with computational modeling and practical demonstration in physical organ phantoms for surgical interventions in organs such as the pancreas, heart, and brain.[1, 6, 7] Here, an external magnetic field via the dual-robot-arm approach will be utilized to remotely manipulate the printed continuum magnetic robots, which will be benchmarked against traditional robots based on molding fabrication methods.

Variable-Stiffness and Shape-Morphing Architected Materials Yifan Wang; Nanyang Technological University, Singapore

Architected lattices are materials that derive their properties from the selection of both their constitutive materials and the geometry of their micro- and meso-structure. Most existing architected lattices are intrinsically passive, with properties fixed once manufactured. These limit their applications in areas where material adaptivity and tunability are required. In contrast, the tight coupling of shape transformation and stiffness tuning in biological organisms have long served as inspiration for next-generation smart material design. In this talk, I will present the development of architected materials whose mechanical properties and geometry can be controlled and adapted to varying environmental conditions. First of all, I will demonstrate a structured fabric with interlocking particles that has controllable stiffness and reconfigurable shape, which can be used for wearable robotics. Then, I will present a robotic structure from architected particle assemblies that combine shape-morphing, stiffness variation and self-sensing into one monolithic body. These works open routes towards creating the next generation of architected materials that mimics the functions of biological organisms and adapt to varying environmental conditions.

3D Shape-Morphing Display Based on Electrothermally-Responsive Variable Stiffness Composite Subin Oh, Sunwoo Lee, Jiheong Kang and Jae-Woong Jeong; KAIST, Korea (the Republic of)

Three-dimensional (3D) displays are being considered for the next-generation displays in terms of enhancing the realism of visual information and possibly integrating displays on curvilinear surfaces. One promising approach for implementing 3D displays is to transform a two-dimensional (2D) display into a 3D display, which can incorporate the merits of 2D display technologies. However, existing rigid displays and emerging flexible/stretchable displays are challenging to freely realize and maintain complex 3D structures and can only be used for specific purposes due to the inherent static mechanical properties of constituent materials. The stiffness-tuning technology can be of use to enable multi-purpose displays that encompass all the advantages of the current display form factor to realize customizable 3D shapes.
In this study, we propose a shape-morphing display (SMD) that can realize complex 3D configurations through electrothermal operation, firmly retain its deformed shapes with cooling and achieve reversible multi-morphological reconfiguration. The SMD is fabricated by integrating a stretchable alternating current electroluminescent (ACEL) device with an electrothermal shape-morphing platform (eSMP). The unique variable stiffness mechanism emerges from eSMP that is constructed using Field's metal (FM)-Graphene nanoplatelet (GNP)-elastomer composite. Field's metal is a key material for eSMP design, which can convert from a solid state with a high elastic modulus (9.25 GPa) to a liquid state at its melting temperature (62 °C). Based on the thermomechanical characteristic of FM, the platform exhibits shape-memory behavior with excellent shape-fixing and restoring abilities under deformation including not only stretching but also non-uniform 3D morphing. To allow rapid, reliable shape reconfiguration through electrothermal operation, GNPs are incorporated into the platform for enhancing electrical and thermal conductivities. The stretchable ACEL device featuring stable electroluminescence and deformability is beneficial to the reliable light-emitting performance of SMDs under 3D reconfiguration. The SMD can be used to realize various unusual 3D structures for a wide variety of applications. We envision that the versatile, user-friendly SMDs can bring out innovative form factors for the next generation display, and open many new opportunities for 3D art displays, transformative wearable electronics, visio-tactile automotive interfaces, and many others.

10:45 AM SF04.06.04
Cottonid—An Old Material for Autonomous Actuation Matthias Langhansl and Cordt Zollfrank; Technische Universität München, Germany

Many material systems have already been developed, which are able to respond to external stimuli such as temperature, light, electric fields, such as temperature, light, electric fields, pH-value or humidity by means of dimensional changes. These materials can react in an energy-efficient way to kinetic energy or mechanical force through volume expansion.

One material in such a system could be Cottonid, one of the oldest known (bio-)plastics. In 1859, the Englishman Thomas Taylor described for the first time the production of this material on the basis of rag paper, which he produced by soaking cellulose fibers in a zinc dichloride bath and pressing several layers under heat. Nowadays, unsized specialty paper made from cotton, pulp or a mixture of both serves as a renewable raw material for industrial production. The treatment with zinc dichloride should only last until the fibers have reacted superficially, otherwise the cellulose chains are degraded and the material is damaged. The exact mechanism of this vegetable parchmentization has not yet been identified in detail. During the process, a tremendous swelling can be observed followed by the decomposition of the paper sheet. The result of this conversion process of the cellulose fibers is a considerable change in the material properties, from soft and flexible to horn-like and hard.

The manufacturing process and the material itself is very sustainable. The zinc dichloride, used as a catalyst, can be completely recycled. The washing water is also almost completely reused. The finished material is free from chemical residues and consists only of cellulose and, for marketing purposes in some cases, pigments. In addition, zinc dichloride is a cost effective and a safe "solvent" compared to commonly used solvent systems for dissolving cellulose. The resulting material is quite hygroscopic and can be perfectly used for sustainable actuators due its dimensional changes in response to environmental humidity.

The presented talk will provide an overview of the possibilities of Cottonid in a bilayered material system for autonomous actuations. Inspired by nature we fabricated actuators with Cottonid as an active layer together with different passive layers and investigated the actuation potential of different systems. Different bio-based and non-bio-based materials and adhesives were usedt to build up a two-layered material. The autonomously actuation potential was investigated inside a climate chamber by alternating humidity. The bending motion was captured with a camera and evaluated. The resulting curvature angles reach from 1° up to 70° depending on the change of the relative humidity and the system itself. We generated a portfolio of different material systems for a wide range of possible applications for which a directed autonomous humidity driven actuation is required.

In summary, Cottonid is a promising material in the field of bioderived and sustainable materials. Due to the topicality of the issues of environmental protection and sustainability, these materials are currently experiencing a renaissance. It has great potential to replace conventional petroleum-based materials with a green alternative. Additionally, the reaction route via zinc dichloride can be transferred to the wide area of all cellulose composites and might lead to a new, even more sustainable way for their fabrication. A possible future field of application for Cottonid-based bilayer actuators could be the so-called bio-architecture. It would be conceivable to use Cottonid-based actuators as an intelligent building envelope, which reacts autonomously to the environment. Even with complex architectural geometries shading systems could be applied In addition to this function as a shading element, combination systems with solar modules, for example, would also be conceivable, in which the Cottonid bilayer adjusts the panel to the position of the sun and follows it.

A Study on the Intrinsic Grain Size Effect of FeMnSi-Based Shape Memory Alloys Ji Young Kim, Wook Ha Ryu and Eun Soo Park; Seoul National University, Korea (the Republic of)

Iron-based shape memory alloys (SMAs), especially Fe-Mn-Si alloys, have great potential in civil engineering structures because of their low cost and shape memory properties based on stress-induced epsilon martensitic transformation (SIEM). In Fe-SMAs, previous researchers have tried to strengthen the parent austenite phase to enlarge the plastic deformation strain range, leading to enhanced recovery strain. Herein, we suggested Fe-SMA with ultra-fine grain to strengthen the austenite phase based on the study of the intrinsic grain size effect. Moreover, to overcome the disadvantage of high annealing twin boundaries density, which is known as an obstacle to reverse martensitic transformation, we fabricated the Fe-SMA with low annealing twin boundaries through subsequent thermomechanical treatment. This study is the first to improve recovery strain through grain refinement, especially with a low density of annealing twin boundaries. Therefore, we expect that this study has both the scientific significance of revealing the intrinsic grain size effect of non-thermoelastic martensitic transformation and the engineering significance of offering a guideline for designing Fe-SMA with high recovery strain.

Prestrain Programmable 4D Printing of Nanoceramic Composites with Bioinspired Microstructure Wei Zhai, Tian Li, Quyang Liu and Haobo Qi; National University of Singapore, Singapore

Four-dimensional (4D) printing enables programmable, predictable, and precise shape changes of responsive materials to achieve desirable behaviors beyond conventional three-dimensional (3D) printing. However, applying 4D printing to ceramics remains challenging due to their intrinsic brittleness and inadequate stimuli-responsive ability. One can draw inspiration from Nature. Concentric cylinder structure is common in biological systems such as scallion, the tracheid of wood, the spicule of Euplectella aspergillum, and the bone Haversian system due to their unique growth organism. Such kind of structure plays a significant role in improving their strength and toughness by increasing the fracture path and energy absorption. Here, this work proposes a conceptional combination of bioinspired microstructure design and a programmable prestrain approach for 4D printing of nanoceramics. To overcome the flexibility limitation, the bioinspired concentric cylinder structure in the struts of 3D printed lattices is replicated to develop origami nanoceramic composites with high inorganic content (95 wt%). Furthermore, 4D printing is achieved by applying a programmed prestrain to the printed lattices, enabling the desired deformation when the prestrain is released. Due to the bioinspired concentric cylinder microstructures, the printed flexible nanoceramic composites exhibit superior mechanical performance and anisotropic thermal management capability. Further, by introducing oxygen vacancies to the ceramic nanosheets, conductive nanoceramic composites are prepared with a unique sensing capability for various sensing applications. Hence, this research introduces a type of high-performance shape-morphing materials for applications under extreme conditions, such as space exploration and high-temperature systems.

SESSION SF04.07: Stimulus-Responsive Architected Materials

3D-Printed Permanent and Impermanent Magnetic Elastomer Architectures—Identifying Key Structure and Processing Parameters for Enhanced Magnetoactive Performance Brittany Nelson-Cheeseman, James Michael Ennis, William Howell, Daniel P. Fagan, Jacob Schewe, Jimmy (Dingming) Lu and Thomas Hoft; University of St. Thomas, United States

Magnetic elastomers are of interest for soft robotic applications where remote contactless activation is desired. These composite smart materials are made of magnetic particulate embedded in an elastomeric matrix and respond to applied magnetic fields with mechanical deformation, termed magnetoaction. It’s been shown that anisotropic structures and properties within these materials leads to increased magnetoactive performance. Magnetic annealing is the main processing technique that has been used to increase magnetoactive performance through the introduction of local anisotropy. For further enhancements to magnetoaction, the 3D-printing technique, Fused Filament Fabrication (FFF), can be used to create additional anisotropy in the structures and properties of magnetic elastomers. FFF architectures create anisotropic sub-structures within a part by extruding 1D lines of the molten material (termed "infill") in 2D patterns that build up to a 3D part. This infill pattern is entirely customizable with respect to orientation and percentage filling allowing for one to readily tune the properties of the resulting part. While it’s been clearly shown that these parameters significantly influence the resulting mechanical and magnetic properties of FFF-printed parts, their influence on magnetoaction (the confluence of mechanical and magnetic responses) has yet to be reported.

Here, we investigate how a variety of parameters on multiple length-scales influence magnetoaction in FFF-printed magnetic elastomers. In particular, we study how FFF *infill percentage* and *infill orientation* relative to applied magnetic field influences magnetoaction of the printed part. We also study a variety of *soft vs. hard magnetic particulates* in order to understand how these distinct magnetic material properties interact with the various 3D printed structural features.

A custom setup and approach has been developed to meticulously measure resulting magnetoactive effects by isolating the deflection and rotational components of any complex motion observed. For both modes, the sample is suspended from a fixed point and a transverse DC magnetic field is applied up to 0.4 T. The degree of magnetoaction is quantified as the angle of deflection or rotation of the sample for a given applied field. The data is captured visually in digital images that are then processed in order to determine the quantitative deflection or rotation angle for a given applied field. Supporting magnetic, mechanical and structure (SEM) studies are utilized to investigate the origins of the differences in magnetoaction.

For the FFF architectures studied, we find that the greatest magnetoaction is found for a combination of lower infill percentages and infill oriented perpendicular to the applied magnetic field. These effects arise from both maximizing anisotropy and limiting infill crosslinking within the structure, which greatly affects mechanical stiffness and resistance to motion. Moreover, we find that the soft magnetic particulates (Fe and Fe_3O_4) give the greatest magnetoaction, but only simple, noncomplex motion; meanwhile, the hard magnetic particulate (SrFerrite) gives complex magnetoactive responses involving motion in multiple dimensions and is intricately dependent on a host of variables studied. All of these results together highlight a number of key structure and processing parameters that lead to enhanced magnetoactive performance in 3D-printed magnetic elastomer architectures.

1:45 PM SF04.07.03
Complex Magnetoactuation of 3D-Printed Hard Magnetic Elastomers—Effects of Infill Percentage and Poling Orientation William Howell, Michael Ennis, Daniel P. Fagan, Jacob Schewe, Jimmy (Dingming) Lu, Thomas Hoft and Brittany Nelson-Cheeseman; University of St. Thomas, United States

Magnetic elastomers are composite smart materials made up of a flexible polymer and magnetic particulate which mechanically articulate in response to an applied magnetic field (H). They allow for highly configurable and untethered actuators. To enhance configurability, 3D-Printing allows for great control of the object’s meso and macro structure, both in terms of shape geometry and property anisotropy. Specifically, Fused Filament Fabrication (FFF) is an additive manufacturing process by which material is extruded in lines (infill) to gradually build up an object through layer-by-layer extrusion. One of the clear advantages of FFF is that it requires no curing time after the piece has been printed. Magnetic elastomers with hard magnetic particulate, due to the presence of large remnant magnetization, have the unique advantage of performing more complex actuation, such as rolling, twisting, and folding. SrF is an excellent hard magnet candidate given its lower price and greater accessibility compared to Neodymium Iron Boride. Poling allows for consistency of the object's remnant magnetization, giving more control and magnitude to its motion. In this study, we explore how the FFF structural parameter of infill percentage, sample orientation relative to H, and poling orientation affect the magnetoactive response of printed elastomer structures made up of SrF particulate suspended within a thermoplastic urethane polymer matrix. Rectangular sample beams are 3D-printed with dimensions of 5mm x 5mm x 60mm.Prior to testing, the samples are first poled in a certain direction, and then the magnetoactive properties are measured by a custom setup where each printed sample beam is suspended vertically and optically tracked for a transverse H up to 0.4 T. In order to isolate different components of the complex movement to see how our variable change affect magnetoaction, multiple orientations relative to H are studied. Sample sets are either studied for rotational motion or deflection, and within each set the sample itself is rotated 90 degrees each new testing cycle for four cycles. A custom MATLAB program overlays the digital images for increasing H in order to quantify the magnetoactive deformation that results. The magnetoactive responses exhibited by the various sample types highlight clear design goals for tailoring large and complex magnetoactive actuation modes. In addition to the traditional transverse bending seen from typical (magnetically soft) magnetic elastomers, we also observe complex twisting and torquing of the beams in multiple dimensions based upon the printed structure and the sample orientation relative to H. These effects are greatest for the orientations and structures that maximize magnetic anisotropy and minimize the infill crosslinking. This work demonstrates the clear potential to tailor complex magnetoactive responses from FFF-printed hard magnetic elastomers, opening the door to highly complex actuators that can be readily and accessibly designed and created.

3:00 PM SF04.07.04
Soft and Switchable Pearls—Capsules that Exhibit Pearlescence on Heating Medha Rath, Taylor J. Woehl and Srinivasa R. Raghavan; University of Maryland, College Park, United States

A pearl-like luster (i.e., pearlescence) is seen in many natural materials like nacre and also in some commercial products such as paints and cosmetics. This optical phenomenon is attributed to the diffraction of light from plate-like particles in the material, with the particle size or spacing being comparable to the wavelength of light. Here, for the first time, we demonstrate the onset of pearlescence in soft capsules that contain no plate-like particles. The capsules (~ mm in size) are transparent and non-pearlescent at room temperature. The thin (~ 500 µm) outer shell of the capsules is a hydrogel of N-isopropylacylamide (NIPA), which shrinks when heated above its lower critical solution temperature (LCST) of ~ 32°C. When heated above this LCST, the transparent capsule spontaneously turns pearlescent. The effect is reversible, with the transparent state being recovered upon cooling. This is the ***first example of reversible pearlescence*** in any material. Spectral reflectance measurements show that the pearlescence of the capsules is comparable to that of real pearls. Interestingly, bulk hydrogels of NIPA do not turn pearlescent on heating ¾ they simply become turbid. Thus, pearlescence is observed only in NIPA-shelled capsules, and we show that it requires both a thin NIPA shell and a water-rich core capable of swelling. When heated above its LCST, the NIPA shell further shrinks, and we postulate that NIPA-rich domains phase-separate within this shell. The size or spacing of these domains is likely to be responsible for the pearlescence. Our work sheds fresh insight into the nature of pearlescence, on how it can be tuned, and on how it can be introduced into various soft materials.

Additive Manufacturing of Robotic Metamaterials Xiaoyu Zheng; University of California, Berkeley, United States

Additive manufacturing has shown the promise of freedom of designs, enabling parts customization and tailorable properties where superior structural performances can be achieved by a fraction of weight density compared to bulk material. However, it is presently difficult to combine different materials (structural, dielectric, conducting and ferroelectrics) to create a complex device with multiple functionalities that responds to multiple stimuli. Unlike biological systems where functions, including sensing, actuation, and control, are closely integrated, few materials have comparable system complexity.
In this talk, I will present a suite of new multi-material additive manufacturing processes and design methodologies to create materials with tailorable structural and functional behaviors. The structural materials consist of a network of micro-unit cells which collectively influence new mechanical behaviors (from high-strength, lightweight to toughening) not seen in their native counterpart. When combined with an electronic and functional phase, these materials turn themselves into a "robotic material" and is capable of motions with multiple degrees of freedom motions and amplification of strain in a prescribed direction in response to an electric field (and vice versa), and thus, programmed motions with self-sensing and feedback control. I will present the manufacturing and synthesis of these materials, as well as their mechanics and design methods underpinning their novel behaviors.

3:45 PM SF04.07.06
Programming Molecular Order of a Liquid Crystal Elastomer with Magnetic-Field-Assisted DLP Printing Yueping Wang[1], Jongwon An[2], Sehui Jeong[2] and Howon Lee[2]; [1]Rutgers, The State University of New Jersey, United States; [2]Seoul National University, Korea (the Republic of)

Shape memory polymers (SMPs) and hydrogels are two major materials classes of stimuli-responsive materials that have been widely used in 4D printing. As such, additively manufactured responsive architected materials are made of either SMPs or hydrogels. SMP can memorize its original printed shape and restore it when needed, but its stimuli-responsive morphing is only one-way in that mechanical processing is always required for shape programming. Stimuli-responsive hydrogels can deform reversibly depending on various environmental changes, but they suffer from extremely slow time-scale for shape change due to a quadratic scaling law for the diffusive water molecule migration process and are not suitable for applications where surrounding water is not available. Recently, liquid crystal elastomers (LCEs), combining polymeric elasticity with liquid crystalline anisotropy, have received growing attention as a new class of a 4D printing material that can overcome the limitations of SMPs and hydrogels.
LCEs can show reversible stimuli-responsive deformation driven by rearrangement of molecular orientation of liquid crystal (LC) molecules. However, alignment of LC molecules has been achieved primarily using mechanical extension or viscous shear, which significantly limits its applicability in additive manufacturing. Here, we report a DLP system capable of printing an LCE structure while selectively programming molecular orientation of LC molecules using a magnetic field. We report a LCE precursor solution that maintains a nematic phase at room temperature. Using a custom-built DLP printing system with an integrated magnetic field generator, LC molecules are aligned in the desired orientation and selectively cured by patterned digital light projection. Therefore, LC orientations can be freely encoded in a single structure. This allows for spatial patterning of LC orientations independent of the geometry of the printed structure. Considering the advantages of DLP printing over other additive manufacturing methods, this approach can offer unmatched opportunities for programming various modes of shape deformation of responsive architected materials.

4:00 PM SF04.07.07
Comparison of Ink Formulations for Direct Ink Writing and Photothermal Actuation of Liquid Crystal Elastomers Michael Ford[1], Yuchen Wang[2], Rodrigo Telles-Arriaga[3], Dominique Porcincula[1], Julie Mancini[1], Mehedi Hasan Rizvi[4], Bryan Moran[1], Joseph Tracy[4], Jennifer Lewis[3], Shu Yang[2], Elaine Lee[1] and Caitlyn C. Krikorian (Cook)[1]; [1]Lawrence Livermore National Laboratory, United States; [2]University of Pennsylvania, United States; [3]Harvard University, United States; [4]North Carolina State University, United States

Light as a stimulus for shape change may be useful for localized actuation that does not require physical contact with the shape-changing material (e.g., as wires that transmit electrical power might require). Thus, the development of liquid crystal elastomers (LCEs) with light responsivity may be important for actuation that is activated at a distance, like for search-and-rescue or medical robots/devices. In this talk, I will outline our approach to formulating an ink that would produce photoresponsive LCEs that are 3D-printable (e.g., using direct ink writing), specifically focusing on the use of gold nanorods (AuNRs) in these inks. We examined the advantages and disadvantages of various formulations by characterizing curing kinetics and molecular weight along with rheological and thermal properties of the inks. Specifically, we considered possible routes for formulating inks. The first approach followed a synthetic scheme that was previously reported for LCEs that incorporated AuNRs. Other synthetic approaches were compared and contrasted with the previously reported approach to formulate an ink that was optimized for actuation strain and compatibility with AuNRs. Finally, we added AuNRs to one of the formulations and characterized the photothermal actuation properties. These printed actuators could respond to locally to light or globally to heat, and the use of direct ink writing was leveraged to form multiresponsive architectures, making these promising functional materials for advanced applications.

SESSION SF04.08: Functional Application of Responsive Materials

9:45 AM SF04.08.01
Physical Unclonable Function of Surface Random Wrinkles with Optical Anisotropic Matter Kitae Kim, Choi Moon Young and Jun-Hee Na; Chungnam National University, Korea (the Republic of)

Periodic microstructures over a large area allow interesting functionalities such as structural color and self-cleaning surfaces and lead to a wide range of applications from adaptive bioengineering and flexible electronics to adhesives. To construct microstructures of diverse classes of materials, lithography has been widely used but often involves inherent limitations to the applicability for non-planar surfaces and the pattern resolution predefined by the stamp. Surface wrinkles can be used in various fields and it has been applied to improve the efficiency of electro-optical devices and the mobility of charge carriers in semiconductor devices. Our work shows that to generate pixelated wrinkles by controlling reactive mesogens (RMs) alignment. A custom-built optical setup employing a spatial light modulator (SLM) illuminates polarized ultraviolet light on a particular area of photo-alignment layers, such as the RMs. Wrinkles produced during the plasma-treatment polymerization of RMs can be aligned accordingly. The pixelated wrinkles can record naturally invisible images by mapping the gray level to the orientation of the wrinkles. As a result, it is shown that pixelated wrinkles enable new applications in optics such as image storage, informative labeling, anti-counterfeiting, and physical unclonable functions(PUFs).

10:00 AM SF04.08.02
A Smart Skin for Hydrogels that Enables Switchable Solute Release Sai Nikhil Subraveti[1,2] and Srinivasa R. Raghavan[1]; [1]University of Maryland, United States; [2]Princeton University, United States

Many applications of hydrogels rely on their ability to deliver encapsulated solutes such as drugs; however, small hydrophilic solutes rapidly leak out of gels by diffusion. A need exists for a way to regulate solute release out of gels - to ensure zero release until a desired time, and thereafter, for the release to be 'switched on' at a high rate. This should ideally be a repeatable switch, i.e., the gel should be cyclable repeatedly between the on and off states. Such perfect, cyclical on-off release of solutes is demonstrated for the first time through a 'smart skin' that is synthesized rapidly (in ~ 10 min) around gels. The thin (~ 50 – 100 μm) and transparent polymer skin is endowed with redox-responsive properties through the use of urethane and acrylate monomers, one of which contains a thioether group. Initially, the skin is hydrophobic and it completely prevents hydrophilic solutes from leaking out of the gel. When contacted with oxidants such as hydrogen peroxide (H_2O_2), the thioethers are converted to sulfoxides, making the skin hydrophilic and thereby 'turning on' the release of solutes. Conversely, solute release can be 'turned off' subsequently by adding a reducing agent such as Vitamin C that reverts the sulfoxides to thioethers and thus returns the skin to its hydrophobic state. The release rate in the 'on' state can be tuned via the skin thickness as well as the oxidant concentration. The ability to regulate solute delivery from gels using smart skins is likely to prove significant in areas ranging from separations to agriculture to drug delivery.

10:15 AM SF04.08.03
Microfluidic Shape-Memory Microparticles for Embolization System Jérémie Caprasse, Raphaël Riva and Christine Jerome; University of Liege, Belgium

Embolization that involves the selective occlusion of blood vessels may be used to control or prevent abnormal bleeding, close off vessels supplying blood to a tumor, eliminate abnormal connections between arteries and veins, or to treat aneurysms. It is a highly effective way to control bleeding and is much less invasive than open surgery. The selection of an embolic agent is based on many considerations, notably on the clinical indication for the procedure, on the desire to produce temporary or permanent occlusion, on the level of occlusion, on flow dynamics/collateral circulation, on the risk of complications such as necrosis or nontarget embolization, and on cost. Microparticles embolics can be made of several types of materials such as hydrogels able to swell after injection until occlusion.[1,2]

Shape-memory polymers (SMPs) are remarkable stimuli-responsive materials able to switch from one stable macroscopic shape to another one, are also of prime interest to afford well-controlled embolization systems. Among shape-memory materials, poly(ε-caprolactone) (PCL) networks are widely studied for biomedical applications since PCL is biocompatible, and biodegradable.

In our work we formulated by a microfluidic system, shape-memory microparticles composed of 4-arms PCL stars end-functionalized by coumarins[3]. The obtained highly monodispersed particles were crosslinked by on-line UV irradiation (365nm). These crosslinked particles that still exhibit crystallinity possess temperature triggered shape-memory properties by heating above the melting temperature, around 50°C, making them promising hydrophobic and biodegradable candidates for embolization aplication.

Cu(I) Coordination Polymer-Based NH_3 Gas Sensor with High Response at Room Temperature TaeHun Im[1,2] and Sohee Jeong[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

High performance in NH_3 gas sensor is highly demanded because ammonia which has highly toxic and corrosive properties causes ailments in human body under the certain concentration of NH_3. Up to date, metal oxide gas sensor (MOS) is widely used for detecting NH_3 gas; however, high operating temperatures and producing costs are considered as limitation in the effective applications.
Here, we report on a new type of NH_3 gas sensor with high response (> 800% at 100 ppm) and low detection limit (<0.25 ppm) at room temperature. The sensor is semiconducting coordination polymers (CPs) containing Cu(I) ions and thiourea derivatives, which can be produced by cost-effective solution-based method within 10 min. For improving NH_3 gas sensing performance, Ag was doped into CPs. It exhibits the excellent gas sensing capability with ~ 2000 % at 100 ppm which is the best of our knowledge. Additionally, response and recovery time decreased by 8% and 70%, respectively compared to that of parent CPs. Ag in CPs was detected by XPS measurements, which verified that Ag elements exist individually inside of CPs. To determine the origin of outstanding gas sensing properties of CPs, we performed a simulation of crystal structure based on the PXRD results. And In-situ FT-IR spectroscopy was used to identify the mechanism of NH_3 gas sensing in CPs. NH_3 gas and NH_4^+ ions acted as Lewis, Brønsted acid site, and additionally NH_3-Cu^+ peaks were observed at 1620 cm^{-1}, and it could be inferred that the high reactivity of the sensor was caused by Cu^+ acting on NH_3 detection.

10:45 AM SF04.08.05
Fabrication of Carbonized Structures with Controlled Pore Direction for Improved CO_2 Capturing Functionality Using Bio-Material Based Nanofibers TaeGeon Kim, Dmitry Sergeev and Ruth Schwaiger; Forschungszentrum Juelich, Germany

Porous architectures demonstrating high strength-to-weight ratio, large surface area and high resilience have been of recent interest for gas storage, battery electrode and fuel cell applications. Desired properties can be achieved in this class of materials by tuning the characteristics of the pores, including wall thickness, pore size and directionality of the pores, and by making use of different constituent materials. Another application of such materials is carbon dioxide capture, which can contribute to halting global warming caused by an increase in atmospheric concentration of CO_2. Early stage of CO_2 capturing research was mainly focused on materials based on chemical absorption, such as metal-organic framework (MOF) materials, which exhibit reduced cyclability due to the low physical strength and low chemical durability including their low resistance to moisture. These drawbacks can be overcome by exploiting physical absorption through surface activation of carbon-based materials. However, previous research has mainly focused on powders, which typically do not achieve high efficiency of CO_2 absorption due to the inefficient and random pathways of gas penetration.
In this work, we fabricated free-standing carbonized structures with oriented pores using nanofiber-type cellulose, chitin, and chitosan bio-materials. Using directional freeze-casting, the directional growth of ice crystals according to an applied temperature gradient functions as a template for the formation of a structure with oriented pores and bio-nanofibers walls. The porous architecture of the materials was controlled by the concentration of bio-materials in the solution. After sublimation of the ice crystals, free-standing structures were obtained with xylem-like architecture, which were then pyrolized resulting in carbonized structures with nanoscale thickness of walls containing cellulose, chitin and chitosan nanofibers. In addition, activation through potassium hydroxide (KOH) was studied for enhancing CO_2 capturing. To characterize the CO_2 capturing functionality, the surface activation of the oriented carbon structures was studied using multiple cycles of CO_2 absorption-desorption by Thermogravimetric analysis (TGA) and Raman spectroscopy. This study will elucidate the correlations between the pore architecture, which is characterized by well-oriented walls of nanoscale thickness, and its effect on the CO_2 capturing properties.

11:00 AM SF04.08.06
Molecular Approaches to the Production of Enzymatic Construction Material towards a Durable, Carbon-Negative Infrastructure Rebecca J. Gilchrist, Shuai Wang, Sara Heidarnezhad, Nima Rahbar, Suzanne Scarlata and Ronald L. Grimm; Worcester Polytechnic Institute, United States

We recently developed an Enzymatic Construction Material, ECM, that utilizes carbonic anhydrase to catalyze the conversion of carbon dioxide into carbonate. The resulting concrete-like material demonstrates high strength, crack tolerane, and self-healing properties throughout the lifetime of the carbonic anhydrase enzyme. Presently we are investigating molecular alternatives to carbonic anhydrase to improve the durability of the catalytic conversion of gas-phase carbon dioxide to crystalline carbonate species. Molecular alternatives include Zn^{2+}-based molecular catalysts that not only replicate the active site of carbonic anhydrase, but the supramolecular environment that orients the water and carbon dioxide reagents and shuttles unwanted proton products from the reaction site. We will discuss free molecular catalysts as well as surface-tethered systems that demonstrate good catalytic rates and durability at the high pH and thermal environments that exist in construction materials.

11:15 AM SF04.08.07
3D Aperiodic Cellular Structures of Polymer Materials by Rotational Layer-by-Layer Stacking for Enhancement Mechanical Properties Seo Rim Park, Seok Kim and Young Tae Cho; Changwon National University, Korea (the Republic of)

Microlattice is a two- or three-dimensional microarchitecture in which unit cells of a specific shape are regularly arranged. It has characteristics such as a high strength-to-weight ratio and shock absorption, so it can be used in various fields. However, due to the mutually exclusive relationship between strength and toughness, it is difficult to simultaneously increase the strength and toughness of microlattice. Bouligand structure is a structure in which chitin-protein fibers parallel to each other rotate at a certain angle around a vertical axis to increase strength and toughness at the same time. This maximizes the energy dissipation of the structure by crack bridging, deflection, arrest, and twisting caused by rotational stacking.
This study proposed deterministic aperiodic cellular structures with enhanced mechanical properties by bioinspired Bouligand rotational stacking of periodic lattices. The aperiodic cellular microstructure was 3D-printed with photopolymer materials and then was performed compression test to analyze mechanical properties. For proof of concept, the printed aperiodic cellular structures were designed by rotational layer-by-layer stacking of periodic hexagonal microlattices.
As a result of the compression test, linear elasticity, yielding, plateau, and densification sections appeared in order in the stress-strain graph as the compressive strain increased. Through this, it was confirmed that it had the same tendency as the microlattice stress-strain graph. However, unlike 3D aperiodic cellular structures, the monolith did not show a yielding section. This is considered to be because monoliths are bending-dominated, but 3D aperiodic cellular structures are stretch-dominated.
The in-plane strength, stiffness, and toughness of 3D aperiodic cellular structures fabricated at stacking angles of 0°, 15°, 20°, 30°, 45°, 60° and 90° were analyzed. Compared to the monolith, the strength, stiffness, and toughness of the 3D aperiodic microlattices were higher at all stacking angles, and among them. The reason for the superior mechanical properties compared to the monolith is that the strut breaks later, similar to the bouligand structure. We believe that these enhanced mechanical properties could be originated from the minimization of stress concentration due to the existence of many struts and the maximization of energy dissipation due to the dispersion of the crack initiation point.

Thermally-Responsive Softening Intravenous Needle for Enhancement of Patient Care and Healthcare Provider Safety Karen-Christian C. Agno, Keungmo Yang, Sang-Hyuk Byun, Subin Oh, Simok Lee, Heesoo Kim, Kyurae Kim, Sungwoo Cho, Won-Il Jeong and Jae-Woong Jeong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Conventional intravenous needles are manufactured from materials with high and fixed stiffness that allows for rigid tissue insertion followed by therapeutic fluid delivery into the bloodstream. Their rigid structure not only causes chronic tissue complications among hospitalized patients receiving IV medication but also heightens the risk of needle stick injuries among healthcare providers after usage. Here, we introduce a liquid metal-based needle that can autonomously change its stiffness by body temperature (~ 37 °C) to match the softness of the delicate blood vessel after rigid tissue insertion. The needle has a rectangular hollow structure formed from U-shaped liquid metal frames which are encapsulated with silicone of high tear strength. We utilize gallium for the channel frames because of its unique phase conversion between solid (elastic modulus = 9.8 GPa) and liquid, low melting temperature (T_{melt} = 29.76 °C) below the body temperature, and biocompatibility. At room temperature (20-25 °C), the needle is rigid and straight like the commercial rigid needle, but it becomes soft and compliant after rigid tissue insertion (~ 37 °C) within 60 seconds as the encapsulated gallium frames melt, achieving three orders of magnitude of independent modulus-tuning ratio. After one usage, the softened needle becomes completely non-reusable because supercooling phenomena prevent solidification of liquified gallium. Our *in vivo* studies indicate that the softening needle has potential to reduce inflammation injury in the injection site owing to its enhanced tissue-adaptability in comparison to commercial rigid IV access device of comparable size. To further add functionality, a nanomembrane temperature sensor was integrated with the softening needle, demonstrating that the integrated system-device can monitor the on-site temperature to measure core body temperature or undesirable fluid leakage during IV administration. Overall, the gallium-based intravenous needle envisions wide-range of clinical applications, as it actively responds to the call of the World Health Organization for the improvement of patient care and safer medical practice.

SESSION SF04.03: Poster Session: Development and Design of Responsive Architected Materials
Session Chairs: Michael Frazier and Xiaoyue Ni
Tuesday Afternoon, April 11, 2023
Moscone West, Level 1, Exhibit Hall

Self-Healing Polymer Composites with Enhanced Strength for Use in Protective Textiles Evan A. Griffiths, Blaine Barrington, Scott Coguill, Brahmananda Pramanik, Richard LaDouceur, Jessica M. Andriolo and Jack L. Skinner; Montana Technological University, United States

Self-healing materials have the potential to increase the lifetime of products exponentially through both non-reversible healing and reversible healing processes. For instance, non-reversible healing has been demonstrated with the use of micro-spheres filled with healing-compounds used to mitigate micro-crack propagation within materials like concrete or asphalt. Upon use however, micro-sphere rupture is irreversible. Reversible self-healing traditionally is manifested in polymeric or rubber materials designed to exhibit both covalent and ionic bonds within the same material. Reversible self-healing materials not only repair other products but can have extended lifetimes themselves. However, reversible self-healing materials are often mechanically weak when compared to non-reversible self-healing materials, thereby limiting applications. In this work, we aim to improve the strength of reversible self-healing materials for sustainability and to increase the extent of applicable uses of these materials. We hypothesize that through the addition of aramid nanofibers, the mechanical stability of reversable self-healing polymers can be improved.

To produce aramid-reinforced polymer composites, aramid fabric will first be dissolved in dimethyl acetamide and lithium chloride to form nanofibers. The aramid fibers will then be dispersed within a self-healing polymer matrix (previously described by Wang et al. in *J. Am. Chem. Soc.* 2019) by sonication to randomly align the fibers for enhanced shear and bulk moduli. To determine a preferable fill concentration, aramid will be distributed in a polymer matrix over a range of concentrations. Aramid-reinforced polymers will then be examined for shear strength using an ASTM D 732 punch tool, and the dynamic stress-strain of the materials will be characterized on a split-Hopkinson pressure bar and Charpy impact tester. The reinforced polymer will also be formed into dog bones using a 3D printed mold for determination of the elastic modulus through quasistatic tensile testing. In addition to these tests, ability and time required for the polymer to repair will be monitored over the range of aramid concentrations used.

The primary objective of this work is to provide self-healing textiles with enhanced strength for soldiers in the field to maintain protection following damage of protective gear or uniforms. Following determination of a preferable aramid concentration in a reinforced polymer matrix, the polymer will be electrospun into fibrous textiles for further testing including self-repair following impact, splitting or ripping due to an encounter with a sharp object. Future work hopes to follow self-healing of these reinforced textiles using lab-on-a-chip technologies and determination of how re-use impacts mechanical properties.

5:00 PM SF04.03.03
Real-Time and Label-Free Biosensing Using Moiré Pattern Generated by Bioresponsive Hydroge Semin Kim, Soeun shin, Yujin Kang and Won-Gun Koh; Yonsei University, Korea (the Republic of)

Bioresponsive hydrogels are smart materials that respond to various external stimuli and exhibit great potential as biosensors owing to their capability of real-time and label-free detection. Here, we propose a sensing platform based on bioresponsive hydrogels, employing the concept of moiré patterns. Two sets of line patterns with different pitch sizes are prepared; a hydrogel grating whose pitch size changes according to external stimuli and a reference grating with constant pitch size. The volume changes of the hydrogel caused by external stimuli changes the pitch size of the hydrogel grating, and subsequently, the pitch sizes of the moiré patterns (moiré signal), whose values can be obtained in a real-time and label-free manner through customized moiré microscopy and signal processing. After confirming that the pH-induced swelling of hydrogel could be monitored using moiré patterns, we performed moiré pattern-based detection of specific proteins using protein-responsive hydrogel that underwent shrinking via interaction with target proteins. Brain-derived neurotrophic factor and platelet-derived growth factor were selected as the model proteins, and our proposed system successfully detected both proteins at nanomolar levels. In both cases, the pitch size change of hydrogel grating was monitored much more sensitively using moiré patterns than through direct measurements. The changes in the moiré signals caused by target proteins were detected in *ex-vivo* environments using a custom-made intraocular lens incorporating the hydrogel grating, demonstrating the capability of the proposed system to detect various markers in intraocular aqueous humor, when implanted in the eye.

On-Demand Selective Chirality of Flower Corolla-Like Micropetal Arrays with Magnetic Twisting Actuation Jeong Eun Park[1,2], Jisoo Jeon[2], Sei Jin Park[3], Sukyoung Won[1,2], Zahyun Ku[4] and Jeong Jae Wie[1]; [1]Hanyang University, Korea (the Republic of); [2]Inha University, Korea (the Republic of); [3]Lawrence Livermore National Laboratory, United States; [4]Air Force Research Laboratory, United States

.Selective chirality has attracted interest in the field of optics to distinctively detect light with a left- or right-circularly polarized direction. Typically, artificial chiral structures are, however, stationary and cannot dynamically change the directionality of the chirality once the structures are fabricated. In this study, we present on-demand selective chirality of the micropetals with radial arrangements of several micropillars, inspired by natural flower corolla with intrinsic chirality. Individual micropetal performs the directional magneto-mechanical twisting actuations toward the linear external magnetic fields. Accordingly, the micropetal arrays appear the dynamic chiral switching from achiral to clockwise or counterclockwise directions depending on the changed direction of the external magnetic fields. Toward realizing the chirality of three-dimensional (3D) microstructure, we will discuss relationships between the chirality and symmetry properties of the magnetically twisted five- and six-micropetal arrays. Along with this, by wetting the achiral and chiral micropetal arrays with a polymeric solution, we would demonstrate 3D capillary-assembled achiral flower corolla and solute-assisted shape-immobilized chiral flower corolla.

5:00 PM SF04.03.05
Magnetoactive Properties of Biocompatible Magnetic Hydrogel Composites—Effects of Magnetic Particulate Type and Magnetic Annealing Jacob Schewe, James Michael Ennis, Jimmy (Dingming) Lu and Brittany Nelson-Cheeseman; University of St. Thomas, United States

Magnetic hydrogels are a novel composite smart material made up of a flexible, tissue-like hydrogel polymer with an incorporated magnetic particulate, producing a material capable of mechanical deformation in response to an applied magnetic field (H). Polyvinyl alcohol (PVA) ferrogels were successfully fabricated by the freezing-thawing (FT) cycle technique, employing magnetite (Fe_3O_4) and strontium ferrite ($SrFe_{12}O_{19}$) as the materials for magnetic, micron-sized, additives. Strontium ferrite was specifically chosen as a hard magnetic additive due to its availability and lower price compared to Neodymium Iron Boride additives. In this study, the differing effects of magnetically soft and hard additives on the properties of PVA ferrogels were investigated by comparing the magnetic, mechanical, and magnetoactive properties of PVA ferrogels impregnated with magnetite and strontium ferrite, respectively. The effects of magnetic annealing on ferrogels during crosslinking were investigated in this study by comparing their resulting magnetic, mechanical, and magnetoactive properties with analogous control samples. Magnetoactive properties are determined by quantifying the angle of sample deflection in an applied transverse magnetic field, via a custom digital image overlay program. To further study the effects of magnetic annealing and material type to create complex magnetoaction, multiple orientations relative to H were adopted during magnetoactive deflection testing. Mechanical properties are determined via tensile elongation testing. The distribution of the magnetic additives was investigated using scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (SEM EDS). SEM EDS analysis revealed an evenly dispersed particulate throughout the hydrogel network at all loading content levels. Mechanical analysis revealed an increase in ferrogel stiffness contingent on an increase in magnetic additive content, regardless of the magnetic properties of the additive. Addition of magnetically hard additives yielded magnetically responsive ferrogels capable of complex motion and actuation. These ferrogels were characterized by a high magnetic remanence, and highly customizable magnetoaction that included a combination of deflection along a transverse magnetic field (H) and twisting around the same field. This complex responsiveness was varied by additive loading content, the presence of magnetic annealing, and sample orientation during testing. In contrast, the inclusion of a soft magnetic additive yielded highly magnetoactive ferrogels with only a single pattern of magnetoaction. These ferrogels were characterized by variable deflection along a transverse magnetic field (H) but were only characterized by their highly deflective magnetoaction, as compared to the deflection displayed by hard magnetic ferrogels yet had no capacity for complex motion. This deflective magnetoaction based upon magnetic additive loading content and presence of magnetic annealing.

Development of Novel Precursors for Lubricious Metal Chalcogenide Coatings Ciaran P. Llewelyn[1], Andrew Johnson[1], Joshua Smith[2] and James Parish[2]; [1]University of Bath, United Kingdom; [2]Infineum International Limited, United Kingdom

Tribology plays an integral role in the development of energy-efficient technologies at numerous levels by increasing the energy efficiency and longevity of components through minimising friction and wear. This covers a wide array of sectors including energy, health, manufacturing, and transport with over 20% of total energy consumption on earth being used to overcome these effects with the majority arising from large industrial processes involving heavy machinery.[1] The development of materials for reducing friction and wear in machine elements is an enormous challenge and one area of significant interest is the automotive sector with a particular focus on the internal combustion engine (ICE).

Currently employed additives in ICEs such as zinc dialkyldithiophosphate (ZDDP)[2,3] and molybdenum dithiocarbamate (MoDTC)[4,5] have been utilised as anti-wear and friction-reducing agents in lubricants for over 80 years. Despite their unquestionable success during this time, the resulting by-products of combustion have been known to damage catalytic convertors forming metallic ash and sulfurous/phosphorus oxide layers over the active sites of the catalyst inhibiting the performance.[2,6] This has led to several governing bodies restricting the amount of sulfur and phosphorus within engine oil.[7] This restriction has led to significant interest in alternative metal chalcogenide systems which could compete with the current additives.

This presentation reports on the design and development of adaptive, multifunctional novel precursors; which act as a delivery molecule for Mo and W chalcogenide systems combined with the ability to decompose in situ to form lubricious metal-containing thin films. These responsive thin films are predicted to offer competitive friction and wear protection whilst limiting the use of sulfur and phosphorus. New tribologically responsive precursor systems have been fully characterised by NMR, TGA and SCXRD, and the tribological performance of the precursors has been analysed using a TE-77 tribometer. The resulting scars from the friction evaluation and wear measurements have been analysed by energy-dispersive X-ray analysis. Responsive metal chalcogenide precursors can be utilised for their tribological properties and aid in minimizing wasted energy with a focus on honing effectiveness and efficiency.

5:00 PM SF04.03.07
Multi-Functional Architected Swarms of Magnetic Microrobot Assemblies Kijun Yang[1,2], Sukyoung Won[1,2] and Jeong Jae Wie[3,4,5]; [1]The Research Institute of Industrial Science, Hanyang University, Korea (the Republic of); [2]Program in Environmental and Polymer Engineering, Inha University, Korea (the Republic of); [3]Department of Organic and Nano Engineering, Hanyang University, Korea (the Republic of); [4]Human-Tech Convergence Program, Hanyang University, Korea (the Republic of); [5]Department of Chemical Engineering, Hanyang University, Korea (the Republic of)

Magnetically responsive microrobots have attracted a significant interest as functional materials for untethered robotic systems operating by external magnetic fields. Research on the magnetic microrobots has generally been focused on the sophisticated locomotion manipulation of individual robots. However, individually moving microrobots have limitations in muti-functionality due to their light weight and tiny size. Herein, we report a programmable architected swarm of magnetic microrobots by controlling magnetic anisotropy in the microrobots. By programming magnetization profiles in magnetic microrobots, the magnetic microrobots can build a long-axial or short-axial assembly. When permanent magnets rotate underneath the magnetic microrobots, the assembled magnetic microrobots rotate with a lift angle, i.e., pivoting. Through the pivoting, the assembled magnetic microrobots can climb obstacles that are five times taller than the body length of the single microrobot. Long-axial assembly of the magnetic microrobots facilitates climbing an obstacle than the short-axial assembly counterpart. Meanwhile, by the short-axial assembly, the magnetic microrobots can effectively transport cargo through rotational force of assembled microrobots. Furthermore, we will discuss collective behaviors of the assembled magnetic microrobots toward atherosclerosis plaque rupture.

5:00 PM SF04.03.08
Effects of Particle Distribution on Maneuver of Nanocomposite-Based Helical Magnetic Microrobots Sukyoung Won[1,2], Jaeyong Lee[3], Young Joon Ko[2], Jong Hoon Jung[2], Jinkon Kim[3] and Jeong Jae Wie[1,1]; [1]Hanyang University, Korea (the Republic of); [2]Inha University, Korea (the Republic of); [3]Pohang University of Science and Technology, Korea (the Republic of)

Three-dimensionally (3D) architected magnetic microrobots can locomote remotely in terraqueous environments by external magnetic fields. To actuate magnetic microrobots, various 3D architectures have been prepared through a conventional lithography technique and a direct laser writing of polymer nanocomposites. Although magnetic nanoparticles are embedded in polymer matrices for magnetic actuation of 3D architected magnetic microrobots, correlations between dispersion of magnetic nanoparticles and robot locomotion have not yet been studied intensively. Herein, we compare solvent evaporation and rapid precipitation strategies of thermoplastic polyurethane (TPU)-magnetic nanoparticle nanocomposites to maneuver the nanocomposite-based magnetic microrobots. Depending on the strategies, magnetic nanoparticles are phase-separated or dispersed in nanoscale in the polymer nanocomposites even with identical chemical compositions and particle concentrations. The dispersion states of the magnetic nanoparticles affect torsion-induced polymer processing which is designed to prepare 3D helical architecture of microrobots from the 2D nanocomposite films. When the helical magnetic microrobots feature dense structures without micro-voids in the 3D helix, they can rotate uniformly and revolve in a regular orbit under a rapid rotation of external magnetic field. We will investigate the effects of nanoparticle dispersion not only on the locomotion of the 3D helical magnetic microrobots but also physical properties of nanocomposites.

5:00 PM SF04.03.09
Magnetically Actuated Modular and Biodegradable Hydrogel Robot Units Portia Rayner, Audrey Sedal and Jianyu Li; McGill University, Canada

Small scale soft robots have been proven to be attractive candidates for applications in dynamic and confined spaces such as inside the human body. An increasing number of stimuli-responsive hydrogels has been developed in recent years, enabling the fabrication of more sophisticated designs. These systems have typically been actuated using remotely applied external stimuli such as heat, light, electric fields, or magnetic fields. Of these options, magnetic fields are particularly appealing because the magnitude, phase, and frequency can be adjusted rapidly with a high degree of accuracy. There are few magnetically actuated hydrogels, however, that integrate sensing, computation, and actuation. This work reports a design for hydrogel building blocks that could be combined in order to produce full robot functionality. An alginate-based scaffold is used as the foundation for these units. Since alginate is a biopolymer, this could allow for biocompatible degradation of the units and subsequent recovery of the magnetic particles, enabling a system-level recycling process. Two types of magnetic particles are compared: carbonyl iron and iron oxide. The effect of the particles, individually and combined, on the mechanical and structural properties of the scaffold in addition to the actuation response of the unit is examined. Multiple unit models are created by varying the type and distribution of magnetic particles as well as the scaffold structure in order to achieve different properties, motions, and responses to magnetic fields. The surface of the units is functionalized in order to allow for assembly. Physical polymer entanglement, chemical bonding, and magnetic adhesion are compared as methods for assembly. The type, number, and relative orientation of the units within the larger structure can be altered in order to achieve different functionalities such as cargo delivery, programmed degradability, and multiple modes of actuation. This approach provides the materials foundation for more sophisticated robotic systems which have previously been difficult to achieve using hydrogels.

5:00 PM SF04.03.10
Universally Applicable Encapsulation and Functionalization Method for Preparing Functional Nanocomposites and Hybrids for Biomedical Applications Artur Feld[1,1], Agnes Weimer[1,1], Jan-Philip Merkl[1], Johannes Ostermann[1], Christian Schmidtke[1], Rieke Koll[1], Lisa Sarah Fruhner[2] and Horst Weller[1,1]; [1]University of Hamburg, Germany; [2]Forschungszentrum Jülich GmbH, Germany

By synthesizing homogenous magneto-responsive nanocomposites and functional nanohybrids, we demonstrate the universal applicability of our advanced encapsulation technique.[1-3]

Our encapsulation technique is based on the micellar encapsulation of various nanocrystals in a polyisoprene-block-poly(ethylene oxide) (PI-b-PEO) diblock copolymer shell with subsequent thiol-ene click reaction initiated cross-linking of the PI block. This leads to a robust and functionalizable polymer shell that provides maximum stability to the nanocrystal in both water and host matrix. These even offer the possibility to perform copper(I) catalyzed click reactions while keeping the fluorescence of the quantum dots. We demonstrate the robustness of the shell by synthesizing a magneto-responsive nanocomposite with homogeneously dispersed superparamagnetic iron oxide nanocrystals in a poly(ethylene oxide) matrix. We present an extensive step-by-step characterization during the different stages of preparation by small-angle X-ray scattering (SAXS) and transmission electron microscopy (TEM), with both methods perfectly complementing each other.[1]

Biocompatibility and functionalizability were demonstrated by a systemic study with human alveolar epithelial cells (A549) and murine macrophage leukemia cell (RAW-264.7). Thereby, we could show that using different polymer architectures besides the variation of the polymers' molecular weight allows us to control the size of the resulting constructs and the permeability of the shell. As a general trend, it can be stated that those coatings, which were most stable against quenchers, also showed the best resistivity concerning unspecific cellular uptake.[2]

All these results underline the vast variability and controllability of the PI-b-PEO diblock copolymer system for the encapsulation and functionalization of nanoparticles for biological applications and magneto-rheological nanocomposites.

5:00 PM SF04.03.11
Exploring the Effects of Magnetic Particle Composition on the Magnetoactive Properties of Magnetic Elastomer Filament and 3D Printed Samples Daniel P. Fagan, William Howell, Sarah Ziemann, Jimmy (Dingming) Lu, Jacob Schewe, Michael Ennis, Thomas Hoft and Brittany Nelson-Cheeseman; University of St. Thomas, United States

Magnetic elastomers are a composite smart material that contains an elastomeric matrix with magnetic particles. This results in a material that can mechanically deform when exposed to a magnetic field (H), termed magnetoaction. The focus of this research was on tuning (1) the type of magnetic particle and (2) the percent-by-volume of magnetic particles in magnetic elastomer 3D printer filament and printed samples. Different types of magnetic particles yield better deflection, some yield better twisting, and some respond at a lower magnetic field. Another factor that needed to be kept in mind was the stiffness increased as the percentage of magnetic particles by volume increased. The 3D printer filament was made by utilizing solvent casting to dissolve TPU pellets to then be able to mix in the desired mixture of magnetic particles. Either solely hard magnetic particles or a combination of hard (permanent) and soft (impermanent) magnetic particles was used in the filament's composition. Strontium ferrite (SrF) and magnetite (Fe_3O_4) were the magnetic particles used. Fe_3O was used for its high magnetic susceptibility and the SrF was used because of its hard magnetic property, which allows the printed sample to exhibit complex motion. The resulting sheets from solvent casting were cut into strips that were then put through a filament extruder. The annealed filament was put through an apparatus that applied a magnetic field as the filament was cooled to preferentially align the magnetic moments. The filament was used to 3D print samples by way of fused deposition modeling (FDM) 3D printing. The magnetoactive properties of the filament and printed samples (rectangular beams) were tested by suspending samples in a magnetic field (H) of up to 0.4T. Digital images were taken at set field intervals and then later put into a custom MATLAB program to measure the deflection angle for both the filament and printed samples and the twisting angle for just the printed samples. Complex motion was observed in the printed and filament samples as a result of the hard magnetic particles. The twisting angle was only recorded for the printed samples due to the difficult nature of measuring the angle of twist for the filament. For this research, a combined percent by volume of 20-25% of magnetic particles were used. It was observed that the magneto action decreased as the percent by volume of magnetic particles increased, and that was due to the increased stiffness of the composite from more magnetic particles. Furthermore, proper dispersion of the particles was verified using scanning electron microscopy (SEM). The combination of Fe_3O and SrF did not yield the results that were expected for magneto action. It was expected that the mixture of Fe_3O and SrF would yield a magnetic elastomer that would yield high deflection at lower fields and would also allow for twisting. However, the deflection for the mixture of two types of magnetic particles was even less than it was for only SrF (hard magnetic particle).

5:00 PM SF04.03.12
Uniform Gallium Microgranules-Based Adaptive Electronic Skin for Advanced Pressure Sensing Beyond Human Touch Perception Simok Lee[1], Sang-Hyuk Byun[1], Steve Park[1,2], Joo Yong Sim[3] and Jae-Woong Jeong[1,2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]KAIST Institute for Health Science and Technology (KIHST), Korea (the Republic of); [3]Sookmyung Women's University, Korea (the Republic of)

Human skin exhibits excellent pressure sensing capabilities, including high sensitivity and wide detection bandwidth. Through these strengths, it can adaptively detect external mechanical forces, ranging from delicate touches to heavy loads. Electronic skin which mimics pressure sensing ability of the human skin can bring a huge impact in numerous fields, such as medical devices, robotics, prosthetics, and human-machine interfaces. However, the current technology is limited due to the trade-off between sensitivity and bandwidth, allowing only a single aspect of sensing performances – that is, either high sensitivity or large bandwidth. Furthermore, the invariant nature of the sensing properties of the electronic skin restricts their applications to the original target uses.
Herein, we introduce an adaptive electronic skin that overcomes the above limitations of existing electronic skin, showing advanced pressure sensing beyond human touch perception. The adaptive electronic skin is built with arrays of tunable pressure sensors based on gallium microgranules embedded in the elastomer matrix. Gallium microgranules undergo the phase shift between the liquid-solid phase through the temperature change, which allows the mode conversion of the pressure sensor between the high-sensitivity mode (soft mode) and the wide-bandwidth mode (rigid mode). The mode conversion allows the pressure sensor to measure pressure from a minimum of 3 Pa in the high-sensitivity mode to a maximum of 1.45 MPa in the wide-bandwidth mode. Considering that the detection range of human skin is from 100 Pa to 400 kPa, our tunable pressure sensor has 97 % higher sensitivity and 262.5 % wider detection bandwidth compared to human skin. We expanded our pressure sensors into large-area sensor arrays to develop an adaptive electronic skin and investigated its practicality in real-life applications ranging from measuring sophisticated blood pressure to measuring body weight. Successful demonstrations of this technology show the great potential of the adaptive electronic skin for robotics, bionics, and health monitoring.

5:00 PM SF04.03.13
Repurposing of Industrial Polymer Waste into Sustainable Built Environment Application and Its Characterization Hengky Chang, See Ying Isabel Ong, Kowee Stanley Luar and Jiale Chew; Nanyang Polytechnic, Singapore

This is a collaboration project between Dow Pacific (Singapore) Pte ltd and Nanyang Polytechnic. Dow is one of the largest acrylic co-polymer producers in the world for use in various coatings, adhesives, and other construction materials. As part of the polymerization process in the plant, certain quantities of polymer solids end up in wastewater tank from clean-up and other related plant processes. The polymer solids are then filtered out before the wastewater is further processed in wastewater treatment facility. Collected acrylic polymer waste was pressed to remove water to form polymer cakes with moisture of less than 10% are disposed which eventually ends up in land fill or sometimes used for waste-to-energy generation. However, in consideration for the contribution towards economic benefit and sustainability, there is a need to find alternative commercial usage to this waste polymer waste cake, such as in the built environment or construction industry, in concrete application for instance.

The utilization of a large amount of waste in concrete production is considered the best alternative for solving the issues associated with improper disposal.

Polymer waste is considered as one of such waste and could be utilized in several applications. The drawback associated with the utilization of a large amount of polymer waste is the decrease in the mechanical properties of the mortar or concrete. The purpose of this project is to study how to repurpose the acrylic polymer waste in short form Polycake waste in the construction material with the main focus on replacing sand in mortar mixture with polycake waste.

In order to achieve the above purposes, firstly it will be the processing of the chunky polycake sample through freezing drying process, it turns into a powdered form which makes it easier to be used as a premix formula in the mortar mixture. After processing the polycake into the powdered form, it is being analysed using various method. The powdered polycake waste sample was initially analysed using scanning electron microscope to observe the powdered polycake sample particle size. It is found that the size distribution of the powdered polycake is very wide and hence need to standardize the size of the polycake particle through sieving.

The powdered polycake waste sample's elemental composition was analysed using X-ray fluorescence, to analyse the chemical composition to ascertain that the chemical composition remains similar to original acrylic polymer after processing it into powder form, and to detect if there is any traces of chemical contaminant of the polycake waste.

The powdered polycake sample's moisture level is tested using thermogravimeter analyzer. This is to ensure the method used to process the powdered polycake sample has a moisture level of less than 5%. The powdered polycake sample's thermal transition would be tested using differential scanning calorimeter. This is to find out the melting point and degradation of the polycake sample.

Next stage is to blend the powdered polycake waste into the mortar mixture to see if it affects the mechanical properties such as compression and flexural strength of the mortar mixture as well as porosity test and water absorption. The flowability of the mortar mixture blended with powdered polycake waste before curing was also analysed and measured using flow table device and viscometer. This is to ensure the mortar that was blended with powdered polycake waste has the same flow property with original standard mortar. This will affect the applicability by the construction worker in applying the modified mortar. Hence, before the powdered polycake waste was added into mortar, the control mortar formulation is needed. The strongest mortar ratio by far would be cement (5): water (4.8): sand (15), which is then used as a control for the study involving powdered polycake to replace a percentage of sand in the mortar mixture starting from 5% to 25% with 5% increment interval.

Effect of Surface Organ-Silanization on SBA-15 Mesoporous Silicas in CO2 Adsorption Precesses—Design, Synthesis and Computational Studies
Eduardo Cueto Diaz[1], Fabián Suárez García[2], Santos Galvez Martinez[1], Eva Mateo Marti[1], Alberto Castro Muñiz[2], María Pilar Valles Gonzalez[3] and María Carmen Torquemada Vico[1]; [1]Instituto Nacional de Técnica Aeroespacial, Spain; [2]Instituto de Ciencia y Tecnología del Carbono, Spain; [3]Instituto Nacional de Tecnica Aeroespacial, Spain

CO$_2$ presents a very unique property among other gases as it absorbs and re-emits IR radiation becoming the most prominent physical driver of climate change together with methane. It has been stablished that the current concentration of CO$_2$ in Earth atmosphere is close to 412 parts per million (ppm), representing a 47% increase since the beginning of the Industrial Age, which may lead in the future to not only an alarming increase in Earth's temperature, but also it could provoke serious health problems if the concentrations exceed 5,000 ppm. As a result of these problems, sensing, monitoring, and ultimately capturing CO$_2$ is of great interest.
The conventional CO$_2$ sensor devices, mostly based on solid-state electrolytes and metal oxides, inevitably show huge cross-sensitivity to other gases and suffer from several other limitations, such as higher cost, heavier weight, less durability, and bigger size; thus, to enable the widespread adoption of CO$_2$ sensing materials in many aspects of modern society, two major requisites are needed, i) their inexpensive mass production and ii) ultralow power demand, as well as overcoming the previously mentioned limitations. As an alternative to these traditional sensing devices, nanomaterial-based sensing machinery are gaining widespread popularity owing to their long-term durability in harsh conditions, low-cost and reduce size properties. However, nano-sensing devices still face certain challenges to fulfill the diverse sensing demands. For example, cross-sensitivity with other gases at high temperatures is still challenging (1) and the production of uniform modified areas in the nanomaterial is problematic.
In the present work, these two major drawbacks have been partially overcome, by building CO$_2$ sensing artifacts following two premises; first, it was carried out the homogeneous surface deposition of nanoparticle (SiO$_2$) monolayers over metallic wafers(2)(3) and secondly, we have implemented a robust protocol for the organic-ligand decoration of silica-based nanomaterials displaying two different morphologies 1) nanospheres(4) and 2) interconnected rod-like.(5) The production of well-ordered and densely packed silica-nanoparticle monolayers was conducted by the chemical modification of gold wafers with 3-mercaptopropyl triethoxysilane groups, allowing the organization of 3D nanospheres in a well-ordered fashion. The total CO$_2$ adsorption capacities of silica-based nanomaterials ranges from 0.9 – 1.7 mmol * g-1 at 25°C, as a function of their morphology and their organic-ligand coating. The absorption selectivity factor (*S*) was also studied in the nanospherical SiO$_2$ nanoparticles, showing remarkable adsorption selectivities of CO$_2$ over N$_2$ >70 matching and even surpassing other solid sorbents designed for the separation of binary mixture of gases. Furthermore, it was demonstrated their high sensitivity towards CO$_2$ at low concentrations (12.4 ppm) using numerous material characterization techniques (XPS, FTIR and UV-Vis spectroscopies, SEM microscopy, etc.). Thus, we expect that the high modulability of silica-based nanomaterials, could open new routes in the development of CO$_2$ chemical sensor and capture devices, under conditions similar to the real indoor environments but also in fields that require sensing at low pressures (planetary environments, enclosed spaces, etc.).

Abstract Presented (ON-DEMAND ONLY) Design of Solar-Driven Self-Cleaning and Antimicrobial Magnesium Oxychloride Cement Panels Luis

F. Rodríguez Alfaro[1], Edith Luévano-Hipólito[1] and Leticia M. Torres-Martínez[2]; [1]Instituto de Ingeniería Civil, UANL, Mexico; [2]Centro de Investigación en Materiales Avanzados, CIMAV, Mexico

In recent years, the use of smart construction materials with photocatalytic activity has emerged as a new alternative technology that can help mitigate air pollution, dirtiness, and the growth of pathogenic microorganisms on building surfaces. The growing interest in this type of material and the promising results obtained in both laboratory and outdoor conditions have encouraged the design and commercialization of different types of building materials on market. Among them, photocatalyst cement as a smart building material has become one of the most popular and used to be applied outdoors as a technological strategy to reduce environmental pollution. This kind of special cement is fabricated when a nanoparticulate photocatalyst is incorporated and mixed into a cementitious matrix, causing this material acquires self-cleaning and antimicrobial activity, as well as air-purifying capacity. However, most of them have been made with ordinary Portland cement (OPC) which is known leaves severe damage to the environment during its production (4.6 billion tons of CO_2 are emitted into the atmosphere annually). For this reason, magnesium oxychloride cement (MOC) is proposed in this study as an alternative material to OPC, as it is considered a more environmentally friendly and eco-efficient material, besides having a more attractive marble-like appearance. The titanium dioxide (TiO_2) nanoparticles were used as photocatalysts to functionalize the MOC cement and to explore for the first time the self-cleaning and antimicrobial activity in this kind of cement. Different prototypes of MOC functionalized with TiO_2 were fabricated and characterized by various analytical techniques such as XRD, FTIR, SEM, EDS, UV-Vis, compressive strength, and nanoindentation tests. Preliminary results indicated that the amount of TiO_2 nanoparticles did not influence MOC samples' composition, morphology, or bandgap energy. Results showed good self-cleaning efficiencies upon 75% in the first 3 h under solar radiation and ~85% in the accelerated weathering chamber. It was noted that the manufactured MOC prototypes showed great photocatalytic stability in the accelerated weathering tests throughout the evaluation time, which suggests good durability over the operation period. On the other hand, the antimicrobial activity was performed against *E. coli* (gram-negative) under artificial visible light. The zone of inhibition (ZOI) showed diameters higher than 21 mm to *E. coli* for samples with 5% of TiO_2 or superior, revealing a high microbial inhibition of the gram-negative bacteria. These results demonstrated that the MOC cement functionalized with TiO_2 nanoparticles has the potential to be applied as self-cleaning and antimicrobial smart materials in outdoor conditions and to contribute to a sustainable environment.

SYMPOSIUM

April 10 - April 26, 2023

SESSION SF05.01: Particle Aggregation I
Session Chairs: Qian Chen and Xin Zhang
Monday Morning, April 10, 2023
Moscone West, Level 3, Room 3012

8:00 AM SF05.01.01
Multi-Component Plasmonic Nanocrystal Gel Assemblies with Thermoreversible Links Jiho Kang, Zachary M. Sherman, Hannah S. Crory, Diana L. Conrad, Marina W. Berry, Benjamin J. Roman, Eric V. Anslyn, Thomas M. Truskett and Delia Milliron; The University of Texas at Austin, United States

Colloidal inorganic nanocrystals (NCs) can display unique properties, such as localized surface plasmon resonance (LSPR), that can be synthetically controlled by their elemental composition, size, and shape. Gelation offers an opportunity to exploit not only the distinct properties of individual NCs but their structure-dependent collective properties. With molecular linkers that can form dynamic covalent bonds, reversible NC gelation can be realized under conditions based on thermodynamic principles, opening door to responsive, tunable functional materials. Recently, we introduced thermoreversible NC gel assemblies using a metal coordination linkage, of which spectroscopic signal enabled in situ quantification of the linking and provided microscopic insights

for gelation. Plasmonic coupling between linked tin-doped indium oxide NCs led to abrupt, yet reversible, infrared absorption shifts at a chemically tunable gelation.
The characteristics of NC assemblies can be tuned in a broader range when two or more distinct components are incorporated into NC networks. Here, we demonstrate randomly-mixed multi-component NC gel assemblies using thermoresponsive metal coordination linkage. Tin-doped indium oxide NCs with different sizes, doping concentrations, and shapes are reliably intermixed in linked gel assemblies, exhibiting collective LSPR response that reflects the contributions of each component while also deviating systematically from expectations based on simple linear mixing. We extend a many-bodied, mutual polarization method to simulate the infrared response of mixed NC gel assemblies, reproducing the experimental trends with no free parameters and revealing that spectral deviations originate from cross-coupling between distinct plasmonic components. Our gelation strategy using thermoreversible metal coordination links enables the modular incorporation of NCs regardless of their doping concentration, size, and shape, giving access to continuously tunable far- and near-field optical properties that are distinct from those of the constituent building blocks or mixed close-packed structures.

8:15 AM SF05.01.02
Engineering Self-Assembly of Nanoparticles into Chiral Superlattices Using Liquid-Phase TEM Jiahui Li[1], Shan Zhou[1], Jun Lu[2], Chang Liu[1], Chang Qian[1], Nicholas A. Kotov[2] and Qian Chen[1]; [1]University of Illinois, Champaign-Urbana, United States; [2]University of Michigan, United States

Achieving chiral nanomaterials from nanoparticle self-assembly has attracted increasing attention due to their strong chiroptical activity and wide range of potential applications. Therefore, understanding the formation pathway at nanoscale is essential for precise chiral nanomaterial fabrication and engineering. Here, by using liquid-phase transmission electron microscopy (TEM) and theoretical interaction calculations based on coarse-grained models, we study the dynamics of chiral pinwheel superlattices formed by achiral tetrahedral gold nanoparticle self-assembly in solution. We show rapid nucleation and growth of low-density tetrahedral bilayer lattices from single particles. Chiral pinwheel superlattices 'compressed' from the low-density state at nanometer precision is experimentally realized by harnessing the energetics. Furthermore, diverse superstructures with variable domain sizes are achieved by engineering interparticle interactions and particle-substrate interactions simultaneously in real-time. Our study proposes a simple and versatile strategy to manufacture chiral and responsive nanomaterials based on the rich library of nanoparticles with unique optical, mechanical, and electronical properties.

8:30 AM *SF05.01.03
Colloidal Nanoparticle Assemblies—Templating Electropolymerizations, Brushes and Viruses Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

Understanding self-assembly in nanomaterials requires hierarchical levels of ordering and structuring: from molecular to macroscopic. Perfect colloidal spheres are able to pack and pattern as thin films, enabling surface assemblies amenable for templating properties that lead to function: from lithographic to non-lithographic methods. Thse layered ordered systems can result in new material stimuli-responsive properties. This talk will highlight the colloidal nanosphere lithography and non-lithographic approaches used by our group to produce systems that include: 1) conjugated polymers, 2) electropolymerized molecularly imprinted sensors, 3) electronanopatterning, 4) polymer brush lithography, and 5) patterned virus assemblies. Novel surface-sensitive spectroscopic and microscopic analytical tools are applied rationally to highlight evidence of order and function. This enables platforms for developing practical devices on electrode surfaces, e.g. sensors and battery electrodes.

9:00 AM SF05.01.04
Engineering the Assembly Pathway of DNA Origami Crystals Daniel C. Redeker[1], Jason S. Kahn[2], Brian Minevich[1], Aaron Michelson[2] and Oleg Gang[1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States

DNA-guided nanoparticle self-assembly has emerged as a promising method to form designable and ordered 3D nanomaterials. However, the isotropic nature of interactions of spherical nanoparticle makes it difficult to form designed structures. In contrast, DNA origami polyhedron frames loaded with nanoparticles can be assembled to form diverse crystal symmetries through the use of directional bonds. Specifically, the directionality of interactions is provided through origami shape and placement of addressable bonds, while the specific DNA sequences prescribe interaction addressability. Recently, an inverse design approach has been developed by our group to form a variety of arbitrary crystal structures from octahedral origami by using different addressable bonds to promote a desired crystal symmetry. However, the assembly pathway plays an important role in structure formation. We investigated how the self-assembly pathway can be controlled through modulating the relative binding energies of DNA mediated interactions. In this work, the assembly of DNA origami octahedral frames with two unique interaction types with varied relative binding energies was studied. Through a combination of small angle x-ray scattering (SAXS) and scanning electron microscopy, we demonstrate that while the local crystal structure is preserved, the long-range crystal order and morphology of the assembled crystal is strongly affected by the relative binding energies and coordination of addressable DNA interactions. We further apply these findings to tune the assembly pathway and promote the formation of a desired crystal structure and morphology.

9:15 AM SF05.01.05
Virus-Based Biomimetic Collagen Supramolecular Structure and Function Inseok Chae[1,2], Woo-Jae Chung[1,3] and Seung-Wuk Lee[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Sungkyunkwan University, Korea (the Republic of)

Collagen is a major component of the extracellular matrix and serves as a scaffold for the growth of minerals and cells in our body. As secreted from osteoblast cells, collagen triple helices spontaneously form a supramolecular structure, mostly fibrils and interact with other constituents in connective tissues from nano- to macroscopic length scales. Various materials were reported to mimic the hierarchical structure and function of collagen; however, creating a higher-order supramolecular collagen-like structure is still challenging. Here we develop a bio-mimetic approach to create the hierarchical collagen-like structure and biological function using M13 bacteriophage (phage). Through phage display – a high-throughput screening process, we identified a new phage engineered with a collagen-like peptide that can strongly bind to bone hydroxyapatite crystals, termed as a collagen-like phage. We then exploit the collagen-like phage to develop bone-tissue like hierarchical structures and tissue functions. Using a self-templating assembly process, we show the collagen-like phage can self-assemble supramolecular structures with a smectic periodic band and quasi-hexagonal packed crystalline ordered structure. The resulting self-assembled structures can direct biomineralization and guide directional growth of cells. Our new approach to develop biomimetic materials will be broadly used for other materials to create a hierarchically organized structure and desired function.

9:30 AM *SF05.01.06
Desirable Nanomaterials through Programmable Assembly and Prescribed Transformations Oleg Gang; Columbia University/Brookhaven National Laboratory, United States

The ability to organize diverse types of functional nanocomponents into the targeted 3D architectures can enable a broad range of nanotechnological applications, from new classes of engineered biomaterials to photonic devices. However, the current top-down methods are limited in their ability to create 3D nanostructures with prescribed architectures and an integration of different types of nanocomponents, while the typical bottom-up methods do not provide a flexibility of a system design. The talk will present our progress in establishing a self-assembly platform for the fabrication of designed large-scale and finite-size nano-architectures from diverse inorganic and biomolecular nanocomponents through the DNA-programmable assembly. The recent advances in creating periodic and hierarchical organizations from inorganic nanoparticles and proteins will be presented. The formed nanostructures can be farther transformed into fully inorganic 3D replica of different materials via nano-templating. The developed assembly approaches were applied to demonstrate a fabrication of functional nanomaterials with nano-optical, electrical, mechanical, and biochemical functions. Finally, the progress for creating reconfigurable nanomaterials with well-defined switchable states will be presented.

10:00 AM BREAK

10:30 AM SF05.01.07
Graph Theoretical Engineering of Self-Assembled Biomimetic Nanocomposites Nicholas A. Kotov; University of Michigan, United States

Biomimetic nanocomposites address the critical bottlenecks of modern technologies from energy storage to wearable devices because they combine multiple application-critical properties that were not available in materials before, exemplified by hard to reach combinations of mechanical toughness, electrical conductivity, optical transparency, and biological compatibility, while being structurally versatile and resource conscious. Their design is however slow and empirical. Since Leonardo Da Vinci engineering of biomimetic materials was based on replication of the geometry of molecules, tissues, and organisms found in biology using non-biological preparatory techniques. It is possible to transition from inexact approach of good-luck-based engineering of nanocomposites to purpose-driven biomimetic materials design using graph theoretical (GT) methodology. Furthermore, GT-based engineering enables one to transition from simple nanocomposites to those with complex multiscale architecture. The organization of biomimetic materials and structures was developed to assess complexity of self-assembled nanostructured particles. It was concomitantly extended to the composites from aramid nanofibers (ANFs) and nanoparticle-based gels. It was shown that mechanical, ion- and charge transport characteristics of these materials are directly related to GT-based structural parameters. Increase of complexity can be paralleled with the increase of combinations of different properties that require multiscale hierarchical organization, which will be established analyzing load-bearing and functional nanocomposites of iconic biomimetic nanocomposites, such as nacre and cartilage. Applications of biomimetic composites for energy, biomedical, and optoelectronic applications batteries will be discussed with particular emphasis for their implementation in energy technologies.

10:45 AM SF05.01.08
Controlling Phases of Isotropic DNA-Grafted Nanoparticle Assembly through Tuning Pair Interactions Daniel McKeen[1], Brian Minevich[1], Runfang Mao[2], Qizan Chen[3], Jeetain Mittal[3] and Oleg Gang[1,4]; [1]Columbia University, United States; [2]Lehigh University, United States; [3]Texas A&M University, United States; [4]Brookhaven National Laboratory, United States

It has been predicted theoretically that isotropic pair potentials with complex shapes can yield targeted lattice organizations, but due to limited experimental implementation methods to engineer pair potentials, realization of such predictions remains challenging. Nanoparticle-grafted DNA shells can direct self-assembly in a tailorable manner by leveraging complementary base pairing and repulsive polymeric effects, presenting a material well-suited to encoding designed pair potentials. We utilize two DNA-grafted nanoparticle types that are independently functionalized with a unique linker to tune the potential through DNA motif design; these linkers have a non-complementary spacer and a hybridization sequence for pairing with complementary motifs on the other particle. Complementary motifs drive attraction causing DNA shells to hybridize at an encoded distance prescribed by shell length and location of the complementary motif. Non-complementary motifs define particle repulsion, the range of which is prescribed by shell length alone. Computational simulations show that isotropic pair potentials are effectively approximated by the ratio of repulsion and attraction ranges. By fixing either linker length or hybridization regime location and altering the other, we experimentally explored a range of ratios. We observed, using small-angle x-ray scattering, structural evolution from body-centered cubic to simple cubic crystals to weakly ordered cubic diamond-like networks as a function of increasing ratio of repulsion to attraction ranges.

11:00 AM SF05.01.09
Biomimetic Control of Sequence-Defined Peptoids Over Ag Nanocrystal Formation and Anisotropic Self-Assembly Biao Jin[1], Emtias Chowdhury[1], Feng Yan[1], Xin Qi[2], Lili Liu[1], Jim Pfaendtner[2], James J. De Yoreo[1] and Chun-Long Chen[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

Controlling the stability and assembly of plasmonic nanoparticles through biomimetic strategies has significant potential for both advancing the fundamental science of biomimetic synthesis and developing functional applications. However, achieving such control remains a great challenge due to a lack of readily programable ligands and limited mechanistic understanding. Here we demonstrate that sequence-defined peptoids, which serve as capping and structure-directing agents, can drive cooperative formation and self-assembly of ~ 2-3 nm Ag nanocrystals (NCs) into nanoribbons in a template-free manner through a two-step process comprised of i) formation of Ag NCs with a ~1.8 nm thick surface-adsorbed peptoid layer, followed by ii) peptoid-driven anisotropic assembly of the Ag NCs. By examining the effects of peptoid side chain chemistry and varying reaction conditions, and comparing the results to computational simulations, we conclude that: 1) the stability of Ag NCs is attributable to the stronger interactions with peptoids than peptoid-peptoid interactions, and 2) self-assembly is initiated by the reorganization of the hydrophobic tails of peptoid ligands to achieve the typical pi-pi stacking seen in 2D sheets formed from similar peptoids in the absence of Ag NCs. The self-assembly behavior of peptoid-stabilized NCs can be rationalized based on the simulation results, which predict that attractive hydrophobic inter-peptoid interactions drive the approach of neighboring Ag NCs and the subsequent reorganization of the peptoids ligands. This work provides insight into how peptoids can be programmed to control both inorganic nanomaterials formation and self-assembly into hierarchical nanostructures, offering a new strategy for the design and synthesis of functional materials.

11:15 AM SF05.01.10
Enantioselective Polymerization on Chiral Nanoparticles Ji-Young Kim[1], Wonji Lee[2], Zhi-bei Qu[3], Chung Man Lim[1], Sangho Cha[2] and Nicholas A. Kotov[1]; [1]University of Michigan, United States; [2]Kyonggi University, Korea (the Republic of); [3]Fudan University, China

Chiral materials constructed using chiral helical polymers (CHPs) are especially interesting, which can be described as biomimetics of natural helical biomacromolecules. CHP materials can be directly constructed from chiral monomers. This approach, however, shows some disadvantages because of the limited variety and number of easily available chiral monomers. To overcome the limitations, many powerful methodologies have been established to prepare CHPs starting from achiral monomers; However, it either requires toxic transition-metal catalysts or suffers from lower regioselectivity. Here, we report helical polymerization of achiral monomers using chiral ceramic nanoparticle (NP) as asymmetric catalyst. The tungsten oxide NP with the chirality of the metal oxide core, with an average size of ca. 1.6 nm, is imparted by aspartic acid ligands via bio-to-nano chirality transfer. The prepared chiral tungsten oxide NPs initiate the stereoregular polymerization of various monomers while their chiral surface provides the chiral bias, resulting the helical conformation of polymers. Depending on handedness of NP used, the resulted NP-polymer composites showed the mirrored spectra for their optical and vibrational circular dichroism. The density functional theory (DFT) calculation also supports that the rotational direction of resulted helical polymer were determined by the handedness of NPs used as the absorption energy of the chiral dimer showed specific enantiopreference on the NP surface. Since the NP played role as not only initiator but also cross-linker of the polymer matrix, the resulted composite structure has more uniformity of NP distribution, enhancing mechanical properties compared to one of simple mixing composite. More importantly, the NP-initiated composites show facinating enantioselective mechanical properties; The stiffness and hardness of composite with complex chirality driven by mixture of L- and D- NPs are up to one order of magnitude higher than the one of composite with homo chirality prepared by pure L- or D- NPs. The reported NP-initiated chiral NP-polymer composites can be used for various applications that needs soft composite with unique chiroptical and strong mechanical properties.

11:30 AM SF05.01.11
Controlling Macroscale Morphology in DNA-Based Assembly Using Acoustic Energy Zohar A. Arnon[1], Silvia Piperno[2], Ornit Nagler Avramovitz[2], Ewelina Randall[1], Hagay Shpaisman[2] and Oleg Gang[1]; [1]Columbia University, United States; [2]Bar-Ilan University, Israel

One of the main challenges of developing bottom-up designed materials is the issue of scaling their formation and shaping them into a desired morphology. A high degree of nanoscale control hinders the ability to form nanomaterials with predefined macroscale morphology. DNA nanotechnology allows accurate spatial control at the nanoscale which enables fabrication of intricate organizations; yet, structural arrangement at the macroscales remains a challenge. We developed an assembly approach driven by acoustic waves in order to control the morphology of DNA-assembled materials at the scales from tens of microns to millimeters, thus complementing a nanoscale assembly regime offered by DNA-guided methods. Specifically, we explored the use of standing surface acoustic waves (SSAW) to direct assembly and control morphology of DNA origami based crystal lattices. By controlling both acoustic forces and temperature, we investigated the assembly process at different scales by a combination of optical microscopy, small-angle x-ray scattering and electron microscopy techniques. We further studied the annealing, crystal fusion and disassembly under different SSAW conditions. The developed approach allows to form macroscale nanomaterials with prescribed morphology, as defined by the acoustic field, while their nanoscale organization is programmed by DNA. The presented approach is further enhanced by microfluidics through a combination of a flow and SSAW for achieving morphology control. Once the morphology is realized, cross-linking of the formed structure is induced, resulting in fixation of the formed macroscale morphology with DNA-prescribed nanoscale structure.

11:45 AM SF05.01.12
Encoding Lattice Symmetry of Nanoparticle Self-Assembly through Programmable Valences Honghu Zhang[1,1], Sha Sun[1,2], Shih-Ting Wang[1], Dmytro Nykypanchuk[1], Yugang Zhang[1], Alexei Tkachenko[1] and Oleg Gang[1,3,3]; [1]Brookhaven National Laboratory, United States; [2]Xi'an Jiaotong University, China; [3]Columbia University, United States

In atomic and molecular systems, directional interactions, as defined by a valence, guide formation of complexly organized lattice structures. Translating the idea of valence-driven interactions to nanoparticle systems would open great opportunity of controlling material fabrications through self-assembly. However, understanding the relationships between directional interactions and the resultant phases and packing structures remains a nontrivial fundamental problem. Here, we present a study of binary self-assembly system built from nano-objects with directional interactions, valence-programmable DNA mesh balls, and with isotropic interactions, inorganic nanoparticles. Our study reveals that controllable phase behaviors can be achieved by tailoring interactions through valence modes and size ratios between DNA mesh balls and nanoparticles. By prescribing 8 different valence modes for mesh balls, we have observed assembly of 2D and 3D crystalline phases with distinct crystallographic symmetries, as uncovered by *in situ* small-angle X-ray scattering. We have established a theoretical framework based on thermodynamics and geometric constrains that explains the discovered self-assembly behavior for the presented binary system with directional and isotropic interactions. Our combined experimental and theoretical work provides a roadmap for rational design of complex self-assembled structures through bonds engineering.

SESSION SF05.02: Aggregation-Induced Emission (AIE) and Molecule Self-Assembly I
Session Chairs: Sijie Chen and Ben Zhong Tang
Monday Afternoon, April 10, 2023
Moscone West, Level 3, Room 3012

1:30 PM *SF05.02.01
Accelerating Biomedical Research through Materials Innovation Bin Liu[1,1,2]; [1]National University of Singapore, Singapore; [2]International Campus of Tianjin University, China

The recent years have witnessed the fast grow of fluorogens with aggregation-induced emission characteristics (AIEgens) in biomedical research. The weak emission of AIEgens as molecular species and their bright luminescence as nanoscopic aggregates distinguish them from conventional organic luminophores and inorganic nanoparticles, making them wonderful candidates for many high-tech applications. In this talk, we summarize our recent AIE work in the development of new fluorescent bioprobes for biosensing and imaging. The simple design and fluorescence turn-on feature of the molecular AIE bioprobes offer direct visualization of specific analytes and biological processes in aqueous media with higher sensitivity and better accuracy than traditional fluorescence turn-off probes. The AIE dot probes with different formulations and surface functionalities show advanced features over quantum dots and small molecule dyes in noninvasive cancer cell detection, long term cell tracing, and vascular imaging. In addition, our recent discovery that AIEgens with high brightness and efficient reactive oxygen species generation in aggregate state further expanded their applications to image-guided cancer surgery and therapy. Recently, we combined accurate prediction of material performance via first-principle calculations and Bayesian optimization-based active learning to realize a self-improving discovery system for high-performance photosensitizers, which can significantly accelerate the materials innovation for biomedical research.

2:00 PM SF05.02.02
Clickable Hydrogels of Cholesteryl Hyaluronic Acid with Tunable Amphiphilicity and Physical Crosslinking for Drug Delivery and Tissue Engineering Shing-Yun Chang and Jie Song; University of Massachusetts Chan Medical School, United States

Synthesis of amphiphilic biopolymers has recently attracted attentions due to their potential for delivering a broad range of biotherapeutics including cells and hydrophobic drugs, as well as dynamic biophysical properties enabled by the conformational changes driven by hydrophobic-hydrophobic interactions. Hyaluronic acid (HA), as one of the major extracellular matrix components in native tissues, plays size-dependent, multifaceted roles in defining a wide range of biological activities. Although HA has long been exploited for regenerative medicine applications due to its excellent cyto- and bio-compatibility, its capacity as a versatile drug delivery carrier remains fully explored.

In this study, HA was chemically modified with cholesterol, a critical hydrophobic cell membrane component known for excellent cell permeability, via copper-free, strain-promoted azide-alkyne cycloaddition (SPAAC) "Click" chemistry. Specifically, azide and dibenzocyclooctyne (DBCO) were first conjugated to HA and cholesterol, respectively, as biorthogonal functional groups. The degree of azidation was restricted to <10% by design to retain core properties of HA. A range of cholesteryl HA was prepared by stoichiometric SPAAC, which exhibited cholesterol content-dependent morphologies. We found that, the cholesteryl HA with higher cholesterol contents spontaneously formed nanoparticles (NP) in aqueous media, with their negative surface charges supporting a cholesteryl core-HA shell configuration. Hydrophoblic drug loading capacity of the NP was visualized by fluorescent hydrophobic dyes. The cholesteryl HA with low cholesterol contents remained as extended polymers where their associated cholesterol units helped form hydrophobic domains within the 3D amphiphilic HA network. Acting as physical crosslinkers, the very low amount of robust cholesterol-cholesterol interactions was enough to significantly enhance the viscosity of HA. For skeletal tissue regeneration applications, the potential of the resulting amphiphilic polymers for sustained drug/biologics release and potential as cellular niches are being examined.

2:15 PM SF05.02.03

Structural Characterization of 5-fluorouracil in the Self-Assembly of the Pluronic Biomedical Hydrogels for Prolonged Drug Release Tz-Feng Lin, Xin-Yu Zeng, Pei-Jung Shih and Wei-Chieh Wang; Feng Chia University, Taiwan

Chemotherapy is the medical treatment for human cancer through intravenous injection or oral administration. However, high dosage of chemotherapeutic drugs was required to de delivered to the malignant tumor. In recent years, the use of polymer composites for local and sustained drug release has become leading research to carry chemotherapeutic drugs without concentrated dosage. Pluronic biomedical hydrogels (PBHs) was proposed to be deployed on the tumor site for precision medicine as a targeted delivery for clinical and practical applications. PBHs also served as a microenvironment and a drug delivery system offering many attractive benefits such as intrinsic biocompatibility, ease of preparation, scalable production. Binary blending of biocompatible Pluronic® F127 and Pluronic® L121 is the main ingredient in the PBHs. Based on the same formulation, the addition sequence of fluorouracil (5-FU) was deployed in three ways when it was individually incorporated with F127-(5-FU), L121-(5-FU), as well as the binary mixing F127-L121-(5-FU).

Small angle X-ray scattering (SAXS) and 19F-{1H} heteronuclear Overhauser enhancement spectroscopy (HOESY) was used to discover the self-assembled structures of the PBHs. According to the SAXS results, structural changes of the micelle and the lamellar affected the distribution of 5-FU. F127-L121-(5-FU) has the fastest drug release rate owing to the undulated amphiphilic boundary. In contrast, L121-(5-FU) has a prolonged drug release rate at 67% for one month of the continuous drug release experiment because the flat lamellar amphiphilic boundary which slows the migration of 5-FU from the hydrophobic core.

Further, HOESY was used to study the micellular environment of the F-containing chemotherapeutic drug 5-FU in PBHs. Results show that the diffusion of the 5-FU medicine in the Pluronic micelles will move across the interface between the hydrophilic corona and the hydrophobic core with respect to elevated temperatures. At 25 °C, the drug loading location of the 5-FU medicine is dominated by PEO segments. As the temperature increases from 25 to 45 °C, the 5-FU medicine migrates aggressively to the hydrophobic core inside the micelles. The 5-FU medicine was embedded into the PPO segment of Pluronic® polymers above 37 °C as a stable micellization. The precise 5-FU loading in the hydrophobic area gives rise to prolonged and sustained drug release in rountine clinical practice. Thus, the drug loading location and drug–carrier interactions can be designed to deliver drugs at predetermined release rates. The chemotherapeutic drugs of 5-fluorouracil (5-FU) were released from PBHs nearly one month without continuous supplementary.

Also, the inhibition of multidrug resistance was developed in this study. The effective ingredient of L121 inhibited multidrug resistance in human pancreatic cancer and caused the malfunction of the ATP binding cassette subfamily C (ABCC) transporter as evidenced by the flow cytometer studies. PBHs effectively suppresses the function of ABCC transporter up to 25 days. 5-FU can accumulate in the cancer cells of AsPC-1 and PANC-1 at a designated effective concentration. This synergy effect of the continuous drug release of 5-FU and intrinsic cytotoxic effects of L121 could inhibited the function of a multi-drug resistance regarding ABCC transporter. Then, a surgical dressing was prepared by 3D bio-printing technology with PBHs cross-linked by sodium alginate. Results show that the surgical dressing of 24 layers with 10 mm x 10 mm would continuously release 5-FU in effective anticancer concentration for six days. The flexibility of the PBHs makes tailored drug delivery system possible and improve the life quality of patients. Sustained and prolonged drug release and 3D printable surgical dressing was completed.

Assembling Bright Fluorescent Polymeric Nanoparticles for Biosensing and Bioimaging Andrey Klymchenko; University of Strasbourg, France

Dye-loaded fluorescent polymeric nanoparticles (NPs) appear as an attractive alternative to inorganic NPs, such as quantum dots (QDots).[1] Primary requirement for fluorescent NPs in biological applications are their controlled small size and brightness. To obtain small NPs, we introduced a concept of charge-controlled nanoprecipitation of hydrophobic polymers in aqueous media.[2] We found that charged groups in hydrophobic polymers, such as poly(methyl methacrylate), favor formation of NPs with controlled small size down to 7 nm.[3] On the other hand, to ensure high brightness of polymeric NPs, aggregation-caused quenching (ACQ) of dyes should be prevented. To this end, we proposed ionic dye insulation by bulky hydrophobic counterions,[4] which serve as spacers between dyes to block ACQ and favor dye encapsulation inside NPs.[5] As a result, we obtained NPs that are ~100-fold brighter than QDots of similar size.[6] Assembling dyes inside polymeric NPs resulted in giant light-harvesting nanoantenna, where ~10000 encapsulated dyes undergo efficient Förster resonance energy transfer (FRET) to a single acceptor, providing >1000-fold signal amplification (antenna effect).[7] The light-harvesting concept was applied to amplify phosphorescence of porphyrins for ratiometric sensing of oxygen with minimal phototoxicity.[8] Functionalization of these nanoatennas with nucleic acids yielded ultrabright FRET-based nanoprobes for amplified detection of oligonucleotides with single-molecule sensitivity,[9] and compatibility with detection by RGB camera of a smartphone.[10] When applied to cells, the small size of NPs was found essential for their free diffusion in cytosol[3] and for their intracellular delivery by electroporation.[11] Moreover, ultrasmall DNA-NPs enabled RNA detection inside cells by fluorescence in situ hybridization. At the animal level, the high brightness of NPs enabled unprecedented single-particle tracking in the mice brain and visualization of crossing the blood-brain barrier.[12] The developed small dye-loaded polymeric NPs open the route to ultrabright tools for sensing and tracking of biomolecules in biology and medicine.

3:00 PM BREAK

3:30 PM *SF05.02.05
Logical Design for Functional NIR Materials Based on AIE-Active Element-Blocks Kazuo Tanaka; Kyoto University, Japan

Near infrared (NIR)-emissive films have attracted tremendous attention as a versatile platform for realizing future optical technology, such as sensors and organic NIR-luminescent electronic devices. However, due to aggregation-caused quenching (ACQ) caused by non-specific intermolecular interactions in condensed state, it is still difficult to obtain intense solid-state emission from film materials. In particular, since conventional NIR-luminescent dyes have expanded π-conjugated system which are essential for inducing NIR emission, critical intermolecular interactions followed by ACQ are induced in NIR-luminescent dyes. Therefore, it is still challenging to develop organic materials with solid-state luminescent properties in the NIR region. We recently established to narrow energy gaps between frontier molecular orbitals (FMOs) without expanding π-conjugated system. By replacing the skeletal carbon, where only the lowest unoccupied molecular orbital (LUMO) is localized, to nitrogen (aza-substitution), it is possible to selectively lower the energy level of LUMO. Finally, we obtained deep-red and/or NIR-luminescent dyes through the aza-substitution without expanding π-conjugated system. Based on this protocol, we obtained deep red-luminescent AIEgens. In this presentation, the basic concept for obtaining NIR emission with the aza-substitution at the isolated LUMO is initially illustrated. Several examples on the deep-red or NIR-emissive AIEgens are demonstrated based on the aza-substitution at the isolated LUMO position. Finally, we will mention NIR-luminescent materials with solid-state luminescent properties.

4:00 PM SF05.02.06
Self-Assembled Monolayers Functionalized Surfaces for VOC's Detection Mandeep Singh[1,2], Navpreet Kaur[2] and Elisabetta Comini[2]; [1]Politecnico di Milano, Italy; [2]University of Brescia, Italy

Self-assembled monolayer (SAM) functionalized surfaces represent an excellent tool for the performance enhancement and selective detection of different chemical analytes such as biomolecules and gases etc. as they offer unique surface-specific interactions.The ability of SAM to generate different functional groups on a single surface can also be used to immobilize variety of biomolecules. The typical structure of SAM contains head and end groups connected via a backbone (aromatic oligomer or aliphatic chain). The head group is attached to the surface via strong bonds (e.g silanes attachment to oxides surface takes place via formation of siloxane bonds). While, the end groups play an extremely important role as they define the surface functionality and can be used for further functionalization and to detect different analytes via molecular interactions with analytes.
Herein, we are presenting novel SAMs functionalized p-type (NiO) and n-type (ZnO) metal oxides nanowires (NWs) for VOC's detection. In particular, the VLS-grown ZnO and NiO NWs were functionalized with mono and mixed self-assembly of organosilanes ((3-aminopropyl) trimethoxysilane (APTES), 3-glycidoxypropyltrimethoxysilane (GOPS), and tetraethyl orthosilicate (TEOS))) to generate different functional groups. Specifically, via functionalization with mono APTES, GOPS and TEOS monolayers, —NH_2, —epoxy and —CH_3 terminated NWs surfaces were generated. On the other hand, in the case of mixed-SAMs (APTES and TEOS), mixed —NH_2 and —CH_3 terminated ZnO NWs surface was generated. The NWs morphology was assessed using scanning electron microscopy, while the surface chemical properties of SAMs functionalized surfaces were examined via X-Ray photoelectron spectroscopy (XPS). Finally, the set of conductometric sensing devices of these functionalized surfaces were prepared and tested for different gas analytes to explore their sensitivity and selectivity.
Both mono (APTES and TEOS) and mixed-SAMs functionalized ZnO NWs showed highly selective behavior toward acetone due to two phenomena. The first one is the modulation of surface electron density caused by SAMs (affecting the electron depletion layer (EDL) of ZnO NWs). Secondly, the molecular interaction between acetone carbonyl groups (C=O) and terminal groups of both SAMs causes their selective behavior. We also observed that mixed-SAMs are a superior strategy for sensing performance enhancement not only from bare ZnO NWs but also from mono SAM provided suitable mixing ratios were selected.
In the case of p-type NiO NWs, we have used these unique properties of SAM to enhance their sensing performance which remains a huge challenge due to their poor electrical properties. In particular, NiO NWs were functionalized with GOPS to modulate the majority carrier concentration near the surface or in hole accumulation layer (HAL). We have observed that the negatively charged terminal-epoxy groups of GOPS enhance the accumulation of holes near the surface that in-turn increase the electron transfer from reducing gases to NWs. As a result, SAM-functionalized sensors showed 9-times higher response as compared to bare NiO NWs at 200 °C. Interestingly, bare NiO NWs able to achieve comparable response values at 500 °C. Hence, the SAM approach not only improves the performance of NiO NWs sensor but also helps to significantly lower the sensor working temperature.
In conclusion, we showed that the SAM functionalization strategy has the greatest potential to develop future high-performance chemical sensor devices not only for acetone but also for other important analytes such as environmental pollutants.

4:15 PM SF05.02.07
Nanomechanical Behaviour of Self-Assembled Metal-Organic Framework Monoliths and Luminescent Composites Michele Tricarico and Jin-Chong Tan; University of Oxford, United Kingdom

Metal-organic frameworks (MOFs) are multifunctional organic-inorganic porous hybrid materials. They consist of metal ions or clusters coordinated to organic ligands that self-assembly into repeating lattice structures, which results in an extraordinary large internal surface area, up to 7800 m^2/g (*i.e.,* the surface area of a gram of this material is larger than the area of a football pitch). Moreover, MOFs offer unique structural diversity compared to other porous materials, for tuning the framework topology, porosity, and functionality to yield numerous potential applications such as gas capture, catalysis, photonic sensors, microelectronics, and lighting.
The majority of MOFs are synthesized as polydisperse microcrystalline powders that present intrinsic limitations, which inevitably reduce the range of practical applications. The synthesis of MOFs in a monolithic morphology is considered a promising way to achieve the transition of this class of materials from academia to industrial applications. The sol-gel process has been identified as a cheap and simple technique to produce a wide range of MOF monoliths. However, the mechanisms involved in this process are not yet clear, since the formation of gel and subsequent drying depend on several parameters. Shedding light on how nanoparticles aggregate to form a monolithic structure and how this affect the mechanical properties is therefore crucial for the transition of MOFs monoliths to industry.
The presentation will be divided in three case studies:
1) The morphology of the single nanoparticles – the building blocks of the monolithic structure – and their nanoscale aggregation for the zeolitic imidazolate frameworks (ZIFs) ZIF-8 and ZIF-71 was studied by means of atomic force microscopy (AFM), X-ray diffraction (XRD) and nanoscale

Fourier transform infrared spectroscopy (nanoFTIR). The mechanical behaviour of the monoliths was studied by means of instrumented nanoindentation. Moreover, for the first time, tip force microscopy (TFM), an extension of AFM, was used to reveal the nanostructure of the ZIF monoliths. We employed finite element (FE) simulations of the nanoindentation tests to establish a suitable constitutive model and determine an improved estimate of the yield stress (σ_Y) of ZIF monoliths. The combination of all the above-mentioned techniques allowed us to identify the deformation mechanisms taking place in this type of materials: grain boundaries sliding (GBS) is dominating at low stresses, then a partial failure of the framework occurs, leading to densification in the contact region. Local nanoFTIR spectra of residual indents confirm the breakage of chemical bonds under a mechanical stress. We also reported the fracture toughness of the monoliths to be appreciably higher than recently reported MOF glasses. This enhanced toughness could be attributed to the fine-grained nanostructures that facilitate grain boundary sliding. [1]
2) The fracture behaviour of four prototypical MOF sol-gel monoliths, namely ZIF-8, HKUST-1, MIL-68 and MOF-808 was analysed. We studied the initiation and crack propagation of cracks by nanoindentation and nanoscratch tests. We observed that shear faults inside the contact area represent the main failure mechanism of MOF monoliths and are the source of radial cracks. MIL-68 and MOF-808 showed a remarkably high resistance to cracking, which can be ascribed to a combination of both the framework structure (within the nanograins) and their consolidated nanostructure. [2]
3) Three novel composites, composed of luminescent dies (fluorescein, rhodamine B and coumarin) embedded in a MOF monolith matrix (namely, UiO-66), were successfully synthetised. We explored the effect of dies encapsulation on the mechanical and luminescent properties.

Constructing Reactivity-Based Fluorogenic Probes for Monitoring Protein Unfolding and Aggregation in Cells Yuning Hong; La Trobe University, Australia

Understanding how cells maintain the functional proteome and respond to stress conditions is critical for deciphering molecular pathogenesis and developing treatments for conditions such as neurodegenerative diseases. Efforts towards finer quantification of cellular proteostasis machinery efficiency, phase transitions and local environment changes remain a priority but still challenging. Herein, we present our recent progress in developing fluorescence-based strategy and methodology for the study of proteostasis. To measure the level of proteostasis efficiency, our approach is to directly measure unfolded protein load in cells, as the decline of proteostasis capacity results in the accumulation of unfolded proteins. To achieve this goal, we designed and synthesized a series of cysteine reactive fluorogenic probes which can react with unfolded proteins with exposed cysteines and exhibit fluorescence turn-on effect. Strikingly, these probes selectively display strong fluorescence with unfolded proteins but only weak fluorescence with proteins bearing surface-exposed cysteine in their folded structure and no fluorescence with small molecule biothiols. We then apply our method to measure proteostasis collapse in cells treated with pharmacological stressors, expressed with mutant proteins in Huntington's disease models, or infected with virus. By combining with advanced fluorescence techniques, we also resolve the changes of subcellular polarity, viscosity and macromolecular crowding in cells under different stress treatment. Our approach will provide a robust strategy for understanding protein unfolding and stress responses, as well as facilitating biomarker discovery for clinical diagnosis and therapeutics development.

SESSION SF05.04: Particle Aggregation II

Designing 3D Optical Metamaterials from Colloidal Nanocrystal Assemblies Cherie R. Kagan; University of Pennsylvania, United States

Colloidal noble metal nanocrystals (NCs) have metal cores and organic or inorganic ligand shells and are known for their size- and shape-dependent localized surface plasmon resonances. Here, we will describe the use of these NCs as building blocks of assemblies with designer optical properties for 3D metamaterials. Chemical exchange of the long ligands used in NC synthesis with more compact ligand chemistries reduces the interparticle distance (*d*) and increases interparticle coupling. This ligand-controlled coupling allows us to tune through a dielectric-to-metal phase transition, seen by a 10^{10} range in DC conductivity and a dielectric permittivity ranging from everywhere positive to everywhere negative across the whole range of optical frequencies. By exploiting the different chemical and physical properties of NC assemblies from bulk thin films, we construct NC/bulk bilayer heterostructures, that upon ligand exchange fold into 3D structures providing a simple route to 3D metamaterials. We exploit these folded, bilayer heterostructures to demonstrate chiral structures that form broadband circular polarizers. We expand on these ideas to include other NC compositions and their use to create stimuli-responsive 3D optical metamaterials.

2:00 PM SF05.04.02
Design, Collapse and Mixing of Nanoreactors for *In Situ* TEM Imaging of Confined Reactions in Liquids Emory Chan and Sardar Alam; Lawrence Berkeley National Laboratory, United States

Nanocapsules are hollow nanoscale shells that have applications in drug delivery, batteries, self-healing materials, and as model systems for naturally occurring shell geometries. In many applications, nanocapsules are designed to release their cargo as they buckle and collapse, but the details of this transient buckling process have not been directly observed. Here we use *in situ* liquid phase transmission electron microscopy to record the mixing of lipid nanocapsules and the electron-irradiation-induced buckling in spherical polymer capsules. We observe in real time the release of aqueous cargo from these nanocapsules and their buckling into morphologies with single or multiple indentations. The *in situ* buckling of nanoscale capsules is compared to *ex situ* measurements of collapsed and micrometer-sized capsules and to Monte Carlo (MC) simulations. The shape and dynamics of the collapsing nanocapsules are consistent with MC simulations. Our experiments suggest design rules for nanocapsules with desired buckling response based on parameters such as capsule radius, wall thickness, and collapse rate.

2:15 PM SF05.04.03
***In Situ* Imaging of Active Assemblies of Nanoparticles Driven by Electric Field** Chang Liu, Zuochen Wang, Chang Qian and Qian Chen; University of Illinois at Urbana-Champaign, United States

Application of electric field to colloidal suspension has been shown as an efficient strategy to create dynamic materials otherwise impossible. Although numerous efforts have been devoted to the understanding and optical microscopy imaging of micron-sized colloids driven by external electric field, how nanoparticles (NPs) interact with electrodes and behave under various flow effects induced by electric field remain underexplored due to the experimental challenge to image them in-situ and the theoretical challenge to consider multiscale effects due to the small size of NPs. Here we will present our recent work on using patterned microelectrodes in a liquid-phase transmission electron microscopy chamber, to apply electric field to a NP suspension and to induce active assemblies. These assemblies are extensively dynamic and exhibit ensemble crawling motions along field gradient. Simulation of velocity flow field and electric field strength further shows how different field-induced hydrodynamic effects concur to control the active assembly. Our study can bridge the fields of active matter and colloidal NPs towards making active nanorobots and dynamic non-equilibrium assemblies.

2:30 PM *SF05.04.04
Liquid-Phase TEM Imaging of NP Self-Assembly and Protein Fluctuation Qian Chen; University of Illinois at Urbana-Champaign, United States

We will present our group's recent progresses on establishing and utilizing electron microscopy to image, understand, and manipulate colloidal and biological systems, in space and time at a nanometer resolution. This involves systems that underpin the fundamentals of structure-functional relationship for a wide range of phenomena and applications. In this talk, we will discuss in detail three types of such systems, including metallic nanoparticles assembling into Moire superlattices as promising optical and mechanical metamaterials, membrane protein lipid assemblies' structure fluctuations and fingering dynamics, and electrochemical energy materials' strain propagation with nano-sizing effects. We will show how we build upon liquid-phase transmission electron microscopy and four-dimensional scanning transmission electron microscopy, and couple them with machine learning and molecular dynamics simulations. This coupling enables us to study the dynamic, squishy, multifunctional soft and biological systems in liquid and at operation, and to study the charge-lattice interactions in an ordered materials' phase transformation.

3:30 PM *SF05.04.05
Interfacial Structure, Interparticle Forces and Assembly Dynamics During Crystallization by Particle Attachment James J. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

Crystallization by particle attachment (CPA) to form hierarchical structures is a common phenomenon and a promising approach to synthesizing functional materials. CPA exhibits diverse styles ranging from oriented attachment (OA), by which individual nanocrystals of the same phase attach with crystallographic coalignment, to mis-oriented aggregation of nanocrystals with disparate phases followed by coarsening to single-phase, ordered structures. CPA leads to remarkable morphological outcomes, including formation of tetrapods, chains and sheets, highly branched nanowires, and self-similar 3D mesocrystals. Moreover, CPA has now been widely observed in semiconductors, metals, silicates, oxides, fluorides, carbonates, organic compounds, peptides, and proteins. While descriptions of CPA must share a commonality with continuum-based DLVO-type theories for simple isotropic colloids, nanocrystals present additional complexities, including face-specificity of dielectric properties, inherent diopolar interactions, structured nanoscale interfaces, solvent-responses at a length scale comparable to particle size, and the impact of organic ligands often used to stabilize nanoparticles on the interparticle potentials. Macromolecular systems add another level of complexity due to their electrostatic patchiness and specific interactions via side chain chemistry. To understand the relationship between interfacial structure, interparticle forces and assembly dynamics, as well as the role of organic ligands and the properties of macromolecules, we are investigating CPA in a range of systems, including noble metals, metal oxides, peptides, and proteins, using a combination of in situ TEM, in situ AFM, and molecular modeling. In this talk I will focus on, 1) the effects of organic ligands in both driving CPA and creating unique crystal morphologies, and 2) the distinct behavior exhibited by proteins, due to their uniform, but anisotropic, dimensions and charge distributions. The results shed light on the mechanisms by which CPA progresses, the interaction potentials that drive the process, and the role of interfacial structure in defining those potentials.

4:00 PM SF05.04.06
Building 3D Circular Nanotubes Using *In Situ* Monitored Self-Assembly Process Zihao Lin, Chunhui Dai and Jeong-Hyun Cho; University of Minnesota, Twin Cities, United States

Tubes with a circular cross-section can be noticed everywhere in daily life, from large ventilation pipes to a human's small capillaries. Circular cross-sections also play an important role in fluidic channels, as it can eliminate the corner flow effect, undermine nonuniform pressure build up, and minimize shear stress in the channel. Moreover, it can largely simplify the fluidic theory model built for corners and improve its accuracy. However, in nanofluidics, fabrication of circular nanotubes (10-1000 nm) remains challenging, especially the curved one remains unsolved. In this work, both straight and curved circular nanotubes are fabricated via electron beam induced in-situ monitored self-assembly. This in-situ monitored ability provides real time images with a nanoscale resolution, leading to extreme fabrication precision for the realization of three-dimensional (3D) nanostructures (circular nanotubes). Two-dimensional (2D) nanopatterns defined on a planar substrate are firstly defined by electron beam lithography, followed by a deposition process and Si etching underneath. An electron beam is used to transform each 2D pattern into segmented 3D cylinder structures. Gaps on the top and between each cylinder are sealed by atomic layer deposition and the diameter of the tube can be precisely controlled from hundreds of nm down to ~10 nm with the resolution of 0.1 nm. To verify its capability for fluidic transportation, through the nanotubes with radius of ~100 nm, liquid flow/evaporation was in-situ monitored using a darkfield microscope via optical scattering effect. From the observations of fluidic flow in the curved circular nanocylinders, the dynamic behavior of the fluid was characterized, and novel counter-intuitive physical effect was discovered: nano pumping through evaporation in a nanocylinder.

4:15 PM SF05.04.07
Connecting Energetics to Dynamics in Particle Aggregation Revealed by Real-Time Observations Lili Liu, Elias Nakouzi, Maria Sushko, Gregory K. Schenter, Christopher Mundy, William Smith, Ben Legg, Xin Zhang, Carolyn Pearce, Jaehun Chun and James J. De Yoreo; Pacific Northwest National Laboratory, United States

Although the physical insights into oriented aggregation of mineral nanoparticles have been recently gained a lot from real-time observations, the impact of many fundamental solution parameters such as particle shape, solution structural and pH, on governing aggregation behavior and dynamic is largely unexplored. Using zinc oxide (ZnO) nanoparticle and boehmite(γ-AlOOH) nanoplatelets as two different anisotropic systems, we combine in situ liquid phase TEM (LPTEM) observations of single particle and ensemble assembly dynamics with simulations of interparticle forces and responses to relate experimentally derived interparticle potentials to the underlying interactions. We also establish the relationships between solution chemistry, forces and response dynamics to address the challenging of the crystal structure in directing the oriented aggregation behavior. Our findings on nanocrystal aggregation and interactions provide insights toward the predictive understanding of nanoparticle growth, assembly, and aggregation, which are of great importance in the strategic development of nanomaterials and nature environments.

4:30 PM SF05.04.08
Formation Mechanism of Flower-like Polyacrylonitrile Particles Huaxin Gong[1], Jan Ilavsky[2], Ivan Kuzmenko[2], Shucheng Chen[1], Hongping Yan[1], Christopher B. Cooper[1], Gan Chen[1], Yuelang Chen[1], Jerika A. Chiong[1], Yuanwen Jiang[1], Jiancheng Lai[1], Yu Zheng[1], Kevin Stone[3], Luke Huelsenbeck[4], Gaurav Giri[4], Jeffrey Tok[1] and Zhenan Bao[1]; [1]Stanford University, United States; [2]Argonne National Laboratory, United States; [3]SLAC National Accelerator Laboratory, United States; [4]University of Virginia, United States

Flower-like polyacrylonitrile (PAN) particles have shown promising performance for numerous applications, including sensors, catalysis, and energy storage. However, the detailed formation process of these unique structures during polymerization has not been investigated. Here, we elucidate the formation process of flower-like PAN particles through a series of in situ and ex situ experiments such as in situ USAXS. We have the following key findings. First, lamellar petals within the flower-like particles were predominantly orthorhombic PAN crystals. Second, branching of the lamellae during the particle formation arose from PAN's fast nucleation and growth on pre-existing PAN crystals, which was driven by the poor solubility of PAN in the reaction solvent. Third, the particles were formed to maintain a constant center-to-center distance during the reaction. The separation distance was attributed to strong electrostatic repulsion, which resulted in the final particles' spherical shape and uniform size. Lastly, we employed the understanding of the formation mechanism to tune the PAN particles' morphology using several experimental parameters including incorporating comonomers, changing temperature, adding nucleation seeds, and adjusting the monomer concentration. These findings provide important insights into the bottom-up design of advanced nanostructured PAN-based materials and controlled polymer nanostructure self-assemblies.

4:45 PM SF05.04.09
Supramolecular Polymerization of Photopolymer Enables Tough 3D Soft Objects Hae Seung Lee[1], Jiyun Kim[1], Hyunchang Park[2] and Jiheong Kang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Stanford University, United States

Light-based 3D printing remains to be the only technique able to build free-form 3D architectures in high resolution. By crosslinking photocurable monomers or macromonomers using UV light, layers of rigid polymer networks are formed to construct a 3D structure. Ever since its development, light-based 3D printing has continued improving printing speed and resolution through optimization of printing systems such as use of dead layers[1], flowing liquid interface[2] and two-photon polymerization[3]. Despite the advance in printability, the lack of photopolymers to print stretchable and durable elastomers has restricted further application of 3D printing to stretchable devices such as bio-implantable devices, E-skin, and soft robots.
Here I present the supramolecular approach to toughen 3D printed elastomers. Our designed photopolymer includes supramolecularly polymerizable 'sticker' in their backbone, which spontaneously polymerize to form a preliminary network even before printing. Due to this supramolecular network, the printed elastomer network shows superior stretchability, compressive strength, toughness, fracture toughness, and fatigue threshold in one system. The key of this result reveals to be suppressing network defect formation. Even though defects are well known to weaken the mechanical properties of polymer networks, conventional photopolymers were not able to avoid defects due to the rapid process of 3D printing. In my presentation, I will discuss details of the design strategy and its toughening mechanism.

SESSION SF05.05: Particle Aggregation III
Session Chairs: Shuai Zhang and Xin Zhang
Wednesday Morning, April 12, 2023
Marriott Marquis, B2 Level, Golden Gate B

8:00 AM SF05.05.02
Tuning Polymerization-Induced Self-Assembly in Polymer Thermosets to Optimize Their Physical Properties Brad H. Jones[1], Samuel C. Leguizamon[1], Sangwoo Lee[2] and Jessica Kopatz[1]; [1]Sandia National Labs, United States; [2]Rensselaer Polytechnic Institute, United States

Polymer thermosets are frequently modified via polymerization-induced self-assembly (PISA), wherein the addition of secondary or higher order components that phase separate during the polymerization is intended to improve a specific property. Generally speaking, it is challenging to control the characteristic self-assembled length scale in such materials beyond a limited range. This presentation will describe an approach to PISA in step-growth polymer networks that enables the length scale to be tuned over a broad range, from nanoscale to macroscale. The key element of this approach is a balance of multiple reactive species that simultaneously favor and disfavor phase separation. We demonstrate how ensuing, systematic variation of the length scale leads to exquisite control over the curing behavior and glass transition of the resultant materials. We further discuss application of this approach in the optimization of physical properties, including for rubber-modified epoxies where toughness is critically impacted by rubber particle size, as well as for the development of materials with improved damping performance. Our results and insights may help guide the future design of polymer thermosets with precisely tailored microstructures and unique combinations of physical properties.

8:15 AM *SF05.05.03
Near Surface Solution Structure Controls the Oriented Attachment of Metal Nanoparticles—Reactive Molecular Dynamics Kristen A. Fichthorn; The Pennsylvania State University, United States

Oriented attachment (OA) of nanoparticles has been recognized as a common mechanism for crystal growth, affecting the micro- and macroscale morphologies over a large variety of materials. However, the role of environmental constraints such as pH, temperature, and ionic concentration in controlling the pathways and kinetics of OA remains unaddressed, which makes it difficult to control and exploit OA syntheses to create unique materials. Experimental studies with *in situ* liquid-cell and *ex situ* transmission electron microscopy indicated that the solution pH affects the OA of Pt nanoparticles.

With pH varying from ~3 -1.5, the attachment facet of Pt nanospheres switches from {001} to {111}. The initial {001} attachment of ~2-5 nm nanoparticles leads to the formation of nanocubes (~50-200 nm), and the subsequent {111} attachment results in the extrusion of Pt nanorods from the surface of the nanocubes. Using molecular dynamics simulations based on a ReaxFF reactive force field fit to results from quantum density-functional theory, we simulated the approach of two Pt nanocrystals in HCl solution under conditions of relatively low and high pH. Our studies confirm the experimental findings and reveal the key role of solution environment in controlling OA.

8:45 AM SF05.05.04
Exploiting Interfacial Assemblies of Nanoparticle Surfactants to Design Reconfigurable Materials and Devices Brett A. Helms; Lawrence Berkeley National Lab, United States

Loading...
The interface between two or more immiscible liquids provides an opportunity to structure the liquids into complex shapes through the interfacial assembly and jamming of nanoparticle surfactant films, whereby nanoparticles (including colloidal nanocrystals) dispersed in one of the liquids bind to the end groups of polymeric surfactants concd. at the interface. When the interface is perturbed, additional nanoparticle-surfactants spontaneously form, lowering the interfacial free energy in the system. As the system evolves in time, so as to minimize the interfacial area between the fluids, the nanoparticle-surfactants jam and the structures of the liquids becomes shape-persistent. I will describe our recent efforts in printing and patterning such structured liqs. with functional nanoparticle surfactants to fabricate, in turn, a variety of useful energy devices, including microreactors, all-liquid electronics, magnetics, and electrochemical cells. The potential to couple chemical and energetic processes across the liquid-liqiod interface, and mediated by the nanoparticle-surfactant film, is distinct from related fluidic architectures and devices in lithographically patterned solid media, and more reminiscent of biological systems that dynamically reconfigure, adapt, and respond to local physiochemical cues and thereby derive new functional properties.

9:00 AM SF05.05.05
Assembly of Prescribed 3D Nanoparticle Organizations Using Inverse Design of Programmable DNA Bonds Brian Minevich[1], Jason Kahn[2], Guolong Zhu[1], Aaron Michelson[2,1], Hamed Emany[1], Kim Kisslinger[2], Shuting Xiang[1], Sanat Kumar[1] and Oleg Gang[1,1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States

The ability to fabricate functional materials and devices by-design at small scales has led to tremendous technological progress over the last decades, primarily through lithographic and additive manufacturing technologies. However, there remains a need for a platform approach for the fabrication of materials with ordered three-dimensional (3D) nanoscale matter with emergent functions, by-design. Here, we will demonstrate the concept and experimental realization of the encoded assembly of nanoparticles into prescribed, hierarchically ordered 3D organizations using DNA programmable bonds. These directional bonds are encoded onto 3D nanoscale DNA origami frames or “voxels”. Our information-constrained, inverse design approach allows for encoding of targeted 3D hierarchical architectures with programmable bonds through identification of repeating mesoscale motifs and their elemental blocks, nanoscale “voxels”, that can also carry a wide variety of encoded nano-cargo. As examples of this approach, we assemble spatially ordered, low-dimensional arrays with coupled plasmonic and photonic scales, a nanoscale analog of face-perovskite lattice, and a hierarchically organized lattice of spiral motifs, each with domain sizes on the order of several microns. Detailed X-ray scattering and electron microcopy studies confirm the correspondence between the designed and realized architectures. We also demonstrate that dynamic DNA nanotechnology elements can be integrated into the bonds to selectively control bond activity and determine the structure of the resultant assembly. This design strategy was shown to selectively regulate the assembly of multiple crystal symmetries from the same pool of “voxels” depending on the particular DNA signal given to the system.

9:15 AM *SF05.05.06
Facet-Dependent Dispersion and Aggregation Behavior of Aqueous Hematite Nanoparticles Jianbin Zhou, Duo Song, Sebastian T. Mergelsberg, Yining Wang, Narendra Adhikari, Nabajit Lahiri, Yatong Zhao, Ping Chen, Zheming Wang, Xin Zhang and Kevin Rosso; Pacific Northwest National Laboratory, United States

The aggregation state of nanoparticles in solution plays a commanding role over their function. In technological applications, particularly in aqueous media, particle dispersion often requires additive sorbents to impart a net repulsive interaction. However, facet engineering of nanocrystals holds promise for achieving clean monodisperse suspensions simply based on facet-specific interaction with solvent molecules. Here, we systematically studied the dispersion/aggregation behavior of three sets of hematite (Fe_2O_3) nanoparticles in various aqueous solutions using ex situ electron microscopy and in situ small angle X-ray scattering (SAXS). Comparison of particles dominated by (104), (001), and (116) facets revealed a unique tendency of (104) hematite nanoparticles to maintain a monodisperse state across a wide range of pH, electrolyte type and concentration, temperature, and aging time. Density functional theory (DFT) calculations reveal how this behavior arises from a relatively inert, densely hydrogen-bonded first water layer unique to the (104) facet that favors interparticle dispersion by saturating interaction sites on the surface. Our finding validates the notion that nanoparticle dispersion can be controlled through expression of specific facets for specific solvents, and thus may help in the development of various nanoparticle applications that rely on their interfacial area to be highly accessible in robustly stable suspensions.

Hierarchically Structured Porphyrin Nanoparticle Photosensitizers Hongyou Fan; Sandia National Laboratories, United States

Design and engineering of the size, shape, and chemistry of photoactive building blocks enable the fabrication of functional nanoparticles for applications in light harvesting, photocatalytic synthesis, water splitting, phototherapy, and photodegradation. Here, we report the synthesis of such nanoparticles through a surfactant-assisted interfacial self-assembly process using optically active porphyrin as a functional building block. The self-assembly process relies on specific interactions such as π–π stacking and ligand coordination between individual porphyrin building blocks. Depending on the kinetic conditions, resulting structures exhibit well-defined one- to three-dimensional morphologies such as nanowires, nanooctahedra, and hierarchically ordered internal architectures. At the molecular level, porphyrins with well-defined size and chemistry possess unique optical and photocatalytic properties for potential synthesis of metallic structures. On the nanoscale, controlled assembly of macrocyclic monomers leads to formation of ordered nanostructures with precisely defined size, shape, and spatial monomer arrangement so as to facilitate intermolecular mass and energy transfer or delocalization for photocatalysis. Due to the hierarchical ordering of the porphyrins, the nanoparticles exhibit collective optical properties resulted from coupling of molecular porphyrins and photocatalytic activities such as photodegradation of methyl orange (MO) pollutants and hydrogen production. The capability of exerting rational control over dimension and morphology provides new opportunities for applications in sensing, nanoelectronics, and photocatalysis.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract

Crystallization of Polymer-Grafted Nanoparticles (PGNPs) Induced by Polymer Additives and Kinetic Pathways of PGNP Interfacial Assembly

Yiwen Qian[1,2], Peter Ercius[2], Yi Liu[2] and Ting Xu[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Growing nanoparticle (NP) crystals has been pursued extensively using ligand chemistries such as DNA and supramolecules, controlled evaporation and patterned surfaces. In this talk, I will introduce a precipitation-induced NP crystallization process where a trace amount of polymeric impurities (<0.1 wt.%) leads to reproducible, rapid growth of high quality 3-D NP crystals in solution and on patterned substrates with high yield. The polymers preferentially precipitate on the PGNP polymeric surfaces inducing the formation of small PGNP clusters, which subsequently act as nuclei to initiate PGNP crystal growth in dilute solution. Formation of 3-D PGNP crystals can be tuned by varying polymeric additives loading, solvent evaporation rate and NP size. This study elucidates how to balance cohesive energy density and PGNP diffusivity in the self-assembly to favor nuclei formation energetically and kinetic growth in dilute solutions.

Further structural diversity is achieved by enabling co-crystallization of two types of PGNPs into binary crystals. Kinetic process of binary PGNP assembly at liquid-air interface is captured by *in-situ* X-ray scattering combined with *ex-situ* TEM characterization, featuring a polymer-like autophobic dewetting process to lower surface energy. Nanoscale microphase separation within binary PGNP mixtures is followed by surface-induced particle reorganization. Metastable structures form through stacking of PGNP layers and short-range diffusion, which can further form “frustrated” lattices. Alternatively, equilibrium crystals nucleate and grow through lattice distortion depending on the compatibility of the preferred local order and global crystalline order. This study helps illustrate the process of how different interactions interplay and influence the final structures and provide guidelines for hierarchical functional materials fabrication.

11:00 AM SF05.05.09

Preparing Chiral Hydrogel by Using Coordination-Assembly Complex of Cobalt Oxide Nanoparticles for Chiromechanical Response Chung Man Lim, Francesco Serafin, Xiaoming Mao and Nicholas A. Kotov; University of Michigan, United States

Nanomaterials are considered as an important class that has found interest in various fields including electrical, optical, catalytical, and biomedical applications. In nanoscale, chemical, biological, and physical properties are all different from the properties of each atom or molecule of bulk materials. Meanwhile, gels also make up a crucial class of materials on account of their large free space between the networks and highly adjustable mechanical properties. Many hydrogel systems have been researched utilizing covalent cross-linking processes, including radical polymerization initiated by temperature, UV, and pH. It is important to understand the physical behavior of these gels, as they are being continuously introduced into various fields like electrical, pharmaceutical, and biomedical applications.

On the basis of previous research about nanoparticles, gels, and chirality, we envisioned that a coordination-assembly complex might be able to couple with nanoparticles to form a chiral gel. The advantage of this method is that it does not require the use of a specific device or conditions. Mechanical properties such as storage and loss modulus showed chirality-response with critical frequency. The aim of this research is to demonstrate unique features of the coordination system of cobalt oxide nanoparticles with cadmium salts to produce a structure that responds to the chirality.

11:15 AM SF05.05.10

Self-Assembly of 3D DNA-Nanoparticle Superlattices on Patterned Surfaces Feiyue Teng[1], Honghu Zhang[1,1], Dmytro Nykypanchuk[1] and Oleg Gang[1,2,2]; [1]Brookhaven National Laboratory, United States; [2]Columbia University, United States

DNA-programmable assembly is a powerful approach to organize nanoscale objects into well-defined 2D and 3D lattices and translate the advances of nanoscale building blocks into mesoscale architectures. However, to integrate the lattices into devices and other material systems, the methods for their precise placements on planar substrates, as well as assembly at the pre-determined surface locations are required. We developed an approach to direct the growth of 3D DNA-nanoparticle lattices at the desired surface locations over macroscopic areas using microscale lithographic patterns. We investigated the factors affecting the growth of 3D superlattices on these patterned substrates and established a robust pattern-guided assembly method. We applied small angle x-ray scattering (SAXS), optical microscopy, scanning electron microscopy (SEM) to reveal the assembly processes and the structure of the resulting lattices. The established approach provides a new material fabrication platform that combines nanoscale control of 3D lattices, as provided by DNA-programmable assembly, with mesoscale and macroscale control of self-assembled materials, as enabled by patterning. The developed method also allows for a systematic investigation of the nucleation and growth of DNA-guided assemblies at the interfaces. The established approach opens a possibility for integration of 3D nanoparticle lattices into devices for precisely positioning assemblies on substrates.

11:30 AM SF05.05.11

Ethanol-induced Condensation and Decondensation in DNA-Linked Nanoparticles—A Nucleosome-Like Model for the Condensed State Qinsi Xiong, One-Sun Lee, Chad Mirkin and George C. Schatz; Northwestern University, United States

Inspired by the conventional EtOH precipitation strategy, ethanol condensation has been applied as a routine method to dynamically tune “bond” lengths (i.e., the distances between adjacent nanoparticles that are linked by DNA) and the thermal stabilities of colloidal crystals engineered with DNA. However, the underlying mechanism of how the DNA bond changes in this class of colloidal crystals in response to ethanol remains unclear. Here, we conducted a series of all-atom molecular dynamic (MD) simulations to explore the free energy landscape toward DNA condensation and decondensation. Our simulations confirm that DNA condensation is energetically much more favorable under 80% ethanol conditions than in pure water, as a result of ethanol’s role in enhancing electrostatic interactions between charged species. Moreover, the condensed DNA adopts B-form in pure water and A-form in 80% ethanol, which indicates the higher-order transition does not affect DNA’s conformational preferences. We further propose a nucleosome-like supercoiled model for the DNA condensed state, and we showed that the DNA end-to-end distance matches the experimentally measured DNA bond length of about 3 nm in the fully condensed state for DNA where the measured length is 16 nm in water. Overall, this study provides an atomistic understanding of the mechanism underlying ethanol-induced condensation and water-induced decondensation, whereas our proposed nucleosome-like model allows the design of new strategies for interpreting experimental studies of DNA condensation.

SESSION SF05.06: Self-Assembly I

A Study on Elastic Behavior of Liquid Crystal Phase of DNA Polymers Evaporating on Geometric Template Soon Mo Park, Hyoungsoo Kim and Dong Ki Yoon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Evaporation process is a complex dynamical system in which fluid flow, known as 'Coffee ring effect', continues to occur and influenced by many factors such as the types of solute, wettability with the substrate, and the evaporation rate. Understanding the phenomenon is positively necessary for providing insights associated with fundamental science and engineering application.
For the improvement, we delved into evaporation process, deposition mechanism and liquid crystal (LC) phase expression of DNA solution on flat substrate and micro-post template and controlled the orientation and morphology of DNA molecules using solution coating method. One of the biopolymers, DNA has recently emerged as a building block because it is abundant in nature, can be functionalized by electrostatic interaction and shows liquid crystal phase depending on the concentration. Their bulk elastic properties are quite different from other materials due to concentration-dependent LC phase. Additionally, predesigned substrates can be applied for confinement and deformation of triple-phase contact line. Then, unique and complex structure can be formed spontaneously due to the interaction between the elastic properties of DNA and confinement effect of the substrate.
Here, we conducted the evaporation-induced experiments on geometrical template and controlled novel and sophisticated DNA microstructures. The pattern of the DNA can be modulated by shear direction and template spacing. This will help to understand the self-assembly of DNA molecules in confinement effect and can provide applications to bio-template for polymers, liquid crystals or other nanoparticles.

1:45 PM SF05.06.02
Three-Dimensional Hierarchically Porous MoS2 Foam as High-Rate and Stable Lithium-Ion Battery Anode Xuan Wei[1,2]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Li Auto, China

Architected materials that actively respond to external stimuli hold tantalizing prospects for applications in energy storage, wearable electronics, and bioengineering. Molybdenum disulfide, an excellent two-dimensional building block, is a promising candidate for lithium-ion battery anode. However, the stacked and brittle two-dimensional layered structure limits its rate capability and electrochemical stability. Here we report the dewetting-induced manufacturing of two-dimensional molybdenum disulfide nanosheets into a three-dimensional foam with a structural hierarchy across seven orders of magnitude. Our molybdenum disulfide foam provides an interpenetrating network for efficient charge transport, rapid ion diffusion, and mechanically resilient and chemically stable support for electrochemical reactions. These features induce a pseudocapacitive energy storage mechanism involving molybdenum redox reactions, confirmed by in-situ X-ray absorption near edge structure. The MoS_2 Foam electrode exhibits extremely high reversible capacities of 1575, 1550, 1515, 1431, 1268 and 1111 mA h g^{-1} at current densities of 0.2, 0.5, 1.0, 2.0, 5.0, 10 A g^{-1}. Furthermore, MoS_2 Foam remains electronically functional and shows the specific capacity of 1000 mA h g^{-1} and 700 mA h g^{-1} even when measured at high current densities of 5 A g^{-1} and 10 A g^{-1} after 1,000 cycles. The extraordinary electrochemical performance of molybdenum disulfide foam outperforms most reported molybdenum disulfide-based lithium-ion battery anodes and state-of-the-art materials. This work opens promising inroads for various applications where special properties arise from hierarchical architecture.

2:00 PM SF05.06.03
A Scalable and Straightforward Approach to the Self-Assembly of Mesoporous Metal Oxide Thin Films David W. Collinson, Thomas W. Colburn and Reinhold H. Dauskardt; Stanford University, United States

Evaporation induced self-assembly (EISA) has been widely applied as an approach to prepare mesoporous ceramics and carbanecous materials. Typically, sol-gel oxide precursors in combination with soft templating agents such as the Pluronic® tri-block co-polymers self-assemble to produce thin films with highly ordered, accessible porosity with pore diameters on the order of 5-10 nm. Depending on the deposition conditions and precursor composition, a wide range of structured mesoporous oxide thin films can be achieved with potential applications in energy, sensors and catalysis.
However, the EISA and mesostructuration process is very sensitive to atmospheric conditions and humidity. The formation of the oxide network also requires extended delicate aging and sintering steps to produce high quality thin films. As a result, producing self-assembled oxide thin films in this manner incurs significant energy and time costs that prevents scalable manufacturing of the mesoporous thin films. The limiting factor preventing the scalable manufacture is not the self-assembly process, which can occur quickly under appropriate deposition conditions; instead it is the time required to condense the sol-gel oxide network and prevent collapse of the film structure. To achieve appropriate condensation and high quality films, extended processing times up to 2 days and elevated sintering temperatures up to 400 ^{o}C are required.
To overcome the limitations of the sol-gel chemistry, we utilize solution combustion synthesis to produce large area mesoporous thin films rapidly with significantly reduced processing temperatures and time. Carboxylic acid species act both as chelating agents and as fuel sources in conjunction with metal nitrate salts to generate a stable oxide network at low processing temperatures and short processing times. In addition, the complexation of the carboxylic acids with metal salts prevents hydrolysis and condensation until the moment the combustion reaction is initiated simplifying the conditions required for self-assembly. Upon initiation, the combustion reaction allows for rapid and efficient oxide network formation before the Pluronic® burns out, preventing loss of the desired self-assembled mesostructure. Further, our chosen chemistry also lends itself to rapid deposition approaches such as spray coating for scalable manufacturing. A suitable choice of metal salt and carboxylic acid can potentially allow for the production of a range of functional mesoporous metal oxide thin films. Finally, we also demonstrate how the self-assembled matrices can then be filled with polymers to produce nanocomposites with potential applications as dielectric layers and barrier coatings.

2:15 PM SF05.06.04
Tailoring Mass and Light Transport in Nanoparticle-Based Aerogels for Gas-Phase Photocatalysis Fabian Matter and Markus Niederberger; ETH Zürich, Switzerland

Aerogels are among the most fascinating human-made materials due to their numerous extraordinary properties. These extremely lightweight materials not only have a very intriguing appearance but also are made up of a finely branched three-dimensional network that offers very high porosity and extraordinary surface area. Due to their structural characteristics, aerogels offer great potential for diverse applications such as detection and sensing, filtration, and catalysis. Aerogels have been fabricated for decades using conventional sol-gel chemistry, a process that, however, is limited in design flexibility. More recently, an alternative method for aerogel fabrication has emerged that uses pre-synthesized building blocks to create such highly porous three-dimensional assemblies.[1] Since the properties of the nanoscale building blocks are typically preserved during the assembly process, the final aerogel can be precisely tailored to a specific application not only in terms of composition, but also in terms of crystallinity, size, shape, and surface chemistry of the underlying aerogel framework.

By using highly crystalline titanium dioxide nanoparticles, for example, transparent monolithic aerogels can be prepared that have a surface area of up to 500 m^2/g and a porosity of up to 99 %. The photoactive backbone can be further decorated with selected co-catalyst nanoparticles to enhance the photocatalytic performance. The potential of particle-based aerogels has been demonstrated in numerous studies, centimeter-sized titania-metal aerogels, for example, have been explored in the photocatalytic conversion of gaseous carbon dioxide [2] and also show excellent activity in hydrogen production from organic feedstocks. [3,4]

In the last decade, the focus has been centered on exploiting new building blocks and tuning their composition to improve light utilization or enhance catalytic activity. [5] In contrast, little attention has been paid to modification at the structural level. This is partly because the internal structure of aerogels is morphologically complex and difficult to characterize, but also because the parameters controlling particle assembly are not yet fully understood.

In this talk, titania-based aerogels will be used as an example to show how structural modifications of particle-based aerogels can be realized in order to tune two essential properties for gas-phase photocatalysis: gas permeability and light transmission. [6] Furthermore, it will be shown how measurements of gas permeability can not only serve as a tool to determine fundamental properties of mass transfer through such particle-based assemblies, but in conjunction with optical measurements, gas sorption analysis, and microscopy techniques can also provide valuable insights into the formation mechanism of this fascinating class of materials.

Programmable Assembly of Semiconductor Mesostructures via Inorganic Phototropism Azhar I. Carim and Nathan S. Lewis; California Institute of Technology, United States

Plants exhibit a phototropic response and direct the addition of new biomass to optimize collection of solar insolation. Analogous inorganic phototropism growth enables the programmable assembly of complex 3D nanoarchitectures with instruction by an incoherent, unstructured, mW cm^{-2} intensity light beam. Inorganic phototropism has been demonstrated via the light-mediated electrochemical assembly of semiconductor deposits from solution-phase precursor ions. No structured light field (no photomask), no lithographic processes and no templating agents (ligands, surfactants, etc.) are utilized. Nevertheless, ordered nanoscale features are conformally assembled over full macroscale (cm^2) areas with feature heights on the order of several um with growth times < 5 min. In-plane anisotropy is a function of the input polarization. Isotropic morphologies consisting of ordered arrays of nanoscale holes were generated using unpolarized illumination whereas linearly polarized light resulted in anisotropic lamellar structures with in-plane orientations set by the polarization direction. The structure pitch was dependent on the spectral distribution of the input light with shorter wavelengths effecting higher feature densities. The out-of-plane growth direction is related to the propagation direction of the input light, mirroring the way in which palm trees develop an observable tilt toward the average position of the solar azimuth. Time-varying optical inputs enable programming of 3D intricacy by evolving the in-plane structure along the out-of-plane dimension, e.g. an abrupt reduction in the input wavelength results in a concomitant increase in the interfacial density resulting in tuning fork structures similar to how blue light effects branching in many shade-intolerant plants. Additional morphological control has also been effected by using multiple simultaneous illumination inputs. Modeling of the growth using a combination of full-wave electromagnetic simulations of light absorption and scattering coupled with Monte Carlo simulations of mass addition successfully reproduced the experimentally observed morphologies and indicated that assembly was directed by evolution of the growth front to maximize anisotropic light collection. The assembly was observed to be a highly emergent phenomenon involving optical communication between neighboring features including cooperative scattering and synergistic absorption and thus is similar to the manner in which neighboring plants exchange information and avoid competition for light resources.

3:15 PM SF05.06.07
Electrostatic Self-Assembly of Magnetic and Plasmonic Nanoparticles on Gold Nanorods Mehedi Hasan Rizvi[1], Ruosong Wang[2], Jonas Schubert[2], Andreas Fery[2,3] and Joseph Tracy[1]; [1]North Carolina State University, United States; [2]Leibniz Institute for Polymer Research Dresden, Germany; [3]Technische Universität Dresden, Germany

Overcoating gold nanorods (GNRs) with plasmonic or magnetic satellite nanoparticles (NPs) can modify the longitudinal and transverse surface plasmon resonances (LSPR and TSPR) through coupling with the satellite NPs. We report use of electrostatic interactions to reversibly assemble different types and amounts of satellite NPs on GNR cores, which allows coupling with and manipulation of the LSPR and TSPR of the GNR core. Cationic Fe_3O_4 NPs and spherical gold NPs (GNPs) functionalized with polyethylenimine (PEI) assemble on the surface of anionic GNRs functionalized with bovine serum albumin (BSA). The distinct extinction spectra of Fe_3O_4 NPs and GNRs make possible quantification of the loading of satellite NPs from optical extinction spectra. pH is a useful lever for controlling assembly and disassembly processes because the electrostatic properties of PEI- and BSA-functionalized NPs strongly depend on pH. Stable assemblies are obtained at pH between the isoelectric points (pH_I) of BSA (pH_I ~5) and PEI (pH_I ~11), because the core and satellite NPs have opposite charges within this window. At lower or higher pH, the core and satellite NPs have like charges, which inhibits assembly. Moreover, disassembly is possible by adjusting the pH to values outside of this range.

3:00 PM BREAK

3:30 PM SF05.06.08
Nanostructure Polymorphism Induced By Rotational Freedom of Self-Assembling Amphiphiles Yukio Cho[1], Yu-Jin Choi[1,2] and Julia Ortony[1]; [1]Massachusetts Institute of Technology, United States; [2]University of California, Santa Barbara, United States

Amphiphiles with strong intermolecular interactions that self-assemble in water have drawn attention due to their high stability and tunability for a range of applications. These strongly interacting amphiphiles tend to be planar and have a high propensity for hydrogen bonding and π-π stacking, thus the morphological design spaces of the corresponding self-assembled nanostructures are constrained. We hypothesized that a broad range of self-assembled morphologies can be achieved by introducing conformational freedom within each amphiphile. In this study, we incorporate a diacetylene domain into the aramid amphiphile (AA) platform, which yields a rotational axis of aramid amphiphile perpendicular to the planes of hydrogen bonding and π-π stacking. We observe polymorphism in AA assemblies with helical, twisted, short planar, or long planar nanoribbons, by varying the concentration and annealing temperature. We demonstrate that polymorphism in AA assemblies originates from changes in molecular packing induced by rotational constraints. This study of self-assembly in AAs serves as a model study for understanding the relationship between rotational freedom and molecular packing within a nanostructure.

3:45 PM SF05.06.09
Structural Diversity in Dimension-Controlled Assemblies of Tetrahedral Gold Nanocrystals Yi Wang[1], Jun Chen[1], Yaxu Zhong[1], Soojin Jeong[1], Ruipeng Li[2] and Xingchen Ye[1]; [1]Indiana University Bloomington, United States; [2]Brookhaven National Laboratory, United States

Polyhedron packings have fascinated humans for centuries and continue to inspire scientists of modern disciplines. Despite extensive computer simulations and a handful of experimental investigations, understanding of the phase behaviors of synthetic tetrahedra has remained fragmentary largely due to the lack of tetrahedral building blocks with tunable size and versatile surface chemistry. Here, we report the remarkable richness of and complexity in dimension-controlled assemblies of gold nanotetrahedra. By tailoring nanocrystal interactions from long-range repulsive to hard-particle-like or to systems with short-ranged directional attractions through control of surface ligands and assembly conditions, more than a dozen of two-dimensional and three-dimensional superstructures including the cubic diamond and hexagonal diamond polymorphs are selectively assembled. We further demonstrate multiply twinned icosahedral supracrystals by drying aqueous gold nanotetrahedra on a hydrophobic substrate. This study expands the toolbox of the superstructure by design using tetrahedral building blocks and could spur future computational and experimental work on self-assembly and phase behavior of anisotropic colloidal particles with tunable interactions.

4:00 PM SF05.06.10
Porous Self-Assembly in Binary Mixtures of Lobed Colloidal Particles Brunno Carvalho Rocha and Harish Vashisth; University of New Hampshire, United States

The self-assembly of colloidal particles is emerging as a promising approach for designing novel advanced materials. During self-assembly, particles spontaneously reorganize to form macrostructures with desired properties for applications in diverse fields, including in tissue engineering, catalysis, and photonics. The addition of attractive hard lobes to the surfaces of the colloidal particles can provide directionality for the interparticle interactions and create more excluded volume around each particle, leading to the formation of porous morphologies. In this work, we performed Langevin Molecular Dynamics simulations of binary mixtures of lobed colloidal particles, where the self-assembly process is mediated by short-range interactions between the lobes of the particles. We investigated the formation of porous macrostructures in mixtures of particles with varying number/size of their lobes across a range of temperatures. Among the self-assembled morphologies, we primarily identified the formation of three-dimensional aggregates, spherical aggregates, and crystalline structures. We observed that the formation of crystalline structures is progressively preferred as the number of lobes in the particles increases, and that the crystalline character of these structures leads to more homogeneous pore sizes, in contrast to random and spherical aggregates that have more heterogeneous pore sizes. We also observed that the larger lobes allowed the self-assembly of the lobed particles at higher temperatures when compared to the smaller lobes. The evolving understanding of how to optimize the bottom-up design of lobed colloidal particles gained by leveraging simulation techniques can serve as a guide for further improving the manufacturing of advanced materials.

4:15 PM SF05.06.11
Light Induced Surface Tension Gradients for Hierarchical Assembly of Particles from Liquid Metals Jiayun Liang and Zakaria Al Balushi; University of California, Berkeley, United States

Achieving control over the motion of dissolved particles in liquid metals is of importance for the meticulous realization of hierarchical particle assemblies in a variety of nanofabrication processes. Brownian forces can impede the motion of such particles, impacting the degree of perfection that can be realized in assembled structures. Here we show that light induced Marangoni flow in liquid metals (i.e., liquid-gallium) with Laguerre-gaussian (LGpl) lasers as heating sources, is an effective approach to overcome Brownian forces on particles, giving rise to predictable assemblies with high degree of order. We show that by carefully engineering surface tension gradients in liquid-gallium using non-gaussian LGpl lasers, the Marangoni and convective flow that develops in the fluid drives the trajectory of randomly dispersed particles to assemble into 100-μm wide ring-shaped particle assemblies. Careful control over the parameters of the LGpl laser (i.e., laser mode, spot size, and intensity of the electric field) can tune the temperature and fluid dynamics of the liquid-gallium as well as the balance of forces on the particle. This in turn can tune the structure of the ring-shaped particle assembly with a high degree of fidelity. The use of light to control the motion of particles in liquid metals represents a tunable and rapidly reconfigurable approach to spatially design surface tension gradients in fluids for more complex assembly of particles and small-scale solutes. This work can be extended to a variety of liquid-metals, complementary to what has been realized in particle assembly out of ferrofluids using magnetic fields.

4:30 PM SF05.06.12
Using CO_2 to Modulate Self-Assembly—Viscosity Increase or Decrease in Surfactant Fluids Induced by CO_2 Mahima Srivastava; University of Maryland, United States

The self-assembly of surfactants in water can be tuned by a number of stimuli, including temperature, pH, and light. In particular, self-assembly into wormlike micelles (WLMs) has been shown to be sensitive to the above stimuli. WLMs are long, polymer-like chains that entange into transient networks. Thus, when WLMs are formed, the solution becomes highly viscoelastic. Conversely, if WLMs are converted into spherical structures (micelles or vesicles), the viscoelasticity is lost and the viscosity of the solution will drop to that of water.

Here, we focus on modulating the self-assembly of WLMs using carbon dioxide (CO_2). CO_2 is of concern due to its role in the atmosphere as a greenhouse gas (thus impacting global warming and climate change). Approaches for CO_2 sequestration often introduce gaseous CO_2 into a solution containing an amine such as diethanolamine (DEA), but such amines are a rather toxic molecules. We are interested in absorbing CO_2 in a fluid that is completely safe and biocompatible. Moreover, could CO_2 absorption transform the viscosity of the fluid?

In this regard, we have devised a fluid containing an anionic fatty acid and a nontoxic amine-bearing molecule. Both the constituents of our fluid are biocompatible and in fact, they are found in the body. We will show that the viscosity of the fluid can be switched from low to high (or high to low) by contact with CO_2. The low-viscosity state corresponds to spherical micelles (or vesicles) whereas the high-viscosity state corresponds to WLMs. By bubbling CO_2 into a fluid of given composition, we can rapidly (within seconds) drive a transition from one type of self-assembly to another. We are interested in exploiting such rapid transitions, not only for CO_2 sequestration but also for certain biomedical applications.

SESSION SF05.07: Poster Session I: Building Advanced Materials via Aggregation and Self-Assembly

Selective Localization of Nanofiller on Interface of Polymer Composites via Surface Energy Modification to Improve Compatibility of Polymer Blends Kibeom Nam, Dong Yun Lee and Kwang Woo Jeon; Kyungpook National University, Korea (the Republic of)

Dispersed nanofillers in immiscible polymer blends prevent phase separation and voids formations being localized at the interface of the blends. The nanofillers can improve mechanical properties, however, the aggregation and agglomeration during the mixing process, such as melt blending and extrusion methods. Insufficient dispersion of nanofillers in polymer blend limits the application of blends works as a defect. Therefore, we present the effects of the surface energy of nanofillers on its dispersion and selective localization in the Poly(lactic acid) (PLA)/poly(butylene adipate-co-terephthalate) (PBAT) nanocomposite. Here in, the modified cellulose nanofiber (m-CNF) and modified silica nanofillers (m-SiO2) were used to prevent self-aggregation via hydrogen bonding reducing the surface energy of them. Then, by controlling the blending time, we confirmed that the localization of modified nanofillers in the nanocomposite. As a result, the modified nanoparticles, located at the PLA/PBAT interface, changed the morphology of the PLA/PBAT nanocomposites, thereby significantly improving the tensile strength and elongation at break by approximately 7% and 16%, respectively. Furthermore, the thermal and mechanical properties of composite were comprehensively enhanced regarding the PBAT mixing sequence and selective localization of the nanofiller. It was found that the selective localization of the nanofillers can be utilized to tune the mechanical properties of the PLA/PBAT nanocomposites with respect to their corresponding morphologies. The selective localization of silica nanoparticles in the PLA/PBAT nanocomposite is described in detail, and the melt blending method is presented for achieving the selective localization in an industrial scale to develop eco-friendly packaging films.

Synthesis of Eco-Friendly Polymeric Biosurfactants with Excellent Environmental Compatibility and Characterization of Their Interfacial Properties for Cosmetic and Household Products KiHo Park, JeongMin Lee and JongChoo Lim; Dongguk University, Korea (the Republic of)

Tightening environmental regulations and increasing awareness for the need to protect the ecosystem have effectively resulted in an increasing interest in biosurfactants as possible alternatives to chemical surfactants. They have advantages over their chemical counterparts in specificity, relative ease of preparation, mildness, and effectiveness even at extreme temperature or pH. Biosurfactants also have the merit of diversity, environment friendly nature such as low toxicity and excellent biodegradability, possibility of large-scale production, selectivity, performance under extreme conditions, and potential applications in environmental protection. Due to their unique functional properties, biosurfactants can be used as emulsifiers as well as demulsifiers, wetting agents, foaming agents, spreading agents, environmental cleanup of pollutants, functional food ingredients and detergents. In this study, 3 types of polymeric phospholipid biosurfactants were prepared using 3 different raw materials such as linoleic acid, rapeseed oil and coconut oil respectively and the structure of the resulting products was elucidated by FT-IR, 1H NMR, and 13C NMR spectroscopies. Biodegradability, acute oral toxicity (LD50), acute dermal irritation and acute eye irritation tests revealed that the newly synthesized polymeric biosurfactants possess excellent mildness and superior environmental compatibility as well as superior interfacial properties, indicating the potential applicability in cosmetic product formulations. The patch test has been performed with 0.1 mL of 0.5 wt% surfactant solution and the result has shown that the newly prepared polymeric biosurfactants indicated no allergic inflammation on a skin during 48 hrs. The prescription test in shampoo formulation prepared with the newly synthesized biosurfactants indicated excellent sensory feeling and foam ability compared with conventional hydrocarbon and silicon surfactants. In particular, LDP-PW(A) can be considered as a strong candidate for the potential applicability in cosmetic product formulations since the newly synthesized LDP-PW(A) polymeric biosurfactant is highly surface active, mild, nontoxic, non-irritating and readily biodegradable.

Mesogen–Containing Multi–Block Poly(ester–carbonate)s Bearing Ether Side Groups and Their Nanostructures Yuya Watanabe, Riki Kato, Kazuki Fukushima and Takashi Kato; The University of Tokyo, Japan

Aromatic condensation polymers such as poly(ethylene terephthalate) and poly(bisphenol-A carbonate) are used in the form of fibers, films, and bottles due to their mechanical and thermal stabilities. Highly aromatic polyesters are known as thermotropic main-chain liquid-crystalline polymers (LCPs), exhibiting high mechanical and thermal properties, chemical stabilities, and processability. The molecular assembly and alignment of rigid moieties, called mesogen, enable the excellent performance of the LCPs .

Aliphatic condensation polymers represented by poly(L-lactic acid) and poly(trimethylene carbonate) (PTMC) are recognized as biodegradable polymers, which can be degraded in compost and aqueous environments including body and marine with the aid of enzymes and microorganisms. These polymers have been used in medical devices such as sutures and drug delivery carriers. Side-chain functionalized analogs of these polymers have been developed to induce additional complex biological functions for applications in the fields of nanomedicine and regenerative medicine. PTMC analogs have drawn attention as the functionalized biodegradable polymers because of the variety of installable functionalities and facile accessibility in the monomer synthesis. However, the PTMC analogs with bio-related functional side chains are often flexible and have low glass transition. A PTMC analog bearing an ether side chain previously developed exhibited a high level of cell attachment and biocompatibility as well as enzymatic degradability. This polymer was a liquid material with a glass transition temperature (T_g) around –20 °C, and thus limiting its use. In the present study, we have introduced an aromatic ester triad mesogen into the backbone of the ether-functionalized PTMC analog to impart the mechanical stabilities, while maintaining the biological functions and biodegradability.

Our macromolecular design includes multi-block structures where oligocarbonate sequences with ether side chains are connected by the aromatic ester triad mesogens. The mesogen–containing multi–block condensation polymers (**P1**) were synthesized via two-step polymerization. In the first step, mesogen-containing oligocarbonates (**P2**) were obtained by ring-opening polymerization of a cyclic carbonate with an ether group, using a bis(hydroxy)-functionalized aromatic mesogen as an initiator. The mesogenic diols showed liquid-crystalline properties. The lengths of the oligocarbonates were controlled by the ratio of the cyclic monomer and the mesogen. The peripheral hydroxy groups of **P2** were then used for chain extension with adipoyl chloride to give **P1** with weight-average molecular weights over 1.0×10^5. Unlike **P2** and the original ether-functionalized PTMC analogs, **P1** exhibited elastomeric properties. Differential scanning calorimetry of **P1** only showed glass transition, indicating that they were amorphous. Polarized optical microscopy of **P1** subjected to shear suggested nanosegregation and alignment of the aromatic mesogens. Furthermore, atomic force microscopy (AFM) of **P1** revealed that **P1** formed nanosegregated structures composed of high modulus domains with approximately 10 nm in diameter, surrounded by soft matrices. Nanomechanical evaluations of the polymer surface of **P1** using the AFM technique indicated that the surface modulus of **P1** was 4-5 times higher than that of the non-mesogen-containing counterparts.

In summary, we successfully synthesized mesogen–containing aromatic/aliphatic poly(ester–carbonate)s bearing ether groups at the side chains (**P1**). The two-step polymerization using ring-opening polymerization and subsequent polycondensation gave **P1** with regulated multi-block structures. Incorporation of the aromatic ester triad mesogens into the main chain of the bio-related side-chain functionalized aliphatic polycarbonates plays an effective role in the enhancement of their mechanical properties.

Development of 2D and 1D ZnO Materials via Self-Assembly of Liquid-Crystalline Zinc Hydroxide Carbonate Takahiro Mikami[1], Riki Kato[1], Nobuyoshi Miyamoto[2] and Takashi Kato[1]; [1]The University of Tokyo, Japan; [2]Fukuoka Institute of Technology, Japan

Liquid crystals are soft materials that exhibit liquid-like fluidity and solid-like ordered structure. Various functional materials based on assembled structures of liquid crystals have been reported. The most common liquid crystals are molecular-based liquid crystals. Inorganic colloidal particles with anisotropic shapes such as rods and disks also form liquid-crystalline (LC) phases. Inspired by the formation process of biominerals such as seashells, bones, and teeth, we developed "biomineral-inspired colloidal liquid crystals". These are organic/inorganic hybrid nanoparticles with rod and disk shapes. The organic components of the colloidal liquid crystals are acidic polymers that interact with inorganic cation species, and the inorganic components are calcium carbonate or calcium phosphate. Most of the biominerals are hybrids of calcium salts and biomacromolecules, while some ants and scorpion hybridize heavy metal elements such as zinc and manganese with biomacromolecules as their stings and fangs. Inspired by these biological materials, we aim to synthesize zinc-based colloidal liquid crystals. Herein, we report the synthesis of new colloidal liquid crystals based on zinc hydroxide carbonate (ZHC) nanoplates. Oriented zinc oxide (ZnO) materials obtained through self-assembly of ZHC nanoplates and subsequent thermal treatment are also described.
The nanoplates of ZHC crystals were obtained by mixing aqueous $Zn(NO_3)_2$ and $(NH_4)_2CO_3$ solutions in the presence of poly(acrylic acid) (PAA) as an additive. The hybridization of PAA with ZHC crystals was supported by Fourier transform infrared (FTIR) spectras. The structures of the mesogenic ZHC nanoplates were clarified by transmission electron microscope (TEM) and X-ray diffraction (XRD) measurements. The TEM images showed that the nanoplates had polycrystalline structures. The cross-sectional TEM images and XRD patterns suggested a layered structure with stacked 2-nm thick ZHC nanosheets. A concentrated colloidal dispersion of ZHC showed a LC texture under polarizing optical microscope (POM). In small-angle X-ray scattering (SAXS) measurements, the LC phase showed anisotropic scattering, which suggests the presence of ordered structure in the colloidal dispersion. We assume that nanoplates of ZHC formed discotic nematic liquid crystals in their dispersions.
We have achieved the development of 2D and 1D ZnO materials by simple methods utilizing the ZHC liquid crystals. The ZHC liquid crystals were macroscopically oriented by external stimuli. Transparent ZHC self-standing thin films were obtained by sandwiching the ZHC liquid crystals between fluorinated polymer sheets and drying them at ambient conditions. The POM images and XRD analysis showed that the ZHC nanoplates were oriented and stacked along the interface of the thin-film surface during drying process. The ZHC thin films were converted to self-standing ZnO thin films by annealing. The annealed samples maintained thin-film morphologies. Out-of-plane and in-plane XRD patterns suggested the *c* axis of ZnO crystals was oriented perpendicular to the thin-film surface. A nanoporous structure due to the water evaporation and the decomposition of PAA was observed by scanning electron microscope (SEM). 1D ZnO fibrous materials were synthesized by thermal treatment of ZHC fibers prepared through injecting the liquid crystals into acetone solvent. The POM images of ZHC fibers revealed the formation of macroscopically anisotropic structures. These results suggested that the ZHC-nanoplates planes were aligned parallel to the injecting direction due to the shear stress and rapid diffusion of water into acetone. The SEM observation showed the ZnO fibers had nanoporous structures as ZnO thin films. As these 2D and 1D ZnO materials have oriented, nanoporous, and polycrystalline structures, they are expected to be used for varistors and catalyst materials.

Solvothermal Growth of Moiré Superlattices in Antimony Telluride Spiral-Type Nanoplates Robert Link, Gabriel Marcus and David Carroll; Wake Forest University, United States

Moiré superlattices (MSLs) of van der Waals (vdW) materials have been found to host emergent quantum phenomena associated with high electron correlations, and while the study of MSLs has surged in recent years, the difficulty of fabricating these structures remains high. In the present research, a one-pot, colloidal solution-liquid-solid (SLS) synthesis procedure for antimony telluride (Sb_2Te_3) spiral-type nanoplates (STNPs) is adapted to create several distinct nanostructures. In particular, Sb_2Te_3 MSLs are synthesized with observed twist angles up to 0.52°. Emphasis is given to modifications of the typical reaction procedure that lead to visible and controllable changes in the resulting nanostructures, observed primarily using Transmission Electron Microscopy (TEM). The simple and scalable synthesis methods put forward in this research hope to facilitate future investigation into the electronic properties of Sb_2Te_3 MSLs.

Facile Synthesis of Cu-Based Metal-Organic Framework/Chitosan Composite Granules as Adsorbents Jinsoo Kim[1], Van Nhieu Le[2] and Thach N. Tu[1]; [1]Kyung Hee University, Korea (the Republic of); [2]Industrial University of Ho Chi Minh City, Viet Nam

The *in situ* synthesis of metal–organic framework crystals incorporated into natural polymers is an efficient approach to manufacturing adsorbents of large size, which is convenient in terms of adsorbent handling, operating, and transportation for practical adsorption processes. Herein, CuBTC/CS (BTC = 1,3,5-benzenetricarboxylate; CS = chitosan) composite granules were successfully prepared by dispersing Cu^{2+} ions into the CS matrix before generating Cu^{2+}/CS composite beads, which subsequently grew into CuBTC crystals incorporated in the CS network. To evaluate their quality, the characteristics of the prepared composites were systematically analyzed, which were observed to be controlled by the amount of Cu^{2+} ions present in the reaction system. The highest quality material was utilized as an adsorbent for toluene uptake, which was estimated via breakthrough data. The adsorptive interaction was investigated by determining the heat of adsorption, whilst the kinetic behavior of the adsorption process was described by pseudo-first-order and pseudo-second-order models. Additionally, the mechanism of diffusion of toluene molecules into the granular adsorbent was examined in detail. Finally, to predict the adsorption behavior via the mathematical models of Yan and Thomas, the experimental breakthrough data were utilized. The herein-developed route allows granular adsorbents to be manufactured in large quantities and used in the practical volatile organic compound adsorption.

Fluorophore Self-Assembly in Liquid Crystals Abstract Mina Mandic[1,2], Kayla Winters[2], Charlotte Slaughter[2], Sophie Ettinger[2], Peter Collings[1] and Arjun Yodh[2]; [1]Swarthmore College, United States; [2]University of Pennsylvania, United States

Liquid crystals (LCs) are a state of matter, characterized by an order called the nematic phase. While past work has investigated how 5CB LC drop configuration transforms under an electric field, 5CB behavior in magnetic (B) fields is yet to be studied. This project uses the fluorophore BODIPY-C5 to visualize the transition of radial 5CB drops in response to B fields. With zero B field, radial drops with 5CB molecules arrange from the center to the edges. As the B field increases, the 5CB molecules rearrange to be aligned with the direction of the field. Similarly, drop defects (regions in which 5CB molecules do not have uniform direction) change configuration, starting as a point defect in the zero B field configuration and converts to a ring defect with an increasing B field. Fluorophores are added to topological defects formed by planar rubbing of PVA-coated substrates to stretch polymers and induce 5CB alignment. Fluorescence microscopy is used to take images of drops and quantify the intensity distribution. Preliminary results show that at zero B field, the intensity is lowest at the center of the radial drops containing the point defect. Future work will use confocal microscopy to analyze layers of drops and quantify intensity change over an increasing B field.

Flash Nanoprecipitation Synthesized Polymer Nanocapsules Yuri Chung and Edward Van Keuren; Georgetown University, United States

With advances in the development of nanoparticles, interest in multicomponent materials has grown. For example, nanocapsules, comprised of a solid shell and liquid core, have found applications in a number of technologies. One method of synthesizing nanocapsules is flash nanoprecipitation, in which a solution of a polymer and a small molecular organic liquid is injected into a rapidly stirring miscible non-solvent. As the two solvents mix, droplets of the polymer solution develop into nanocapsules; the polymer diffuses more slowly than the smaller molecules of the organic compound, forming a shell around it. An initial model of polystyrene-shelled nanocapsules with n-hexadecane liquid cores has been proven successful. The process may also be used to create nanocapsules using a variety of combinations of polymers, solvents, and organic compounds for different applications, primarily in biomedical imaging and drug delivery applications.

Biomimetically Engineered Amyloid-Shelled Gold Nanocomplexes for Discovering α-synuclein oligomer-Degrading Drugs Hyo Gi Jung, Jae Won Jang and Yonghwan Kim; Korea University, Korea (the Republic of)

The assembly of α-synuclein (αS) oligomers is recognized as the main pathological driver of synucleinopathies. While the elimination of toxic αS oligomers shows promise for the treatment of Parkinson's disease (PD), the discovery of αS oligomer degradation drugs has been hindered by the lack of proper drug screening tools. Here, we report a drug screening platform for monitoring the efficacy of αS-oligomer-degrading drugs using amyloid-shelled gold nanocomplexes (ASGNs). We fabricate ASGNs in the presence of dopamine, mimicking the *in vivo* generation process of pathological αS oligomers. To test our platform, the first of its kind for PD drugs, we use αS-degrading proteases and various small molecular substances that have shown efficacy in PD treatment. We demonstrate that the ASGN-based in vitro platform has strong potential to discover effective αS-oligomer-targeting drugs, and thus it may reduce the attrition problem in drug discovery for PD treatment.

5:00 PM SF05.07.10
Aqueous Synthesis of DNA-Nanoparticle Cluster Composites Using Various Types of Metal Ions and DNA Structures Jeesu Moon and Jae-Seung Lee; Korea University, Korea (the Republic of)

Nanoparticle clusters (NPCs) are of great interest in the field of nanotechnology owing to their distinctive properties compared to those of the single nanoparticles. To date, there have been extensive efforts to synthesize NPCs based on diverse molecular interactions. Despite the recent emergence as a new pathway to synthesize functional nanomaterials, metal ion (M^{n+})-induced DNA condensation has rarely been investigated as a tool for the synthesis of NPCs. In this presentation, we demonstrate a noble method for the synthesis of NPCs based on M^{n+}-induced condensation of linear and spherical DNA using thirty different M^{n+}s. Two types of the M^{n+}s are selected as representatives for further thermodynamic and kinetic investigation of their effects on the cluster structures of the NPCs. As a model system of clusterization, gold nanoparticles (AuNPs) are employed to elucidate the synthesis mechanism based on their advantageous properties such as intense localized surface plasmon resonance and a large atomic number of Au, ideal for optical and electron microscopic analysis. Furthermore, our approach has also been successful for the synthesis of other types of NPCs using the similar approach, proposing its effectiveness as a versatile strategy for the synthesis of NPCs.

5:00 PM SF05.07.11
Self-Assembly of Ultrahigh Porous Aramid/Poly(ether imide) Nanofibrillar Separators for Lithium-Metal Batteries Lee Donggeun and Bongjun Yeom; Hanyang University, Korea (the Republic of)

Nanoporous separators have been utilized to reduce the growth of Li dendrites for Li-metal batteries via delocalized distributions of Li ionic flux over the Li metal anode surfaces. However, the levels of the battery performances still require improvements for commercialization. Herein, we report the preparation of ultrahigh porous nanofibrillar separators with self-assembled aramid nanofibers (ANFs) with poly(ether imide) (PEI). 3-D nanoporous structures with high porosity of 95% are achieved via reprotonation-assisted self-assembly for the ANF/PEI nanofibrillar network structures. Such high porosity in the fibrillary nanostructures enables to increase ionic conductivity > 3 mS/cm. In addition, the ANF/PEI nanofibrillar separators show high Li-ion transference numbers > 0.8 that can be attributed to preferential adsorption of lithium salt on the nanofibrils and high Li ionic mobility. Combination of high Li-ion transports and delocalization of Li ionic flux via 3-D nanoporous structures enables to suppress the formation of Li dendrites on the Li-metal anodes. Li/Li symmetric cell and full-cell test results show highly stable cycle performances. Self-assembly assisted formation of the nanofibrillar network structures can be one of promising routes for the fabrications of advanced separators for energy storage devices.

5:00 PM SF05.07.13
Strain-Induced Anisotropic Alignments of Bacterial Nanocellulose Ionogels and Their Dynamic Mechanical Properties and Ionic Conductive Behaviors Wonseok Choi, Amith Abraham, Byongin Sang and Bongjun Yeom; Hanyang University, Korea (the Republic of)

Ionogels have attracted great attentions for various electrochemical applications due to their high physical and electrochemical properties. However, for practical usages, their mechanical properties and ionic conductivities still require improvements. Herein, we report anisotropically aligned bacterial nanocellulose (BC) ionogels and their dynamic mechanical properties and ionic conductive behaviors. Wet-stretching in water allows the BC nanofibers to be well-oriented throughout the films. After drying in the stretched state, the aligned BC films are obtained and the ionogels are prepared with swelling with ionic liquid of 1-ethyl-3-methylimidazolium. The aligned BC ionogels present superb mechanical properties of modulus about 5 GPa and ultimate strength of 300 MPa in the static tensile tests, majorly attributed to strengthening via anisotropic alignments of the nanofibers and molecular interactions between hydroxyl groups of glucose units. Additionally, the ionic conductivities of the ionogels are in the range of 0.12-0.45 mS cm^{-1}, even with such high values of the mechanical properties. It is possibly originated from the formation of Helmholtz-like electric double layers around the BC nanofibers that enables the fast ion transport of non-bound ions through the ionic channels. As a result, the combination of dynamic mechanical properties and ionic conductivities shows about 8.1 of E′σ values that surpass limit line value of E′σ = 5. These values were difficult to be achieved by previous ionogel materials. This approach provides the pathways to overcome the conflicts between mechanical properties and ionic conductivities for the ionogels and relevant systems.

5:00 PM SF05.07.14
Enhancing C_{2+} Products Selectivity in CO_2 Electroreduction via Metal-Organic Framework Driven Copper Nanoaggregates Sungjoo Kim[1], Dongwoo Shin[2] and Hyunjoon Song[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Due to the energy and climate issues in contemporary society, there has been an attempt to apply electrochemical CO_2 reduction reaction (eCO_2RR) into real world for converting CO_2 into value-added chemicals. Especially, copper is widely investigated for generating C_{2+} products from eCO_2RR, because of its moderate binding energy against CO* intermediate. One of the approaches for preparing copper electrocatalysts is to use metal-organic frameworks (MOFs) as precursor materials. These MOF-driven catalysts are advantageous in that their synthetic protocols are simple and possess numerous open active sites. Herein, we designed a synthetic route for nanocrystalline copper MOFs by nucleation and growth control. Then, copper oxide nanoaggregates were obtained by calcining copper MOF nanoparticles at specific temperature. The MOF driven copper oxide nanoaggregates showed improved catalytic activity on eCO_2RR, with Faradaic efficiencies of 63 and 81% at −1.01 V vs. reversible hydrogen electrode (RHE) upon ethylene and C_{2+} products, respectively. In addition, the catalysts exhibited prolonged stability up to 10 h in neutral condition. The partial current density of C_{2+} products was also able to be boosted to −255 mA cm^{-2} in alkaline flow cell configuration. Detailed analyses on the activated nanoaggregates revealed that smaller sized MOF crystals enabled the entire particles to receive thermal flux evenly at lower temperature, resulting in highly developed grain boundaries without agglomeration, which is one of the critical factors for C_{2+} products selectivity and durability in eCO_2RR catalysts.

Remote-Controllable Molecular Knob with Photochromic Chiral Dopant for Optically Tunable Devices DongMin Yu, Eunji Jang, Subin Kim, Woojin Kim, Junhwa Jang and Kwang-Un Jeong; Jeonbuk National University, Korea (the Republic of)

To fabricate the optically tunable device, photo-responsive chiral dopant (AZ_4ICD) was newly designed and successfully synthesized. AZ_4ICD is composed of photo-responsive azobenzene moiety and chiral isosorbide central core. Therefore, AZ_4ICD can be used as a remote-controllable molecular knob for the control of molecular orientation in the helical mesophases. First, the phase structures are investigated by using thermal, microscopic, and scattering analyses. Based on the experimental results, AZ_4ICD exhibits one liquid crystalline phase (SmA*) at high temperatures and two crystalline phases ($SmCr_1$ & $SmCr_2$) at lower temperatures. To find out detail molecular structures and symmetries in the ordered phases, 2D WAXD patterns are obtained at different temperatures. From the analysis of 2D WAXD patterns, the two AZ_4ICD molecules are self-assembled to the anticlinically tilted crystalline structure in $SmCr_1$ and $SmCr_2$ phases. In SmA* phase, anticlinically tilted bilayer structure transforms to the simple layered structure. Due to the photo-responsiveness of azobenzene mesogen, a photo-reversible molecular conformational change can be induced by UV and visible light. Upon irradiating UV light, the uniaxially oriented SmA* phase is transformed into an isotropic phase by *trans*-to-*cis* isomerization of AZ_4ICD. The isotropic phase is returned to the SmA* phase in the absence of UV irradiation, and this process can be accelerated by irradiation of visible light. AZ_4ICD dopant exhibits good compatibility with the nematic LC host (E7) due to the mesogenic properties of azobenzene and its side chain. To fabricate a chiral nematic (N*) thin film, the mixture composed of chiral dopant R811, AZ_4ICD, and E7 was injected into the sandwich cell. The chirality is inversely proportional to the *trans*-to-*cis* photoisomerization of AZ_4ICD, indicating the helical pitch is controlled by the UV and visible light irradiation. Another chiral mesophase that normally formed between N* and Iso phase is called by blue LC phase (BP). As the content of AZ_4ICD in the BP mixture increases, the temperature range of BP is expanded. To further investigate the photoisomerization behavior of AZ_4ICD in a 3D helical superstructure, a BP film was also prepared. Under irradiation with UV, the double twisted cylindrical alignment of BP building block is broken by the metastable *cis*-AZ_4ICD molecules. Such N* and BP films can induce the reversible phase transformation and change of reflected color without any degradation. The AZ_4ICD LC films with remote-controllable molecular knob can provide a lot of opportunities in the various applications. This work was supported by the BK21 FOUR, Mid-Career Researcher Program (2021R1A2C2009423) and Basic Research Laboratory Program (2020R1A4A1018259).

5:00 PM SF05.07.17

Norbornene-Based Dendronized Polymer with Azobenzene for Remote-Controllable Switches Mintaek Oh, Youngjae Wi, Jaeseok Hyeong, DongMin Yu, Sanghee Kim and Kwang-Un Jeong; Jeonbuk National University, Korea (the Republic of)

For the fabrication of remote-controllable switches, we newly designed and successfully synthesized norbornene-based macromonomers. The macromonomer consists of hydrophilic linkers, photochromic azobenzene mesogens, and hydrophobic alkyl chains. Hydrophilic ethylene oxide linker and hydrophobic alkyl chain were introduced to form an ordered structure by π- π interaction. Azobenzene mesogens were introduced to fabricate photoresponsive actuators. The azobenzene-based dendronized polymer (AZ-P) were polymerized by ring-opening metathesis polymerization (ROMP) to prepare high molecular weight and low polydispersity index (PDI). The high molecular weight (Mn = 173 kDa) with low polydispersity (PDI = 1.05) was confirmed by size exclusion chromatography (SEC) trace of the polymer. The photochemical properties were investigated by ultraviolet and visible light spectroscopy (UV-Vis). The initial π-π* absorption represented *trans*-rich state of azobenzene. When exposed to 365 nm UV light and 450 nm Visible light, reversible photoisomerization was confirmed through an increased π-π* and n-π* absorption peaks, respectively. We analyzed thermal phase behaviors of the AZ-P and three different phases (SmF, SmC and SmA) were identified through differential scanning calorimetry (DSC) thermograms and polarized optical microscopy (POM) images of the finally synthesized azobenzene-based polynorbornene. Uniaxially oriented AZ-P films were prepared by mechanical shearing process. The ordered packing structures were investigated through small-angle X-ray scattering (SAXS) and wide-angle X-ray diffraction (WAXD) at different temperatures. 1D SAXS and WAXD patterns indicated that the order is lowered as the temperature decreased, and the side chains are packed closely in the layers. The detailed molecular packing structures were investigated through two-dimensional wide-angle X-ray diffraction (2D WAXD), resulting that the backbones were arranged perpendicular to the film normal (FN) and the side chains were oriented parallel to FN, tilted as the temperature decreased. Irradiation of UV and visible light to the AZ-P film resulted in *trans*-to-*cis* isomerization indicating photodynamic reversible behaviors. When UV light was exposed to the film, it becomes a *cis*-rich state by *trans*-to-*cis* isomerization in the light source direction and actuated by anisotropic volume contraction. In order to impart electrical conductivity, silver layer was coated on the AZ-P film and an electrical circuit was formed to fabricate wireless switches by light. When a film was exposed to UV light, it was bent by photo-induced actuation and the electric circuit switched with the light-emitting diode (LED) color changes. Upon irradiation of visible light, the film returned to its original shape and switched to the initial electric circuit and LED color. As a result, the AZ-P film has shown that it can be used as remote-controllable switches, and the photoresponsive azobenzene denpol will be practical in remote-controllable devices. This work was supported by the BK21 FOUR, Mid-Career Researcher Program (2021R1A2C2009423) and Basic Research Laboratory Program (2020R1A4A1018259).

5:00 PM SF05.07.18

Uniaxial Alignment of Discotic Liquid Crystal for Heat Dissipating Materials with High Thermal Conductivity Youngjae Wi, DongMin Yu, Jaeseok Hyeong, Eunji Jang, Sanghee Kim and Kwang-Un Jeong; Jeonbuk National University, Korea (the Republic of)

For the development thermal management system in the electronic, display, and automobile industries, high heat transfer property is required. In this research, triphenylene-based liquid crystal reactive discogen (LCRD) monomers containing the vinyl and thiol functional groups were newly synthesized for the heat transfer materials with enhanced thermal conductivity. The LCRD mixtures exhibits columnar liquid crystal phase by self-assembly of doscogen, and those phases were fixed by photopolymerization. Based on POM and DSC, the phase of mixture was measured according to temperature and composition of vinyl monomers. The mixture had various phase under each condition. The 50vinyl-50thiol mixture (1:1 molar ratio) at 80 °C show the isotropic structure and tilled hexagonal columnar structure coexist. Under this condition, the LCRDs were polymer-stabilized by irradiating 365 nm UV light for 1 h. After polymerization, the network morphology of the fabricated LCRD films was identified. Through POM, it was confirmed that the dark area and the birefringent area coexist in the film. This means that the isotropic domains are percolated the liquid crystal matrix. In-plane thermal conductivity of the LCDR films produced by curing at different temperatures was measured and compared at room temperature by the transient plane source technique. The LCDR film in which the isotropic structure and hexagonal columnar structure coexist show thermal conductivity up to 1.09 W/mK. This value is higher than conventional heat dissipating organic materials, high density polyethylene, calamitic liquid crystal organic materials. The high thermal conductivity of the LCRD film due to the ordered structure by self-assembly and the hexagonal lattice structure of triphenylene core. The alignment of the columnar structure in the film was controlled by magnetic field for higher thermal conductivity than the previously prepared film. The LCRD films were fabricated using a static magnetic field and a rotating magnetic field, respectively. The columnar axes oriented using a static magnetic field were perpendicular to the direction of magnetic field but not aligned in the one direction. To solve this problem, a rotating magnetic field was used. It was realized through 2D WAXD that the columnar axes of LCRDs were aligned perpendicular to the direction of magnetic field and one direction. The uniaxially oriented LCRD film exhibits enhanced thermal conductivity normal to the columnar axis. The oriented film along the transverse direction of the film plane shows higher thermal conductivity than the aligned film along the longitudinal direction of the film plane and the film without magnetic and field up to 3.00 W/mK. High thermal conducting properties as well as excellent mechanical and chemical stabilities of LCRD films make them possible to be effectively available for heat management organic materials. Optically Controllable Secret Ink Based on Kinetics of Supramolecular Structure Junhwa Jang, Jaeseok Hyeong, Subin Kim, Woojin Kim, Kwang-Un Jeong and Sanghee Kim; Jeonbuk National University, Korea (the Republic of)

Simultaneous manipulation of both fluorescence and transparency of organic fluorescent materials is one of the biggest challenges in various fields such as security inks, memory devices, organic light-emitting displays, and biomedical imaging. Conventionally, the development of materials with transparency and fluorescence has been made by mixing nano-sized fluorescent particles with transparent amorphous polymers. However, this production process has limitations such as the heterogeneous dispersion of fluorescent particles and the low fluorescence intensity from the low fluorescent substance loading. To solve this problem, we newly designed and synthesized a monopyrene-based dendron (abbreviated as MD) molecule that has both transparency and fluorescence. MD is a molecule in which three alkyl chain groups are linked by amide bonds to monopyrene. Because of the strict distinction between the solvophilic alkyl dendrons and the solvophobic pyrene groups, we predicted that MD molecules would assemble a hierarchical superstructure at the molecular level. To confirm our hypothesis, we conducted morphological analysis via both scanning calorimetry (DSC) and cross-polarized optical microscope (POM). Interestingly, it was confirmed that when there was insufficient time for molecular assembly a metastable crystalline phase (C_{ms}) appeared, and when there was sufficient time a stable crystalline phase (C_s) appeared. In addition, if the quenching process is performed with little time for assembling molecules, an optically transparent crystalline phase (C_t) is obtained. Surprisingly, the supramolecular structure of C_t was equal to C_{ms}. To confirm the molecular packing of the polymorphic MD superstructure in more detail, the molecular packing structures of C_s and C_{ms} were investigated with wide angle X-ray diffraction (WAXD) and transmission electron microscope (TEM). As a result, when the assembly time of molecules in a thermodynamic equilibrium state is sufficiently provided, stable C_s is a fully packed layered structure where a dimeric building block is assembled. In the opposite case, metastable C_{ms} is a layered structure where the head-to-head dimers are alternatively interdigitated. Furthermore, the optical properties of MD had a significant change due to the polymorphic superstructure induced by the balance between intermolecular interactions and nanophase separation. These optical properties were identified by transmittance and photoluminescence (PL) measurement. In addition, to control organic materials with transparency and fluorescence, the optical properties of MD were evaluated under various external stimuli such as solvent fuming, and thermal annealing. The transparent fluorescent superstructure of MD under UV and visible light was constructed by the quenching process. Because the supramolecular structure was changed by the fuming and annealing processes, the MD materials became opaque, and the fluorescence wavelength shifted. Based on the previous results, it was found that the transparency and fluorescence of MD were controlled by molecular packing kinetics as well as external stimuli. Our research highlights that the optically controllable smart materials were available as secret ink. The letter was written in an isotropic state using secret ink and quenched. Encrypted letters were not visible in daylight but, were easily observed under UV light. However, Secret letters could be observed with the naked eye through fuming and annealing processes. Also, the decrypted letters can be converted back into the initial state by manipulating the molecular packing structure of a fluorescent molecule via kinetic control. This work was supported by the BK21 FOUR, Mid-Career Researcher Program (2021R1A2C2009423), and Basic Research Laboratory Program (2020R1A4A1018259).

5:00 PM SF05.07.20
Planarity Control of Porphyrin Based Supramolecules for Enhanced Thermal Conductivity Jaeseok Hyeong, DongMin Yu, Eunji Jang, Subin Kim, Woojin Kim and Kwang-Un Jeong; Jeonbuk National University, Korea (the Republic of)

As heat management becomes more important in the electronics industry, many researchers have tried to improve the low thermal conductivity of organic materials used in flexible and miniaturized devices. In this regard, many researches have enhanced thermal conductivity of soft materials through utilizing the mesogen with the extended π-conjugated length or increasing crystallinity. However, there are not enough studies on enhancing and adjusting the thermal conductivity of polymers by deep understanding the correlation between the supramolecular packing structure and thermal properties. For this kind of study, porphyrin-based reactive metallomesogens (PBRM-n; n= -2H, -Ni, -Cu, - Zn) were newly designed and synthesized. Porphyrin core is purposely selected due to the extended π-conjugated aromatic chemical structure and easy metal-substitution. Its substitution with different metals changes the molecular planarity, which can induce the different molecular packing structure and thermal conductivity. Based on thermal and scattering analyses, it is realized that PBRM-2H exhibits discotic columnar hexagonal structure that is tilted and obliquely stacked without π-π stacking. PBRM-Ni has discotic columnar hexagonal structure without π-π stacking. On the other hand, PBRM-Cu, and Zn exhibit columnar rectangular structure with π-π stacking. When we confirm the energy-minimized core geometry of PBRM-n compounds in the isolated gas phase by using molecular simulation and the measured macroscopic property, the tilted angle from molecular horizontal plane depending on the substituted metal atoms is 5.4°, 17°, 8.8°, 3° (PBRM-2H, -Ni, -Cu, and Zn, respectively). It indicates that PBRM-Zn has relatively small distortion because Zn atom matches well in the hole of the porphyrin core. Therefore, PBRM-Zn could have dense molecular packing structure and higher crystallinity than other species. PBRM-2H has relatively high planarity in the isolated gas phase, but it has a mesomorphic structure due to its large in-plane distortion in the solid state, resulting in relatively loose molecular packing and low crystallinity. PBRM-n films were prepared by irradiating UV light at 50 °C for 2 hours and then their thermal conductivity and several stabilities were evaluated. The fabricated PBRM-n films have no micro voids in the cross-section and endure scratch up to 2H (hardness). In addition, PBRM-n films show good chemical stability in various organic solvents and are thermally stable up to 350 °C due to polymer network structure. The thermal conductivity of PBRM-n films is measured to be 0.88, 1.02, 0.97, and 1.2 $Wm^{-1}K^{-1}$ (PBRM-2H, -Ni, -Cu, and -Zn, respectively). It is realized that the PBRM-Zn film has the highest thermal conductivity (1.2 $Wm^{-1}K^{-1}$) due to the flattest porphyrin core and high crystallinity. As a result, this study proves the importance of understanding the correlation between chemical structure, chemical conformation, supramolecular packing and thermal conductivity when we develop advanced thermal interface materials. This work was supported by the BK21 FOUR, Mid-Career Researcher Program (2021R1A2C2009423) and Basic Research Laboratory Program (2020R1A4A1018259).

5:00 PM SF05.07.21
The Development of Smart Window Stabilized by Polymer Walls and Liquid Crystal Physical Gels Eunji Jang, Subin Kim, Woojin Kim, Junhwa

Jang, Mintaek Oh and Kwang-Un Jeong; Jeonbuk National University, Korea (the Republic of)

Liquid crystal (LC) smart windows are attractive technology because they can protect privacy as well as control indoor environments by switchable electro-optical properties. However, conventional LC smart windows require a high driving voltage and nematic LC (NLC) in LC smart windows can leak when severe mechanical stimuli are applied. Therefore, we newly developed a dual stabilization (DS) process to fabricate mechanically stabilized LC smart windows which operate at a lower voltage than conventional LC smart windows.
The DS cell was fabricated with two components. The first one is composed of NLC (5CB) and macrogelator with photoisomerizable azobenzene moiety (BTAG) for the formation of liquid crystal physical gel (LCPG). The other component is composed of photopolymerizable low molecular weight monomers (LMWM) for the construction of partition walls. The DS process is performed by irradiating UV light under a photomask. Upon irradiating UV light on the DS cell, LMWMs in the UV light-exposed region are polymerized. Because of the concentration gradient, LMWMs move from the UV light-protected region to the UV light-exposed region resulting in the construction of partition walls. At the same time, BTAG molecules in the UV light-exposed region are photoisomerized from *trans*-isomers to *cis*-isomers resulting that the 3D network structures which are formed by intermolecular hydrogen bonding between BTAG are collapsed. The *cis*-isomers move to the UV light-protected region by the concentration gradient of the macrogelator, resulting in the formation of physical 3D networks.
The electro-optical properties of the DS cell were investigated for smart window application. The DS cell is opaque due to the mismatch of the refractive index between the randomly dispersed NLC domains. Under the electric field, the NLC molecules are homeotropically aligned because the 5CB has a positive dielectric anisotropy. Thus, the mismatch of the refractive index is disappeared, and the DS cell turns transparent. When the electric field is removed, the NLC molecules are randomly dispersed in the LCPG domain again, and the DS cell returns to the opaque state. According to the voltage-dependent transmittance curves, the driving voltage of the DS cell is lower than the conventional smart windows.
To demonstrate this phenomenon, the DS cell was observed by polarized optical microscopy (POM) equipped with a quarter-wave plate. Unlike the randomly dispersed NLC molecules, the NLC molecules near the partition wall are homogeneously aligned. Hence, the NLCs in the LCPG domain can be easily reoriented at low voltage.
To confirm the mechanical stability, we fabricated a flexible DS smart window with the partition wall in the ITO-coated polyethylene terephthalate (PET) films. Because the partition wall improves the adhesion between the flexible films as well as serves as spacers, the flexible DS smart window is mechanically stable even if external stimuli such as pressing, cutting, and bending are applied. In conclusion, the dual stabilized LC smart window by the partition wall not only operates under a low voltage but also has excellent mechanical stability. This work was supported by the BK21 FOUR, Basic Research Laboratory Program (2020R1A4A1018259), and Mid-Career Researcher Program (2021R1A2C2009423).

5:00 PM SF05.07.22
Controlling the Orientation of Liquid Crystal for Thermal Managing Materials Subin Kim, Woojin Kim, Junhwa Jang, Mintaek Oh, Youngjae Wi and Kwang-Un Jeong; Jeonbuk National University, Korea (the Republic of)

With the integration and miniaturization of electronics, the demand for thermal managing materials (TMM) that effectively dissipate the problematic heat has continuously increased. Much research has been conducted for composite materials consisting of high thermal conductive additives. But the limitation of processability with using large amounts of fillers makes it difficult to develop the advanced TMMs due to the intrinsic low thermal conductivity of organic polymer matrix. Therefore, improving the thermal conductivity of organic polymers can be an effective strategy for developing thermal conducting materials with a small amount of filler. In this study, a liquid crystal monomer (LCM) was newly synthesized for the fabrication of thermal conducting polymer (TCP) films which can be applied to the advanced TMMs. Based on thermal and structural analyses, it was realized that the synthesized LCM exhibited a smectic A mesophase. By using temperature-dependent properties of LCM, TCP films were fabricated at both liquid crystal and isotropic phases using photopolymerization process. Due to the mesogenic core of LCM which has a highly ordered lattice structure providing high phonon transfer pathway, photopolymerized TCP films show outstanding thermal conductivity over 1 W/mK regardless of the molecular self-assembly structure. Moreover, the heat transfer performance of TCP films can be further enhanced in a certain direction by controlling the orientation of LCM molecules in liquid crystal network. The uniaxially oriented TCP film can be fabricated by polymerizing under the magnetic field at Liquid crystal state. Due to the high intermolecular interaction of the LCM which forms the liquid crystalline domain at liquid crystal state, the magnetic coupling energy can overcome the thermal motion that disordering the molecular alignment. The uniaxially oriented TCP film exhibited outstanding thermal conducting property which was estimated to be 2.5 W/mK along the liquid crystal director. To compare the thermal conductivity of the polymeric films according to the molecular orientation, the TCP films were monitored using an infrared (IR) camera. Thermal imaging demonstrated that polymeric films with highly ordered lattice structure show improved heat-conducting performance. In addition, the anisotropic liquid crystal network in magnetically aligned TCP film can remarkably dissipate heat along the long axis of the mesogenic core. Therefore, TCP films with high thermal conducting properties can be applied as advanced thermal management materials. This work was supported by the BK21 FOUR, Mid-Career Researcher Program (2021R1A2C2009423) and Basic Research Laboratory Program (2020R1A4A1018259).

5:00 PM SF05.07.23
Multichromatic Polarizer Using Redox Responsiveness Woojin Kim, Junhwa Jang, Mintaek Oh, Youngjae Wi, Sanghee Kim and Kwang-Un Jeong; Jeonbuk National University, Korea (the Republic of)

For developing multichromatic thin films, perylenediimide-methacrylic anhydride (PMA) was newly designed and synthesized. Conjugation system of PMA core can be reversibly changed by redox responsiveness because the imide groups can stabilize the radical anions. This reversible change of conjugation system causes the shift of the absorption wavelength band of PMA core. Then, the PMA solution’s color changes from red to dark purple because the reduced PMA mostly absorbs all the wavelength of visible light. When the reduced PMA solution is exposed to oxygen or polarized on anode, the solution’s color returns to red because the oxidized PMA specifically absorbs absorption band at $\lambda = 500$ nm. Another characteristic of PMA core is suitable for anisotropic optical properties because of its high dichroic ratio. But, in generally, perylendiimide-based molecules have low solubility in both polar and nonpolar solvents due to strong intermolecular π-π interaction. In addition, stability of organic molecules is essential in various circumstance for application feasibility. So, Introduced ionic groups and polymerizable groups at perylenediimide core improve the solubility for process and impart the stability through polymerization. Based on the results of X-ray diffraction and polarized optical microscopy, it was confirmed that the PMA molecule exhibits a lyotropic chromonic liquid crystal (LCLC) phase which is composed of both attractive force (π-π interaction and lateral correlation between perylenediimide core) and repulsive force (between ammonium bromide). To fabricate the multichromatic PMA polarizer, PMA solution was coated on transparent substrate by mechanical shearing and then photopolymerized. The polymerized PMA polarizer exhibits excellent mechanical strength and chemical resistance in both acidic and basic solution than unpolymerized state. Spectroscopic and optical properties of fabricated PMA polarizer was confirmed by ultraviolet-visible spectroscopy and polarized optical microscopy. The results of ultraviolet-visible spectroscopy show that when the polarization direction and shear direction are parallel state, the transmittance is higher than when they are perpendicular state. PMA polarizer shows the characteristic of E-type polarizer which absorbs only the ordinary wave at $\lambda = 500$ nm and transmits the extraordinary wave. Thus, the polarized optical microscopy images show the color of the transmitted light presents red image when the polarization direction is perpendicular to shear direction. On the other hand, colorless and transparent state present when the polarization direction is parallel to shear direction. These characteristics show the manufactured PMA polarizer can be applied to sign encryption as well as multichromatic smart window. This work was supported by the BK21 FOUR, Mid-Career Researcher Program (2021R1A2C2009423) and Basic Research Laboratory Program (2020R1A4A1018259).

Non-Covalent Reconfigurable Microgel Colloidosomes with a Well-Defined Bilayer Shell Xin Guan and To Ngai; The Chinese University of Hong Kong, Hong Kong

Microgels have been successfully used to stabilize emulsion droplets. Compared to conventional rigid particles, the use of microgels as stabilizers offers several distinct advantages: (1) being soft and porous, they become deformed and flattened at the oil-water interface. The deformability of the particles makes it possible to achieve larger interfacial loading, which in turn alters the interfacial tension and the rheological properties of the interface; (2) being responsive, microgels allow one to prepare emulsions that can be triggered by environmental stimuli, which is especially desirable in industrial and emerging applications.

Whilst soft microgels have been demonstrated as being extremely interesting stabilizers for emulsions, previous studies mainly focused on the preparation of oil-in-water (O/W) emulsions due to their intrinsic hydrophilicity and thus initially dispersed in water. Very few studies have reported on the preparation of water-in-oil (W/O) emulsions using microgels as the sole emulsifier. In addition, there have been no attempts to control over microgel-assembled structure at the interface, thus limiting our ability to exploit particle monolayers or bilayers more broadly in advanced materials applications. On the other hand, the rheological properties of colloidal bilayers from soft particles self-assembled at interfaces to resulting emulsion characteristics, have not been explored yet.

In this work, we show that by introducing octanol into poly(*N*-isopropylacrylamide-*co*-methacrylic acid) (PNIPAM-*co*-MAA) microgels, octanol-swollen microgels can rapidly diffuse from the initially dispersed oil phase onto the water droplet surface. This facilitates the formation of microgel-laden interfacial layers with strong elastic responses and also generates stable inverse W/O Pickering emulsions. More importantly, these emulsions can be used as templates to produce microgel colloidosomes, herein termed 'microgelsomes', with shells that can be fine-tuned from a particle monolayer to a well-defined bilayer consisting of self-assembled binary microgels with opposite charges via non-covalent interaction. The microgelsomes can then be used to encapsulate and/or anchor nanoparticles, proteins, vitamin C, bio-based nanocrystals or enzymes. Moreover, the programmed release of these substances can be achieved by using ethanol as a trigger to mediate the shell permeability. Thus, these reconfigurable microgelsomes with a microgel-bilayer shell can respond to external stimuli and demonstrate tailored properties, which offers novel insights into microgels and promise wider application of Pickering emulsions stabilized by soft colloids.

5:00 PM SF05.07.25
A New Methodology for the Reproducible Elaboration of SiO_2-Based Colloid Crystals as a Template for Inverse Opals Structures Federico Fookes[1,2], Luis Polo-Parada[1] and Maria M. Fidalgo de Cortalezzi[1]; [1]University of Missouri-Columbia, United States; [2]INTEC-CONICET, Argentina

Photonic crystals (PCs) are nanomaterials with photonic properties made up of periodically modulated dielectric materials that reflect light between a wavelength range located in the photonic band gap. Colloidal PCs (C-PC) made from monodisperse nanoparticles have been employed in coatings, films for surface-enhanced Raman scattering, chromatographic columns packing, and reflectometric interference spectroscopy. Additionally, C-PC have been studied as sacrifice templates to create inverse opals (IO) employing inorganic, organic, metallic, and ceramic materials, which are exact inverse replicas of C-PC structures and therefore maintain their optical properties. Several manufacture techniques have been applied for the fabrication of C-PC that involve the self-assembly of monodisperse colloidal particles by spin and spray coating, interfacial assembly and inkjet printing, sedimentation, or vertical deposition. In practice, due to its simplicity, C-PC crystals based on convective particle aggregation are elaborated either by the method of convective assembly by solvent volatilization or vertical lifting deposition. Although capable of producing good quality crystals, these methods have low uniformity between deposits in terms of thickness, and reflectance spectrum characteristics, most likely due to slight variations in temperature, humidity, arrangement geometry and particle suspension properties that influence the outcome.
In this work, a robust protocol for the elaboration of photonic crystals based on SiO_2 particles (SP) deposition using vertical lifting method was studied. A wide range of lifting speed and particles suspensions concentration were investigated by evaluating C-PC reflectance spectrum key parameters such as maximum reflectance (% R max), wavelength at % R max, and reflectance peak full width at half maximum (FWHM). The experimental conditions that led to the best performance were selected and employed for reproducibility tests.
Thinner and higher reflectance peaks were obtained with a decrease in the lifting speed and an increase in the SP concentrations up to certain values. Seven batches of 12 C-PC employing a SP 3 % suspension and a lifting speed of 0.28 μm/s were prepared to test the reproducibility of this method. Every C-PC fabricated in this assay have a wavelength peak in a range between 528 and 538 nm and a FWHM lower than 90 nm. IO polymeric films with a highly porous and interconnected morphology were obtained using the developed C-PC as a template. In the current work, we found the optimized conditions that allows to fabricate reproducible colloidal crystals that could be prepared in a large scale and a short period of time employing a simple device. These findings provide a step forward to scale-up to the fabrication of C-PC, 3D microporous structures, and IOs as those employed for the elaboration of photonic polymeric sensors.

SESSION SF05.08: Self-Assembly II

The Influence of Molecular Design on Structure-Property Relationships of a Supramolecular Polymer Prodrug Nivedina Sarma, Kelsey DeFrates, Ahmad Omar and Phillip B. Messersmith; University of California, Berkeley, United States

Supramolecular self-assemblies of hydrophilic macromolecules functionalized with hydro-phobic, structure-directing components have long been used for drug delivery. In these systems, loading of poorly soluble compounds is typically achieved through physical encapsulation during or after formation of the supramolecular assembly, resulting in low encapsulation efficiencies and limited control over release kinetics, which are predominately governed by diffusion and carrier degradation. To overcome these limitations, amphiphilic prodrugs that leverage a hydrophobic drug as both the therapeutic and structure-directing component can be used to create supramolecular materials with higher loading and controlled-release kinetics using biodegradable or enzymatically cleavable linkers. Here, we report the design, synthesis, and characterization of a library of supra-molecular polymer prodrugs based on poly(ethylene glycol) (PEG) and the proregenerative drug 1,4-dihydrophenonthrolin-4-one-3-carboxylic acid (DPCA). Structure–property relationships were elucidated through experimental characterization of prodrug behavior in both the wet and dry states using scattering techniques and electron microscopy andcorroborated by coarse-grained modeling. Molecular architecture and the hydrophobic-to-hydrophilic ratio of PEG–DPCA conjugates strongly influenced their physical state inwater, ranging from fully soluble to supramolecular spherical assemblies and nanofibers. Molecular design and supramolecular structure, in turn, were shown to dramatically alter hydrolytic and enzymatic release and cellular transport of DPCA. In addition to potentially expanding therapeutic options for DPCA through control of supramolecular assemblies, the design principles elaborated here may inform the development of other supramolecular prodrugs based on hydrophobic small-molecule compounds.

8:15 AM SF05.08.02
Probing Self-Assembly Pathways in Solvent Vapor Annealed Block Copolymer/Homopolymer Blends Gregory S. Doerk[1], Ashish Kulkarni[1], Susrut Akkineni[2,3], James J. De Yoreo[2,3], Ruipeng Li[1], Semih Cetindag[1], Beatrice Bellini[4,1], Sanat Kumar[4] and Jasmine Willard[5]; [1]Brookhaven National Laboratory, United States; [2]University of Washington, United States; [3]Pacific Northwest National Laboratory, United States; [4]Columbia University, United States; [5]Alfred University, United States

The self-assembly of block copolymer (BCP) thin films into ordered nanopatterns by microphase separation can be used to create designer functional materials, from optical metasurfaces to ultrafiltration membranes. The sluggish kinetics of macromolecular assembly, however, impedes its real-world implementation as a practical manufacturing method. Solvent vapor annealing and blending BCPs with low molecular weight homopolymer (HP) plasticizers synergistically speed up self-assembly, while solvent-HP interactions alter the free energy landscape in unexpected ways. Using *in situ* characterization during solvent vapor annealing of BCP/HP blends by grazing incidence small-angle X-ray scattering (GISAXS), we have shown that interactions of very short (~3 kg/mol) polystyrene (PS) and poly(methyl methacrylate) (PMMA) HPs with weakly selective tetrahydrofuran solvent vapors can promote the formation of highly-ordered metastable morphologies in an ultrahigh molecular weight (> 1000 kg/mol) PS-block-PMMA BCP [1]. On the other hand, solvent vapor annealing using acetone, a PMMA-selective solvent, results in assembled morphologies that align more closely with expectations based on the overall volume fraction of PS and PMMA. We hypothesize that the blended HP, untethered to domain interfaces, effectively enhances BCP dilution or segregation depending on the solvent selectivity. These metastable nanopatterns are readily transferred into other materials such as silicon, which we use in combination with a novel irradiation-controlled thermal reflow technique to fabricate structural color patterns [2]. Finally, we introduce a prototype spraying instrument designed to enable dynamic control over solvent-polymer interactions for directing self-assembly along specific pathways.

Self-Assembling Polymer-Directed Hierarchical Porous Structures for Low Carbon Solutions Kwan W. Tan; Nanyang Technological University, Singapore

Hierarchically porous structured materials with multifunctional properties and higher order dimensional complexities are highly desirable for many applications. In this talk I will describe our recent synthesis approaches of directed–self-assembly with block copolymers to generate well-organized porous hierarchically ordered structures of amorphous polymers/carbon, polycrystalline ceramics as well as single-crystal semiconductors. New understanding and control in the formation pathways of self-assembled materials via rapid nonequilibrium synthesis routes will be discussed. Such advanced functional self-assembly-derived materials are of fundamental and technological relevance for emerging low-carbon technologies, e.g., solid-state carbon dioxide adsorbents, separation, energy conversion and storage.

9:00 AM SF05.08.04
Control of Macroscopic Polymer Mechanics through Supramolecular Nanostructure Hyunchang Park[1,2] and Jiheong Kang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Stanford University, United States

Nature utilizes supramolecular architectures to sustain life. One significant role thereof is to resist external stimuli including mechanical stress and damage. The programmed assembly of biopolymers into the supramolecular structures enables precise control of macroscopic properties and leads to superior functions including mechanical toughening and self-healing. Such supramolecular structures are constructed by the elaborate arrangement of chemically imprinted non-covalent bonds in biopolymers. In the case of synthetic polymeric materials, however, it is challenging to implement stable supramolecular structures in the condensed polymeric matrix where molecular motion is highly restricted. In this study, we have proposed a new strategy to incorporate well-defined supramolecular nanofibers into the polymer matrix and clearly demonstrated the effect of the fibers on the macroscopic mechanical and dynamic properties. We employed flexible PDMS (polydimethylsiloxane)-based polymers with periodically positioned urea functional groups and different structural flexibility around the urea motifs. With low flexibility, the consecutive hydrogen bonding between urea motifs is less feasible due to the limited chance of physical contacts. In contrast, strong consecutive hydrogen bonding can be achieved by high structural flexibility, which enables the growth of stable, robust, and well-defined supramolecular fibers even in highly entangled polymer matrix. The formation of supramolecular fibers in the polymer with high structural flexibility was confirmed by AFM imaging, X-ray scattering, and UV-vis spectroscopic studies. This polymer having rich supramolecular fibers shows higher elastic modulus, compressive strength, and more solid-like behavior compared to the polymer without supramolecular structure, despite the subtle differences in the chemical structure and molecular weight. More intriguingly, we found that selective and orthogonal self-healing takes place when the fibers are embedded in the polymer matrix, which means the fibers recognize each other. To the best of our knowledge, this is the first example of macroscopic self-sorting in self-healing process. We anticipate that our design strategy modulating the structural flexibility around dynamic bonding will provide new insights into the development of versatile, multi-functional supramolecular polymeric materials.

9:15 AM SF05.08.05
Multifunctional Structural Carbon Fiber Composites Using Macropore-Infused Nanocomposite Emulsion Thermosets (MINETs) Yogin Patel, Rituparna Mohanty, Charm Nicholas and Jonathan P. Singer; Rutgers, The State University of New Jersey, United States

Acknowledgement: ONR N00014-21-1-2605
Macropore-infused nanocomposite emulsion thermosets (MINET) are a new class of nanocomposites made from epoxy, nanoparticles, a liquid porogen, and a small quantity of surfactant. These ingredients form an intermediate between a conventional surfactant and a Pickering emulsion to create a bicontinuous network of oil and epoxy composite throughout the processing. After a room temperature cure and usage of different functional nanoparticles, selected based on the performance requirements of a given application, it is possible to design a composite with a range of functionalities, including flexibility, inertness, and electrical/thermal conductivity. By further extraction of the oil phase through rinsing, MINETs can be converted into porous (30~60% open volume) structures without considerable volume shrinkage (~1~5%). The pore size (between 100~10,000 nm) and chemical functionality of the pores is tunable by the constituent nanoparticles, allowing for, for example, hydrophilic or hydrophobic pore surfaces or the incorporation of antimicrobial particles. Simultaneously, the matrix resin can change mechanical properties and use of silicone nanoparticles as a filler can establish flexible behavior. These novel thermosets molded into centimeter to micrometer scale structures that possess interconnected pore networks through the entire

component.
Here, we explore the integration of MINETs into carbon fiber composite (CFC) structures. CFCs are widely used in aerial vehicles due to their low density and high strength. We have developed carbon fiber composites with MINET as a replacement for the resin matrix. Multiple functionalities can be introduced on the same part due to the viscosity of MINET materials and through use of a common resin backbone, which allows the spatial selection of particulate function. Using these MINET materials in combination with CFCs will allow for the selection of desired multifunctionality. Each target functionality requires co-optimization of the mechanical properties of the resulting composite along with the target additional functionality. This process necessitates new fundamental understanding of each component of the MINET blend along with their interaction with each other and with the CFC. As one example, MINETs created with graphene particles can possess electrical conductivities of up to ~10 S/m, which is promising for RF shielding and energy storage applications; however, the co-optimization of processability requires that the samples also have favorable viscosity for molding with carbon fiber, leading to usable conductivities of ~1 S/m. The net outcome of this combination of materials will be a new platform for incorporating multifunctionality in future aerospace structures.

9:30 AM SF05.08.06
Frontal Polymerization-Triggered Simultaneous Ring-Opening Metathesis Polymerization and Cross Metathesis Affords Anisotropic Macroporous Dicyclopentadiene Cellulose Nanocrystal Foam Jinsu Park[1] and Seung-Yeop Kwak[1,2,3]; [1]Seoul National University, Korea (the Republic of); [2]Research Institute of Advanced Materials (RIAM), Seoul National University, Korea (the Republic of); [3]Institute of Engineering Research, Seoul National University, Korea (the Republic of)

Multifunctionality and effectiveness of macroporous solid foams in extreme environments have captivated the attention of both academia and industries. The most recent rapid, energy-efficient strategy to manufacture solid foams with directionality is the frontal polymerization (FP) of dicyclopentadiene (DCPD). However, there still remains the need for a time efficient one-pot approach to induce anisotropic macroporosity in DCPD foams. Here we show a rapid production of cellular solids by frontally polymerizing a mixture of DCPD monomer and allyl-functionalized cellulose nanocrystals (ACs). Our results demonstrate a clear correlation between increasing % allylation and AC wt%, and the formed pore architectures. Especially, we show enhanced front velocity ($\mathbf{v}_f$) and reduced reaction initiation time (t_{init}) by introducing an optimal amount of 2 wt% AC. Conclusively, the small- and wide-angle X-ray scattering (SAXS, WAXS) analyses reveal that the incorporation of 2 wt% AC affects the crystal structure of FP-mediated DCPD/AC foams and enhances their oxidation resistance.

Block Copolymer Self-Assembly-Directed Chiral Metal Oxide Nanostructures with Visible-NIR Chiroptical Activities and Magneto-Chiral Effects Minju Kim[1], Jiweon Kim[1], Hyunjeong Lee[1], Hyeohn Kim[2], Ki Tae Nam[2] and Dong Ha Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Chiral metal oxide nanostructures have intrigued tremendous attention in nanotechnological applications owing to their remarkable chiroptical and magnetic properties. However, current synthetic methods rely on the use of amino acids as chiral inducers, limiting a large-scale production and a precise control over the synthesis. Here, a general approach to fabricate chiral metal oxide nanostructures with wide spectral responses and tunable magneto-chiral effects is devised, using block copolymer (BCP) inverse micelle templates with supramolecular chirality generated through the complexation with *R/S*-mandelic acid (MA). Diverse chiral metal oxide nanostructures are prepared by the selective occupation of precursors within micellar cores followed by the oxidation process, exhibiting intense chiroptical properties with a g-factor up to 7.0×10^{-3} in the visible-NIR range for the Cr_2O_3 nanoparticle multilayer sample. The BCP inverse micelle is found to inhibit the racemization of MA, allowing MA to act as a chiral dopant that imparts chirality to nanostructures via hierarchical chirality transfer. Notably, for paramagnetic nanostructures, magneto-chiroptical modulation is realized by regulating the direction of the external magnetic field. This BCP-driven approach can be extended to the mass production of chiral nanostructures with tunable architectures and optical activities, which may open up a new horizon for the development of chiroptical functional materials.

Selective Chain Mobility Control of a Self-Assembled Gradient Block Copolymer Yemin Park, Seung Won Song and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Ultra-high-resolution patterns have become necessary for the development of semiconductor integrated circuits, and extreme ultraviolet lithography (EUVL) is a leading candidate for the mass production of sub-10nm patterns. However, EUVL has stochastic issues that lead to the formation of defects such as bridges, broken lines, and missing holes. As a solution, directed self-assembly (DSA) of block copolymers (BCPs) can be utilized for the formation of a defect-free encapsulation layer on EUV pattern masks.
To achieve sub-10 nm patterns, BCPs with high Flory-Huggins parameters (χ) are generally required for high quality pattern resolution. However, although high-χ BCPs can be obtained, it is challenging to obtain aligned patterns due to their slow self-assembly kinetics. As an alternative, gradient BCPs are advantageous for high resolution patterns due their rapid self-assembly kinetics. A gradient block consists of gradual composition change from the block junction region to the tail, which creates enough surface energy difference between the polymer blocks to energetically drive perpendicular lamellar formation. Yet, although EUV-scale patterns can be achieved with gradient BCPs, the χ values are not sufficiently high for low roughness. Therefore, a new method for the treatment of patterned BCPs is required for the improvement of pattern quality.
Here, we suggest a simple and novel treatment method that selectively increases the mobility of block junction polymers of gradient BCPs using a pinpoint solvent vapor treatment system. For demonstration, we newly synthesized a styrene (S)/2,3,4,5,6-pentafluorostyrene (PFS) gradient with an Si-containing 4-(tert-butyldimethylsiloxy)-styrene (4BDSS) copolymer block (P(S-g-PFS)-b-P4BDSS) via reversible addition-fragmentation chain-transfer polymerization. PPFS and P4BDSS form the block junctions, and the key to the pinpoint solvent vapor treatment system is to selectively provide solvent vapor-induced mobility to PPFS chains in metaphase after annealing. Solvents with high swelling ratios and solubility parameters similar to those of the polymers were chosen for solely targeting PPFS. When the solvents plasticize the target polymers, it leads to the reduction of the effective glass transition temperature of PPFS whereas P4BDSS remains unaffected. While it is challenging to synthesize BCPs with high χ values, this simple pinpoint solvent vapor treatment system provides a universal method for increasing the morphology quality of various self-assembled BCP patterns. Ultimately, the pinpoint treatment method resolves the stochastic issues of EUV-scale BCP patterns, on which an encapsulation process is performed for EUV-mask formation.

10:45 AM SF05.08.09
Self-Regulation and Long-Range Coordination in Nanocomposite Blend Self-Assembly Emma Vargo and Ting Xu; UC Berkeley, United States

Blends of nanoparticles, polymers, and small molecules can self-assemble into optical, magnetic, and electronic devices with structure-dependent properties. Across this range of applications, a nanocomposite blend's performance is a function of both its microscopically-averaged structure and its individual nanoscopic defects. Previously, top-down approaches have been employed to control nanocomposite structures and defect densities, including lithographically-patterned templates, external fields, and/or lengthy annealing processes. The strength and beauty of self-assembly, however, comes from its bottom-up nature. We hypothesized that nanocomposite systems could achieve precise structures and extremely low defect densities through self-regulation alone. Guided by this principle, we successfully fabricated nanocomposite multilayer films with large periodicities (172 nm) and the lowest defect densities reported to date (< 0.06 stacking defects / μm^2). To produce each film, a solution of diblock copolymers, organic small molecules, and nanoparticles was drop-casted and left to dry. Successful self-assembly was achieved across a range of substrates (silicon, glass, polyester), thicknesses (1 µm films to bulk solids), and drying times (30 minutes to multiple days). The films' excellent order does not come from optimized processing conditions, but from self-regulation across increasing distances during the assembly process. Systematic neutron and x-ray scattering experiments suggest that self-assembly occurs in two stages. First, chain entanglement drives the growth of high-aspect-ratio sheets from the polymer, nanoparticle, and small molecule building blocks. After the sheets form, they proceed to self-assemble as colloidal platelets, neatly stacking to maximize entropy. The self-regulation demonstrated by the nanocomposite spans six orders of magnitude in size, from the molecular building blocks to the millimeter-sized grains of nearly-perfect layers. The combination of low defect densities and large microdomains make the nanocomposite an efficient dielectric coating material. The nanocomposite blend can be redissolved and recast without loss of structure, providing a readily-recycled alternative to existing laminated composites. Overall, this work demonstrates how microscopic and macroscopic features contribute to the performance of a technologically-useful nanocomposite, and proposes self-regulation as a means of achieving order at—and beyond—the nanoscale.

Helicity Control in a Chiral Twist-Bend Nematic Phase of an Achiral Conjugated Polymer Using Cosolvency Effect Zhuang Xu and Ying Diao; University of Illinois at Urbana-Champaign, United States

The chiral twist-bend nematic (N_{tb}) phase composed of heliconical structures formed by an ensemble of achiral bent-core-like mesogens is the newest nematic phase, having only been identified experimentally in 2011. To date, there are still many unknowns regarding the nature of its phase behavior and material universality. For example, such a phase has rarely been reported in a lyotropic or polymeric system. Herein, we show the formation of N_{tb} phase of an isoindigo-bithiophene-based conjugated polymer in the mixture of two seemingly poor yet selective solvents, which is governed by the balancing of the polymer backbone and side chain interactions. More importantly, by varying solvent mixing ratio, we show a fine control of liquid crystalline phase behaviors, including the aspect ratio of nematic tactoids and their critical size for homogeneous-to-bipolar transition in the coexistence region of the isotropic + nematic phase, and the helical pitch at multi-length scales in the N_{tb} phase. The underlying mechanism involves the rigidity modulation of the polymer fibers serving as building blocks for the liquid crystalline phases. This study opens up perspectives on assemblies of achiral polymeric materials into chiral N_{tb} phase with controllable helicity and phase behavior.

Self-Assembly Beyond Water—Forming Lipid Vesicles and Vesicle-Gels in Polar Organic Solvents Faraz Burni, Srinivasa R. Raghavan and Niti Agrawal; University of Maryland, United States

Surfactants added at low concentrations can thicken or gel water by two routes. In one case, they can self-assemble into long, flexible chains called wormlike micelles. In a second case, surfactants can form vesicles, which can close-pack and fill the volume. Laundry products such as fabric softeners are known to contain close-packed vesicles. Vesicles are nanoscale containers where a bilayer of surfactants encloses an aqueous core. They are extensively used in drug delivery. While vesicles in water are well-known, there are *no reports of vesicles in polar organic solvents* like glycerol, formamide, or ethylene glycol (EG). Here, we demonstrate the formation of nanoscale vesicles in the above solvents using the common phospholipid lecithin (derived from soy). Our samples are mixtures of lecithin and the solvent with no additional cosurfactants or salt. Lecithin spontaneously gives rise to viscous fluids at low concentrations (~ 3%), with structures ~ 200 nm detected by dynamic light scattering. At higher concentrations (> 10%), lecithin forms clear gels that are strongly birefringent at rest. Dynamic rheology confirms the elastic response of the gels. Images from cryo-SEM indicate that the concentrated samples are **'vesicle-gels'**, with close-packed multilamellar vesicles. The discovery of vesicles and vesicle-gels in polar solvents widens the scope of systems that can be created by self-assembly. Interestingly, vesicles in polar solvents are stable indefinitely whereas in water, vesicles tend to aggregate or coalesce over time. The stability is attributed to refractive-index-matching between lipid bilayers and the solvents, i.e., these vesicles are relatively *invisible* and thus experience only weak attractions. The ability to use lipids (which are 'green' or eco-friendly molecules derived from renewable natural sources) to thicken and form gels in polar solvents could also prove useful in a variety of areas, including cosmetics, pharmaceuticals, and lubricants.

11:30 AM SF05.08.12
Secondary Self-Assembly Switches on Singlet Fission David J. Jones; University of Melbourne, Australia

Multiple exciton generation (MEG) through singlet fission (SF) is a spin allowed process whereby a singlet excited state is split into two triplet excitons. Inclusion of MEG chromophores into solar cells raises the maximum theoretical efficiency of a solar cell from the Shockly-Queisser limit of 33% to around 45% by effectively harvesting the energy from high energy photons. SF has been reported and extensively studied in crystalline acenes, and more recently acene dimers to better understand the fundamental photophysics and materials requirements for SF. Incorporation of these SF materials into functional solar cells, although demonstrating modest efficiency enhancements, has had limited success. In our efforts to produce higher efficiency printed organic solar cells we had the desire to incorporate solution processible SF materials in printed organic solar cells, however most of the reported SF materials are highly crystalline and either do not promote SF in the solid state or controlling crystallisation in the deposited films is difficult.
Singlet fission yields are stronly dependent on crystal packing with different polymorphs resulting in low or no singlet fission.The strong pi-pi interactions of a fluorenyl-substituted hexabenzocoronene (FHBC) donor, generate a hexagonally packed discotic liquid crystalline structure, with pendant triplet host chromophores (THCs). Through design of intra-molecular singlet fission materials, with a linker designed to promote secondary self-assembly, we have demonstrated the ability to enhance highly ordered thin films and high solid state singlet fission yields[1].
A number of promising SF chromophores do not support SF in the solid state, due to crystal packing that does not appropraite orbital overlap. Recently we have discovered that we can turn on singlet fission in these chromophores, when the THC is linked via a molecular core that promotes secondary self-assembly, for some chromophores that do not promote SF due to poor crystallisation.
In this talk I will discuss new systems being developed in my laboratory for siolid state SF, where the secondary self-assembly is key in generating high SF yields. The materials have been extensively studied in solution and in thin film by steady state and ultra-fast spectroscopy, both transient absorption, and GIWAX. for example, thin films of the discotic liquid crystalline FHBC(TDPP)$_2$ material forms hexagonally packed columns and has a singlet energy level of 2.00 eV. SF studies on FHBC(TDPP)$_2$ demonstrate a triplet yield of 150% in amorphous thin films, increasing to 170% in thermally annealed films.

Soft Capsules That Change Shape and Exhibit Structural Color Due to Nanoparticle Assembly in Their Cores Medha Rath, Taylor J. Woehl and Srinivasa R. Raghavan; University of Maryland, College Park, United States

Dyes and pigments are the primary source of color for most materials. However, they are susceptible to environmental (light, heat, etc.) or chemical damage and can easily fade over time causing the color to fade. Coloration that is resistant to damage and fading is desirable. For instance, structural color or iridescence is a phenomenon primarily observed in nature (butterflies, mollusks, birds, etc.) that shows brilliant colors due to the nanoscale morphology and structure of the material instead of chemical dyes. Structural color emerges due to the long-range ordered arrangement of non-absorbing nanostructured particles that diffract light at a particular wavelength corresponding to their size. Since structural color emerges from nanoscale morphology of the material, the colors are non-fading if the microstructure remains. Most natural and synthetic materials exhibit permanent structural color, while complex nanocomposites are required to generate materials that exhibit reconfigurable structural color.
Here we demonstrate a simple approach to obtain structural color within a millimeter sized hydrogel capsule. We fabricate a thin spherical polymer hydrogel shell of alginate surrounding an aqueous liquid core containing a concentrated dispersion of silica nanoparticles. The hydrogel shell acts as a selective permeation barrier, allowing water and small molecules to pass between the liquid core and surrounding fluid, but excluding large polymers and nanoparticles. Placing the capsule in a concentrated polymer solution (*e.g.*, polyacrylic acid, sodium alginate) induces a positive osmotic pressure gradient on the capsule that causes water to diffuse out of the capsule, causing it to collapse. Nanoparticles are entrained in the fluid flow out of the capsule and captured on the inner surface of the hydrogel shell. Electron microscopy and dark field optical microscopy show that the nanoparticles formed a conformal layer and colloidal crystal particles that were tens of microns in size on the inner hydrogel surface. Video rate fluorescence microscopy of fluorescent polystyrene tracer particles show there were recirculating fluid flows inside the capsule during osmotic pressure-induced collapse, which deposited the colloids onto the inner surface of the hydrogel shell. The final collapse step of the capsule, where the hydrogel shell with positive curvature buckled into a complex 3D shape with negative curvature, such as a bowl or folded shape, served to pack the colloids into ordered structures responsible for structural color. We demonstrate that this phenomenon is reversible and can be applied to a range of nanoparticle sizes. Interestingly, we find that the final shape and geometry of the collapsed capsule is dependent on the type and concentration of osmolyte used.

SESSION SF05.09: Application of Assembled Materials I

Optimal Binding Affinity for Sieving-Type Separation of Propylene from Propane in an Oxyfluoride Anion-Based Metal-Organic Framework Yi Xie; The University of Texas at San Antonio, United States

Highly efficient adsorptive separation of propylene from propane offers an ideal alternative method to replace the energy-intensive cryogenic distillation technology. Molecular sieving-type separation via high-performance adsorbents is targeted for the superior selectivity but the limit in adsorption capacity remains a great challenge. Here we report an oxyfluoride-based ultramicroporous metal-organic framework **UTSA-400**, [Ni(WO_2F_4)($pyz)_2$] (pyz = pyrazine), featuring one-dimensional pore channels that can accommodate the propylene molecules with optimal binding affinity while specifically exclude the propane molecules. The exposed oxide/fluoride pair sites in **UTSA-400** serve as strong functional sites for strengthened propylene-host interactions, resulting in a significantly enhanced adsorption uptake, while the propane molecules are excluded due to the regulated host dynamics. The strong propylene binding enables near saturation of propylene in the pore confinement at ambient conditions, leading to full utilization of pore space and superior packing density. Dispersion-corrected density functional theory calculations and *in situ* infrared spectroscopy clearly unveil the nature of boosted host-guest binding. Direct production of polymer-grade (>99.5%) propylene with remarkable dynamic productivity is demonstrated by column breakthrough experiments. This work presents a feasible strategy to break the trade-off in adsorptive separation through guest binding optimization in molecular sieve.

Self-Assembled Artificial Water Channels—Structural Determinants of for Enhanced Membranes Filtration Performances Mihail Barboiu; Institut Europeen des Membranes, France

Artificial water channels-AWC and their natural aquaporin counterparts are selectively transport water. They are a tremendous source of inspiration to construct biomimetic membrane technologies, including desalination. These biomimetic membranes contain variable nanochannel constructs with adaptative architectures and morphologies. Herein, we critically discuss the structural details that can impact on performances of biomimetic I-quartets AWCs obtained *via* adaptive self-assembly of alkylureido-ethyl-imidazoles **HC4-HC18** in bilayer or polymeric desalination membranes. We first revisit I-quartet performances and transport behaviors in bilayer membranes, identifying that hydrophobicity is an essential key parameter to increase water permeability. We compare various channel types with different hydrophobic tails (from **HC4** to **HC18**) and we found in particular that a huge increase in single channel water permeability from 10^4 to 10^7 water molecules/s/ channel is obtained by increasing the size of grafted alkyl tail. Quantitative assessment of biomimetic AWC-polyamide membranes formats show that pure water permeability increases from roughly 2.09 to 3.85 L m^{-2} h^{-1} bar^{-1}, for **HC4** and **HC6** membranes while maintaining higher salt rejection (99.25-99.51%) while the **HC8** loading induce a drop of performance reminiscent with a defective membrane formation. We show that the production of nanoscale defects can be obtained with insoluble low soluble and low dispersed particles of AWCs, explaining observed subpar performance. We conclude that optimal solubility enabling breakthrough performance, must be considered to maximize the inclusion and the stability in the bilayer membranes or to find an optimal homogeneous distribution of percolated particles that minimize the defects in hybrid polyamide membranes.

2:00 PM SF05.09.03
Induced Fit of Adsorbates inside Nano-Sized Quantum Confinements Aisha Ahsan[1,2], Luiza Buimaga-Iarinca[3], Lutz A. Gade[4] and Thomas A. Jung[2,1]; [1]University of Basel, Switzerland; [2]Paul Scherrer Institute, Switzerland; [3]CETATEA, Romania; [4]Universität Heidelberg, Germany

Host-guest architectures provide ideal systems to investigate site-specific physical and chemical effects. Condensation events in nanometer sized confinements are particularly interesting for the investigation of inter-molecular and molecule-surface interactions. They may be accompanied by conformational adjustments representing induced fit packing patterns. Here, we report that the symmetry of small clusters formed upon condensation, their registry with the substrate, their lateral packing as well as their adsorption height is characteristically modified by the packing of cycloalkanes in confinements. While cyclopentane and cycloheptane display cooperativity upon filling of the hosting pores, cyclooctane and to a lesser degree cyclohexane diffusively re-distribute to more favoured adsorption sites. The dynamic behaviour of cyclooctane is surprising at 5K given the cycloalkane melting point above 0°C. The site-specific modification of the interaction and behaviour of adsorbates in confinements plays a crucial role in many applications of 3D porous materials as gas storage agents or catalysts/bio-catalysts.

Super Diffusive Self-Aligning Vertical and Lateral Interconnect Formation by Gas Phase Electrodeposition Leslie Schlag, Nishchay A. Isaac and Heiko O. Jacobs; TU Ilmenau FG Nanotechnologie, Germany

This presentaion reports self-aligning metallic vertical and lateral intterconnect formation by gas phase electrodeposition. Key operational parameters to fabricate vertical ruthenium and rhodium interconnects (via) with a diameter of 100 nm are discussed. Moreover, airgaps are implemented during the deposition process, which utilizes spark discharge to generate a flux of charged nanoparticles. An inert gas flow transports the nanoparticles through a reactor chamber close to the target substrate. As well, the talk will introduce a super diffusive approach for gas phase electrodeposition, which uses a substrate with pre-patterned resist openings to guide the nanoparticles in the self-assembling manner into the openings by an interplay of drag, Coulomb force, and Brownian motion. Five process parameters were identified, which impact the morphology and conductance of the resulting interconnects: spark discharge power, gas flow rate, micro lens via dimensions, substrate surface potential, and in-situ flash lamp power. This parameter set enables a controlled adjustment of the vertical and lateral interconnect morphology and its minimum feature size. Gas flow rate in combination with spark discharge power contribute significantly to the morphology of the interconnect. Spark power and micro lens via dimensions have the largest influence on the surface potential of the insulating resist cover, which enables a localized micro lensing gas phase electrodeposition of a via with a controlled ratio between conducting diameter and airgap. To get a better insight into the growth characteristics, a statistical model leads to a better understanding of gas phase electrodeposition. The model implements that added to usual standard diffusion with random walks in a certain direction, long flights occur to a particle as well, if there is an additional the electrical field. As a result, the diffusion factor D is not a constant anymore and follows the approach of super diffusion.

Nucleation Enhancement Mechanism of Ruthenium Metals Thin Films by Atomic Layer Deposition Amnon Rothman, Dionysis Tsousis and Stacey F. Bent; Stanford University, United States

Noble metal thin films have attracted much attention due to their unique properties and structure, leading to a wide variety of applications in microelectronics, catalysis, energy and photovoltaics. Different parameters determine the metal properties for these applications, where an important one is the deposition process. One of the common deposition methods is atomic layer deposition (ALD), a surface-sensitive thin-film deposition technique. The self-limiting surface reactions during the ALD process promote the layer-by-layer growth mechanism, thus providing significant control over the film thickness and conformality. However, due to an island growth mechanism and nanoparticle formation, it can be difficult to achieve the formation of continuous and pinhole-free layers from noble metal ALD on oxide surfaces, leading to poor-quality films. These nonidealities are mainly due to a lack of nucleation sites for the noble metal ALD on oxide substrates and a poor wettability of these low-surface energy surfaces. In order to maximize the potential of ALD, it is important to fully understand the nucleation and growth mechanism of the ALD process. This work focuses on nucleation enhancement of ruthenium ALD as a model system. Ruthenium metal is a promising candidate in thin film technology because of its low bulk resistivity, high work function, thermal stability even at a higher temperature, low specific electrical resistivity even in its oxidized state, and low solid solubility with strong adhesion to copper. These properties make ruthenium an attractive barrier metal or seed layer for copper electroplating.
We study the nucleation enhancement of ALD ruthenium layers on silicon substrates by using single organometallic monolayers, with and without H_2O exposure, prior to deposition. The nucleation enhancement is demonstrated for ruthenium ALD using three different ALD precursors with different ligands. The results show that pretreatments with organometallic molecules (trimethylaluminum or diethylzinc, with and without H_2O, prior to deposition) reduce the nucleation delay of the ruthenium layer. The surface pretreatment strongly influences the ruthenium nucleation, yielding up to a 2.1-fold increase in surface coverage. The ruthenium ALD nucleation and growth mechanism are studied using scanning electron microscopy (SEM), ellipsometry and X-ray photoelectron spectroscopy (XPS) on the treated and untreated substrates. A theoretical model based on the Avrami nucleation model is developed and fitted to the experimental results, pointing to the possible growth enhancement mechanism, which we propose occurs by increasing the surface diffusion of nanoparticles/adatoms on the pretreated surface. Implications of the nucleation enhancement strategy applied to other metal ALD systems will be discussed.

3:45 PM SF05.09.06
Nanopore Wettability and Transport Laura Despot, Adnan Khalil and Annette Andrieu-Brunsen; TU Darmstadt, Germany

Porous inorganic-organic hybrid materials can be prepared using evaporation induced self-assembly (EISA) and they are of particular interest in the field of nanofluidics, as understanding and design of wetting-transport interplay as well as wettability-defined liquid infiltration into porous materials is not fully understood but important for improving transport-related applications. Here, we investigated the interplay of wetting and molecular transport in mesoporous silica layers. Via post-functionalization of mesoporous thin films with perfluorinated silanes or co condensation of tetraethoxysilane with methylated silanes mesoporous thin films with tuneable wettability were obtained. Wettability dependent water sorption, molecular transport and water imbibition were studied using ellipsometry and cyclic voltammetry as well as cameras and image analysis for fluid imbibition evaluation. Among others, we show the direct correlation between wetting properties of mesoporous silica thin films and ionic mesopore accessibility determining two different transport mechanisms. Furthermore, we show the influence of wettability on the imbibition area around a water droplet, deposited on the mesoporous surface. We show the importance of wettability dependent evaporation resulting in fluid front oscillations. The obtained results improve the understanding of solid-liquid interaction in nanopore confinement and help to improve nanopore transport-related applications such as nanofluidics.

4:00 PM SF05.09.07
Ultrasound-Assisted Directed Self-Assembly Digital Light 3D Printing of Composites Wei Zhai, Xinwei Li, Guanjin Li and Kian M. Lim; National University of Singapore, Singapore

The advent of advanced manufacturing technologies brings about the possibilities of novel materials with potentially unprecedented material properties. Through ultrasound-assisted directed self-assembly digital light processing, we present a novel class of composite – the discontinuous interpenetrating-phase com- posite (d-IPC) – where the cellular filler phase is based on lines of particle assemblies, as opposed to continuous materials. Through yttria particle doping, we fully illustrate the unique microstructural-specific mechanical properties of the d-IPC. Despite being fully bulk and having a similar density (1.18 g/cm3) and strength (68 MPa) as the matrix polymer, it presents an additional plateau-deformation behaviour under large compressive strains and hence a 218% increase in specific energy absorption up to 37 J/g. The enabling mechanism is derived from the peculiar discontinuous and macroscopically aligned particle-based struts which do not contribute to a notable diminution of strength but can yet modulate high-strain deformation via induction of progressive localized failures. The concept of d-IPC is also extendable to solid fillers of all materials, morphology, and reasonable sizes, allowing the d-IPC to be highly customizable with multifunctional potentials. Through this work, we also aim to demonstrate the potential of using advanced microstructural-controllable manufacturing techniques to achieve conceptually new and advanced composite materials.

4:15 PM SF05.09.08
Multifunctional Electroactive Foams within Flow Catalytic Reactions Jamie Mannering; University of Leeds, United Kingdom

Nanostructured carbon networks assembled into 3D macroscopic foams are exploited as a versatile heterogeneous support framework for flow-based catalytic reactions. The network composition which includes the type of building block (graphene or carbon nanotubes), interconnectivity, pore structure and pore volume fraction all influence the overall macroscopic properties of the foam (i.e. surface area, electrothermal conductivity and mechanical profile) enabling support frameworks that can influence reaction dynamics and provides new avenues of research within heterogeneous catalysis.[1] Here, I explore two distinct functional features of graphene-based macroscopic foams and highlight a burgeoning area of research that encapsulates a wide range of applications from energy storage and generation to (electro)chemical catalysis and environmental remediation.[2]
The first developments utilise graphene-based foams as electroactive sorbents for homogeneous molecular catalysts introducing a novel approach towards a controlled capture-release mechanism providing a modern alternative for a low-cost recyclable system addressing many of the challenges currently facing the pharmaceutical industry. As a consequence, we also reveal how this capture-release mechanism affords interesting opportunities for molecular functionalisation of carbon supports and a unique method of studying heterogeneous-homogeneous catalytic relationships.
Secondly, applying a rapid heating approach within electrothermally conducting ruthenium precursor functionalised graphene-based foams we explore a powerful and generalised tool for the rapid formation of catalytically active metallic nanoparticles that can be regenerated upon reaction deactivation. Moreover, control over the network structure within catalyst functionalised foams provides an interesting approach to explore reaction dynamics to gain an understanding of the implications of fluidic turbulence within a support-induced micromixing environment. Structure-function relationships are examined utilising a templating approach within model graphene-based foams creating different lamellar networks and combining experimental X-ray and electron tomographic data with computational fluid dynamics simulations to quantify the impact of foam structures on reaction output with broad scope implications for various applications.

4:30 PM SF05.09.09
Tailoring Electrode Architectures via Self-Assembly for Scalable Energy Storage Systems Zhengyu Ju and Guihua Yu; The University of Texas at Austin, United States

Replacing fossil fuels-powered vehicles with electric ones is an indispensable part of achieving carbon neutrality in the near future. Although the past decade has witnessed the unprecedented growth of electric vehicle market, long endurance and fast-charging capacities are the two main challenges remained. This asks for lithium-ion batteries, the heart part of the electric vehicle, with both high energy/power and scalability. In this talk, I will present our recent research progress on understanding the underlying charge transport kinetics and designing tailorable electrode architectures via self-assembly enabling high-rate capabilities in scalable thick electrodes. First, electrode-scale alignment is achieved via assembling porous magnetite (Fe_3O_4) nanosheet building blocks under a controllable magnetic field. Electrode architecture-correlated electrochemical properties are quantitatively explored, revealing the merit of low tortuosity characteristics for rapid charge transport from the nano- to microscale. In addition, a high-density yet low-tortuosity electrode is fabricated by magnetic-assisted self-assembly and drying-induced densification of Fe_3O_4 nanoparticle-decorated graphene oxide building blocks. Vertically assembled channels ensure good electrolyte penetration and material utilization, enabling well-maintained charge storage capability when scaling up the electrode thickness. Besides, a universal bidirectional freeze casting methodology is also explored to artificially induce material assembly to form the densely-packed lamellar structure. Simultaneous high areal capacity and rate capability could be realized in various materials-based electrodes attributed to the efficient mass transport in the ordered assembled architecture. Coupled with advanced three-dimensional visualization techniques, our research provides an in-depth understanding of the spatial mass distribution effects on electrochemical properties in thick electrodes, which could offer multiscale design considerations for next-generation scalable energy storage systems.

4:45 PM SF05.09.10
Generalized 3D Microprinting of Functional Nanocrstal-Based Inorganic Aerogels Minju Song and Jae Sung Son; UNIST, Korea (the Republic of)

Aerogels are porous materials with low densities and exceptionally high surface areas made up of non-fluid colloidal nanoscale networks. Due to their distinctive properties, aerogels are excellent materials for a number of applications, such as thermal and acoustic insulation, energy storage, catalyst, adsorbents, filters, electrodes, and sensors. Numerous materials, including oxides, polymers, carbons, metals, and even semiconductors, have thus far been synthesized as aerogels using sol-gel chemistry techniques or by the gelation of clusters or nanocrystals. However, aerogels' inherent brittleness hinders their processability through subtractive processes like machining. For instance, using conventional subtractive manufacturing techniques, the precision micro-processing of aerogels has never been accomplished.
The development of additive manufacturing enabled the fabrication of a wide variety of materials into unique shapes and dimensions, which is regarded as a next-generation manufacturing technique. Furthermore, micro-stereolithography methods based on multiphoton absorption or using a projection lens, as well as direct ink writing with microneedles, enable the development of microscale 3D architectures that have the potential to revolutionize the production of microscale components for a variety of applications, including microelectronics, micro-electromechanical systems (MEMS), and biomedical systems. Recently, 3D-printed aerogels achieved by an extrusion process using viscoelastic inks containing active particles were reported. Although these reports describe the feasibility of 3D printing for aerogels comprised of some specific materials, such as graphene, silica, and cellulose, the methods described have low resolution and are limited to only a few printable materials. For example, the resolution of reported 3D-printed aerogels is generally in the scale of several hundreds of micrometers, and sub-100-micrometers have rarely been achieved. These reported strategies adhere to the common ink extrusion process that requires a viscoelastic formulation of inks to ensure printability. Particularly, the polymer-based viscosifiers used as additives in aerogel-based inks for inorganic materials deteriorate their intrinsic functionality.
Here, we demonstrate an inorganic ligands-capped nanocrystal ink being directly written in the gelation bath as a generalized approach of high-resolution wet 3D microprinting for inorganic aerogels. Our process was designed to immediately link the thiometallate-based inorganic ligands with the coordinating metal ion linkers in the bath, thereby generating multibranched gel networks of various inorganic materials, such as metals, semiconductors, magnets, and oxides, without any organic additives. This method is designed to produce 3D microarchitectures of purely inorganic aerogels while combining the many advantages of conventional nanocrystal-based aerogels, such as material diversity and integrity of crystalline nanostructures. The microscale aerogel

filaments are printed with precisely controlled dimensions from 7 µm to 44 µm. Complex 3D structures are achieved by layer-by-layer deposition of aerogel filaments with highly porous microstructures and high specific surface areas, comparable to those of traditional nanocrystal-based and silica aerogels. In addition, the functionality of primary nanocrystals, including the magnetic, electrical, and luminous properties, were well preserved in the printed aerogels. Additionally, our technology produced multi-material aerogels by sequentially printing each nanocrystal or mixing nanocrystal inks.

SESSION SF05.10: Poster Session II

5:00 PM SF05.10.01
Submicron TiO_2-Polystyrene Hybrid Hollow Spheres from Pickering Emulsion Polymerization for Visible Light Scattering Liangdong Liu and To Ngai; The Chinese University of Hong Kong, Hong Kong

Opacity, or hiding power, is one of the most important parameters of white coatings. It is dominated by multiple scattering of visible light among pigment particles, which is determined by the light scattering efficiency of the pigments. With the same pigment material, the light scattering efficiency can be varied by adjusting the size of the pigments. However, it does have an upper limit, highest light scattering efficiency, positively related to the reflective index (RI) of the material.
The most widely used white pigment is titanium white (TiO_2) owing to its high RI (2.50-2.80), poor light absorbance in visible region, and high fastness. However, white coating development has been suppressed by the aggregation and sedimentation of TiO_2 pigments, which is caused by their high density (~4 g/cm^3).
To overcome the limitations, we presented a new method to prepare TiO_2-polystyrene hybrid hollow spheres. The hollow structure can not only reduce the density of pigments but also increase the light scattering efficiency. In detail, an organic acid-modified TiO_2 nanoparticle stabilized oil-in-water Pickering miniemulsion was prepared firstly as the template, in which the TiO_2 nanoparticles would be absorbed onto the oil/water interface. Then the droplets were further converted to hollow spheres by interfacial polymerization, which not only reinforced the interface but also bound the TiO_2 nanoparticles together. The hollow spheres can be used for visible light scattering in coatings and have high opacity and stability when compared to other white pigments contributing by their hollow structure. At the same time, a stronger combination between nanoparticles and polystyrene shell is achieved that can resist the shearing force during homogenization. Moreover, the production scale of the method can be further enlarged by using a high-pressure microjet homogenizer, which brings extensive industrial application prospects to the hollow spheres.

5:00 PM SF05.10.02
Tracking Directional Movement of Nanomotors with Liquid Cell Electron Microscopy Jiawei Wan[1,2], Qiubo Zhang[1], Jiayun Liang[2], Karen Bustillo[1], Zakaria Al Balushi[2], Mark Asta[1,2] and Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Liquid cell transmission electron microscopy (TEM) has become a powerful tool for the study of nanoparticle movement and self-assembly. By tracking the individual nanoparticle motion, mechanisms of the movement can be achieved. Extensive studies have demonstrated that various interaction forces contribute to the nanoparticle motion, which lead to the self-assembly of nanoparticles into one-dimensional chains, two-dimensional patterns, and three-dimensional architectures. Nanoparticle motion can be introduced predominantly by electron beam illumination, in which nanoparticles resemble the light-activated nanomotors. Herein, using cadmium chloride tetrahydrate ($CdCl_2·4H_2O$) nanomotor as an example, we studied the relationship between the configurational asymmetry and consequent motion of a nanomotor. Using in situ liquid cell TEM, we observed the directional motion of a $CdCl_2·4H_2O$ nanomotor under electron beam irradiation. The movement dynamics were regulated by the configurational asymmetry of the nanoparticles, which was caused by the difference in the reaction activity of various crystal facets. High resolution TEM images and numerical simulations showed a working mechanism that was related to the electric field generated around the nanomotor. This work points out the influence of asymmetry on the dynamics of nanomotors. Also, this study contributes to the understanding of mechanisms on nanoparticle movements and self-assembly, and suggests a new strategy for designing nanodevices for applications.

5:00 PM SF05.10.03
Exclusive Production of Icosahedral and Single-Crystalline Photonic Colloidal Clusters through Osmosis-Induced Consolidation of Emulsion Droplets Yehun Choi and Shin-Hyun Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Monodispersed colloids can spontaneously form crystalline lattices, which have been used as photonic materials with bandgap properties. Emulsion template provides spherical microparticles with colloidal crystals through a confining spherical geometry. The photonic microspheres have different photonic properties compared with film format as their varied crystalline structures. Therefore, the photonic microspheres have served differentiated applications with a bulk film format such as structural colorants, colorimetric microsensors, and optically-encoded microcarriers. In addition, the emulsion template provides a tool to study the crystallization behavior of colloids under confining spherical confinement. The microsphere composed of ih and fcc colloidal arrays has anisotropic optical properties as the orientation of the microsphere responsible for different crystalline faces. Therefore, the fcc and ih microspheres show various reflection colors and patterns as their rotate. These unique properties, distinguished from optically isotropic onion-like or polycrystalline microspheres, render the fcc and ih microspheres potentially appealing for advanced structural colorants and active color pixels.
To assemble colloids confined in droplets, the emulsions are usually exposed to air to let the dispersion medium of the droplet phase dissolves into and diffuses through the continuous phase and finally evaporate into the air. Although fcc structures and ih structures are more energetically stable than onion-like or polycrystalline structures in spherical confinement, these structures are only produced when the colloids are condensed slowly enough to arrange the colloids even after the nucleation from the droplet interface. Nevertheless, the fraction of fcc structures is not high because the evaporation rate of emulsion droplets varies depending on the position of droplets; the evaporation of medium is faster for the droplet closer to the emulsion-air interface due to the shorter diffusion length.
In this work, we suggest the osmotic extraction of water from particles-laden emulsion droplets using salt-dissolved droplets for the consolidation of colloidal particles at a consistent and controlled rate. Two different emulsion droplets containing polystyrene particles and salt are respectively prepared by a microfluidic device to have uniform size, which are randomly mixed to induce a water flux from the particles-laden droplets to salt-dissolved droplets. Therefore, the particle droplets gradually shrink whereas the salt droplets inflate. The rate of shrinkage is consistent as most particle droplets are subjected to a similar number of neighboring salt droplets for the random mixtures. Moreover, the narrow gap between two distinct droplets leads to fast water flux owing to a short diffusion length. Importantly, the rate of shrinkage is controllable in equal temperature conditions by adjusting the concentration of salt.

An optically-anisotropic fcc and ih structure is produced at a high fraction for slow consolidation with a low concentration of salt. It seems that the reduction of osmotic pressure difference and loosening of particle droplet-to-salt droplet contact in a course of the osmosis gradually slows down the shrinkage of droplets, which facilitates the particle rearrangement near the critical volume fraction responsible for spontaneous crystallization, enabling the production of fcc or ih structure even for a short overall consolidation time with high fraction. In addition, it is possible to produce an optically-isotropic polycrystalline structure for relatively fast consolidation with a high concentration of salt. This osmosis-induced consolidation protocol is applicable for polydisperse emulsion droplets produced by bulk emulsification, potentially providing a simple yet reliable means for the large-scale production of photonic microspheres.

5:00 PM SF05.10.04
Design and Assembly of Colloidal Quantum-Dot-Based Three-Dimensional Optical Nanostructures Geon Yeong Kim, Shinho Kim, Min Seok Jang and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

An optical nanostructure can be rationally designed in the way of desired light interactions. The coupling between nanostructure and electromagnetic wave enables manipulating a light traveling path, phase, and polarization state. Realizing high-performance optical components such as light sources, antennae, filters, and photodetectors has been focused on for decades. In particular, periodically arranged subwavelength optical nanostructures have been spotlighted owing to their excellent light controllability beyond conventional bulky optical components. 3D nanostructure, along with its 2D counterpart, has attracted significant interest in optics over decades due to the potential for omni-direction manipulation of electromagnetic waves. Various tools for the fabrication of artificial nanostructure have been demonstrated, including e-beam, focused ion beam, dip-pen, laser interference, nanosphere, and nanoimprint lithography. However, the inherent constraints of materials, complex and time-consuming fabrication, and limits in large-scale production have hindered the potential for high-performance 3D nanostructure. Above all, the fabrication of 3D structures with colloidal nanoparticles (cNPs) is yet considered to be challenging technically. Hence, for functional cNP-based optoelectronics, the developed fabrication method providing versatile platforms is necessary. Here, we report a new scheme of nano-transfer printing to build cNP-based 3D optical nanostructures. The transferred patterns feature outstanding pattern quality on a centimeter scale. A 3D structure can be formed with fully suspended multiple layers. The individual layer of a few hundred-nanometer thicknesses can be stacked with arbitrary angles, giving tunability in 3D structure symmetry, which is an essential requirement for high-performance 3D optical applications. Our strategy is adaptable for various nanoparticles covering all surface energies through controlling polymer brush and picking layer. Among potential applications of colloidal quantum dots (cQDs)-based optical nanostructures, two functional 3D optical nanostructures are demonstrated; emissive CdSe QDs for down-conversion QD film and absorptive PbS QDs for a circularly polarized light detector. Matching the absorbed energy of both devices to the resonance frequency of each nanostructure is crucial for substantial absorption efficiency. As the matched wavelength with the periodic structure results in optical resonance, this can increase light absorption into the incorporated QDs with more extended light-matter coupling. Consequently, a significant increase in photoluminescence in the CdSe structure and circular dichroism intensity in the PbS structure are achieved, both corresponding to high-performance devices.

5:00 PM SF05.10.05
Molecular Self-Assembly of Organic Semiconductors on Strained Graphene Jisang Park[1], Jinhyun Hwang[1], Hyo Chan Lee[2] and Kilwon Cho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Myongji University, Korea (the Republic of)

Graphene has been utilized as a growth template for self-assembly of organic semiconductor thin films (OSCs). Synthesis and transfer of graphene on a target substrate can cause a non-uniform strain field in the graphene, so morphology and crystallinity of the deposited OSC films can be altered. A strain field in graphene also introduces pseudo-electric field in graphene. The effects of strain in graphene template on graphene-organic molecule interactions during epitaxial growth of organic molecule have not been considered yet. Here, we investigated the effects of strain and strain-induced pseudo-electric field of graphene template on the self-assembly of organic molecules. We examined early stage of the growth and nucleation behavior of C60 thin films on the strained graphene. We propose that the strain-induced pseudo-electric field in graphene modulates the binding energy of organic molecules on the graphene. Our study on the growth of OSC thin films on strained graphene would lead to the understanding of the relation between the organic-graphene molecule interactions and the pseudo-electric field of graphene.

5:00 PM SF05.10.07
Confinement Driven Self-Assembled Fibrous Liquid Crystalline Polymer Jae Gyeong Lee[1], Jae Gwang Kim[2] and Jeong Jae Wie[1]; [1]Hanyang University, Korea (the Republic of); [2]Texas A&M University, United States

Liquid crystalline polymers have drawn a significant attention as a programmable material owing to their self-assembly capability with directed molecular orientation. In a hydrophilic media, liquid crystalline molecules, mainly consisting of hydrocarbon, construct spherical micelles to minimize the surface tension. Recent study reported formation of branched fibrous networks with liquid crystalline oligomers in an aqueous media, driven by molecular heterogeneity. Alteration of balance between interfacial energy and elastic energy generates the kinetic fluctuation during the construction of vesicles upon the oligomerization. In this study, we constructed fibrous liquid crystalline polymer with a high aspect ratio in a microchannel filled with aqueous media. The micro-channel induces confinement effects in liquid crystal oligomer droplets, providing the directional self-assembly. We will discuss analysis of fractal dimension and lacunarity to quantitatively demonstrate linearity of the liquid crystalline fiber.

5:00 PM SF05.10.08
Multi-Scale Investigation of Self-Assembly Induced by Capillary-Forces in Arrays of Carbon Nanotubes—From Density Functional Theory to Gecko's Effect Stefania Carapezzi[1], Aida Todri-Sanial[1,2] and Gabriele Boschetto[1]; [1]LIRMM, University of Montpellier, CNRS, France; [2]Eindhoven University of Technology, Netherlands

Self-assembly is a large ensemble of bio-mimicking strategies, where the organization of components into desired geometries is achieved without human intervention. This can be purposeful exploited to drive the fabrication of aggressively miniaturized devices, overcoming the material and engineering limitations of fabrication of non-planar 3D structures at such scales. However, self-assembly may have also a detrimental impact. This is the case with procedures involving wet etching or cleaning of vertically aligned nanostructures with high aspect ratio, such as nanowires and carbon nanotubes (CNTs). Then, the associated drying process involves a capillary menisci between adjacent nano-pillars, where the induced lateral forces may be strong enough to bend and finally assemble these nano-objects together. The consequent misalignment resulting from the processing of densely-packed arrays of 1D nanostructures affects negatively the physical properties associated to the preservation of their vertical direction.
The ability to engineer and control self-assembly is critical both to avoid undesired effects or, on the contrary, to exploit them smartly to build nanoarchitectured materials. In particular, the elasto-capillary driven self-assembly of arrays of 1D nano-structures is a complex phenomenon where different aspects play a role, such as the mechanical properties of the nano-structures, the geometrical properties of the array, and finally the evaporation rate and the surface tension of the fluid. In this work, we propose a multi-scale investigation of capillary-force-driven self-assembly of arrays of CNTs. In particular, density functional theory is used to predict the dependence from diameter and chirality of the relevant mechanical properties of CNTs: Young's modulus, Poisson's ratio, and surface energy. Then, we combine these physics-based parameters with a theoretical model describing the contact behavior

of fibrillar interfaces in lizards (Gecko's effect). Finally, we illustrate the inferences that our approach yields regarding the occurrence of self-assembly induced by capillary-forces in arrays of CNTs.

Bio-Engineered Polydopamine Nanoparticles for Biomedical Applications Swetha Lingamgunta; University of Cambridge, United Kingdom

Polydopamine (PDA) is a eumelanin-like biopolymer that is gaining popularity for various medical applications such as photothermal therapy, drug delivery and antimicrobial applications.[1] PDA can be synthesised through the oxidation of dopamine under basic conditions and utilised as nanoparticles, coatings and films.[2] Furthermore, PDA has remarkable adhesive properties which stem from various functional groups present within the structure of PDA (amino, imino, hydroxyl and catechols) and π-π interactions.[2] Its anti-oxidant pro-oxidant properties have also allowed it to be utilised by researches to enhance photodynamic anticancer therapy (PDT).[3] Functional groups present such as phenol groups, catechol, carboxy, o-quinone, amino, imine, which have a strong ability to combine with metals via chelation, π–π stacking interactions, electrostatic interaction, hydrogen bonding.[4] In this work, we utilise this characteristic of PDA for antimicrobial applications (e.g. we explore microwave enhanced PDA-silver nanoparticles) or to be used as a nanocarrier for radiolabels (e.g. chelator free labelling of many metals). In the context of drug delivery, plentiful aromatic rings in PDA makes it possible to load chemical drugs or dyes on their surface via π–π stacking and/or hydrophobic–hydrophobic interactions.[5,6] To enhance drug loading and delivery, we attempt to increase the PDA nanoparticle surface area and loading capabilities. In this work, we describe methods by which PDA NPs can be utilised to maximise drug delivery and radiolabelling for imaging.

5:00 PM SF05.10.10
Reconstruction Engineering of Oxygen-Deficient Metal-Oxide Nanoparticles Toward Effective Chemical Conversion and Energy Applications Mansu Kim[1], Jonghwan Park[2], Namgee Jung[3], Dongmok Whang[2] and Joseph T. Hupp[1]; [1]Northwestern University, United States; [2]Sungkyunkwan University, Korea (the Republic of); [3]Chungnam National University, Korea (the Republic of)

Metal-organic frameworks (MOFs) typically consist of coordinated metal ions or clusters and multitopic organic bridging ligands, utilized as precursors for metal oxide-based catalysts on 3D porous networks. Here, we report on the formation of well-dispersed ZrO_2 clusters with a size of less than 1 nm from atomic-level ordered MOFs in a perfectly controlled annealing environment. Heat treatment in a high temperature and inert environment forms oxygen defects in the ZrO_2 particles, which inhibits particle growth and increases the uniformity and formation of defective ZrO_2 nanoclusters. Also, MOFs containing various transition metal precursors show completely different trends after annealing in the same environment. In MOF, the Zr ion of Zr_6 node and metal precursor ions compete to occupy preferred oxygen in an oxygen-deficient environment, which affects the size and structure of ZrO_2 particles after the annealing process. Restructuring engineering of metal oxide nanoparticles opens up a wide range of applications and particle formation at very small levels that have not been approached by conventional methods.

5:00 PM SF05.10.11
Investigating Crystallization Pathway of DNA Voxel Assembly Katerina R. DeOlivares[1], Zohar A. Arnon[1], Daniel McKeen[1], Aaron Michelson[2,1], Brian Minevich[1] and Oleg Gang[1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States

The ability to design and engineer complex, functional and tunable nanoscale architectures remains a continual challenge in the field of nanotechnology. Currently, many conventional nanofabrication techniques lack the specificity and control required to develop precisely organized three-dimensional (3D) nanomaterials and are limited in their ability to incorporate nanoparticles. Self-assembly approaches offer a viable alternative, as such methods enable the integration of a diverse array of nanoparticles. Particularly, a DNA-based assembly approach leverages the specificity and programmability of Watson-Crick base-pairing to form designable organized architectures with high precision at the nanoscale. DNA can be folded into origami frames and integrated with nano-cargo, thus creating a unit block, or a so-called material voxel. Previous studies from our group have shown that these individual voxels can reversibly self-assemble into 3D crystal lattices through DNA-driven assembly and thermal annealing. While the structures of a variety of DNA voxel lattices have been extensively characterized, less is known about the mechanism of nucleation, crystal growth and disorder-to-order transition. Specifically, there is limited understanding of how the thermal protocols promote the transition from amorphous assembly to a crystalline lattice, and how the assembly pathway affects the formation of intrinsic defects and imperfections in the lattice. We utilized in-situ synchrotron-based small-angle X-ray scattering (SAXS), scanning electron microscopy (SEM) and transmission electron microscopy (TEM) to gain insight into structural evolution during the assembly process and thermal annealing. In addition, we investigated the crystallization pathway with single nanoparticle resolution using x-ray nano-tomography to visualize 3D structure and occurring defects at different pathway stages. The presented work provides insight on structure and morphology of intermediate states during self-assembly, which is critical for minimizing defects. The established methodology will lead to improvements in the design of self-assembly pathways and the realization of more complex engineered nanomaterials.

5:00 PM SF05.10.12
Design of Nanoreactors—Role of Dimensionality on Thermodinamics and Kinetics of Reactions Cecile Malardier-Jugroot and Manish Jugroot; Royal Military College of Canada, Canada

From the medical field to new technologies, the potential applications of nanomaterials and their impact in the development of smart materials capable of reacting to their environment is thriving. The characterization of phenomena at the nanoscale has revealed novel properties for natural as well as synthetic materials and unveiled the complex nature of the interactions occurring at that scale requiring an interdisciplinary approach to successfully develop new and revolutionary applications. In particular, biomimetism has shown great promises in the development of sensors, nanocatalysts, green processes for the use of sustainable energy sources. Biomimetism is divided in two main research areas: reproducing structures of biological systems or mimicking its function and physical properties. The first approach often combines biological systems (like enzymes) to artificial systems to take advantage of the high efficiency of the biological system optimized for specific physiological conditions. However, due to the high sensitivity of biological systems to change in their environment, the efficiency of these structures can decrease significantly with small perturbations. The second method that will be detailed in the presentation, mimics the physical properties and enhanced reactivity of biosystems has the distinct advantage of allowing the development of tailored structures stable under various conditions retaining the very high efficiency of their biological counterparts. The presentation will highlight the crucial role of confinement in equilibrium interactions and rates of reaction, as well as the effect of dimensionality on the thermodynamics and kinetics of reactions within the nanoreactors. The design and characterization of the nanoreactors and metal catalysts (Pt and Au) combines molecular modelling, dynamic light scattering, quasi-elastic neutron scattering and UV-Vis. The insight gained on the development of nanoreactors has allowed the synthesis of highly catalytically active monoatomically thin Au layers, stable under normal temperature and pressure conditions.

5:00 PM SF05.10.14
One-Dimensional, Lepidocrocite-Based Nanofilaments and Their Self-Assembly Kaustubh Sudhakar, Michel Barsoum, Hussein Badr and Avishek

Karmakar; Drexel University, United States

Water stable, one dimensional, 1D, materials are few and far between and none are titania-based. Herein we react inexpensive, water insoluble titanium-based precursors - TiC, TiB_2 and TiN - with 25 wt. % tetramethyl ammonium hydroxide (TMAH) in water at 80°C, under ambient pressures to produce C-containing, 1D sub-nanometers lepidocrocite-based inorganic polymer chains that, depending on reaction times - varied between 2 and 5 days - and processing details self-assemble into a plethora of hierarchical microstructures that range from 2D flakes to 1D nanofilaments with subnanoscale cross-sections. Using X-ray diffraction, X-ray photoelectron, Raman, transmission and scanning electron micrographs, and selected area diffraction we determine that regardless of the experimental conditions, nanofilaments are omnipresent along with a relatively small fraction of nanoparticles. The cross-section of these nanofilaments is 5x5 $Å^2$ and can be microns long. In all cases, however, like in organic polymers, the 1D nature of the material is preserved.

The first-of-a-kind *dual bottom-up* strategy prompted nanoengineering of 2D materials could build up new roadmaps towards fabrication of functional materials for sustainable future.

5:00 PM SF05.10.15

Switching Lattice Parameters of 3D DNA Frameworks Dayoung G. Lee[1], Zohar Arnon[1], Brian Minevich[1], Daniel McKeen[1], Daniel C. Redeker[1] and Oleg Gang[1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States

Nanomaterials with switchable and stimuli-responsive properties, such as repairing, sensing, and reconfiguration, are of great interest for medical, optical, and energy applications. However, the challenge remains to implement such dynamic properties into nanomaterial systems. DNA has demonstrated the capability to self-assemble into nanostructures with well-defined geometries and nanoscale precision, due to its unique programmable properties based on complementary base pair binding. Recent advancements in DNA nanotechnology show that it is possible to design and generate diverse three-dimensional (3D) nanoscale polyhedral frames constructed from DNA with ability to carry a variety of nanoscale cargo. Individual 3D DNA frames have external complementary bonds, known as sticky-ends, that are responsible for inter-frame binding. These programmable interactions drive the assembly of the frames into well-ordered superlattices with different crystal symmetries and provide an opportunity to implement stimuli-responsive capabilities. Here, we present a switchable and reversible control over DNA framework lattices with a switchable motif integrated into inter-frame linkers. The length of the switchable linkers can be changed on demand in response to the DNA signals. This allows for changing lattice parameters of the 3D superlattice in a facile and rapid manner. Furthermore, we explored the differentiation and control of switchable linkers for different axis in response to specific signals to enable anisotropic responses. Small-angle X-ray scattering (SAXS) techniques and electron microscopy methods were applied to study the structure and reconfiguration of the discussed system.

5:00 PM SF05.10.16

Assembly of Donor-Acceptor Stenhouse Adducts onto Cotton Textiles via Two-Step Immobilization Approach Jennifer J. Leung and Juan Hinestroza; Cornell University, United States

Smart textiles are emerging innovations adding technology to the basic textiles known. Many industries require the use of textiles that can accommodate and support their niche functions and environmental demands. A subset of smart textiles includes photochromic textiles. Photochromic dye molecules are situated into textiles to create commonly done via microcapsules or implementing traditional dye methods. Once integrated and stimulated by a light source, the photofunctionality is induced in the polymer matrix and can also be reversed. This reversibility can occur through heat activation or light irradiation, classifying the photochromic molecules as either T-Type or P-Type, respectively. Donor-Acceptor-Stenhouse-Adducts (DASAs) are a recent discovery of photochromic photoswitches that can be integrated in a variety of materials to advance the efficacy of smart textiles. Compared to other photoswitching molecules, DASAs offer advantages such as easier synthesis, hydrophilic-hydrophobic molecular micelle stability, high yield, fatigue resistance, and fine tunability. The simplified mechanism of DASAs isomerizes a colored, hydrophobic linear molecule into a colorless, hydrophilic cyclic version via visible light irradiation. Heat can then be applied to induce the cyclic to linear DASA reversibility of the T-type photochromic molecule. Upon its discovery, DASAs have been studied into generations to better understand its utilities, improve their limitations, and extend their capabilities. DASAs offer a platform of photoswitching capabilities that can be integrated in a variety of materials to advance the efficacy of smart textiles. In first generation DASAs, the donor-acceptor structure is composed of an alkyl amine with typically either a Meldrum's acid or barbituric acid. Successful and effective self-assembly and reversibility for first generation DASAs are reliant on solvent choice. Different solvents can either drive or inhibit the mechanisms at which the DASA enters a phase change in the photoswitching process. DASA photoswitching has been successfully demonstrated on polymers and surfaces from DASA modified polydopamine coated silica micro/nanoparticles on glass substrates to DASA-azobenzene-polystyrene mix on glass substrate to DASAs onto TiO_2 anatase surfaces but not on textiles. First generation DASAs are integrated on cotton for the first time via a two-step assembly approach. Cotton fabric is amine functionalized via the attachment of N, N-methyl(2-bromo-ethyl) ammonium bromide, creating secondary amines on the cotton samples. Then, the DASA compounds, 5-(furan-2-ylmethlene)-2,2-dimethyl-1,3-dioxane-4,6-dione, are self-assembled onto the cotton fabric. DASAs aggregate and stabilize themselves onto the cotton samples. Environmental stimuli such as visible light irradiation, water, and heat were induced onto the DASA-modified samples to understand the photochromic intensities and reversibility in unique situations. The confirmation of successful DASA attachment was confirmed through characterization and measurements including H-NMR and C-NMR spectroscopy, FTIR, and CIELAB Color Space (L*a*b). The characterizations and measurements displayed successful immobilization of first generation DASAs onto cotton. The stimuli induced onto the modified cotton gave insights into how DASAs on cotton could respond on a larger scale in various environments.

5:00 PM SF05.10.17

The Influence of the Roundness of Polymer-Grafted Nanocubes on Their Self-Assembly Behavior Priscilla F. Pieters[1], Emma Vargo[1], Yiwen Qian[1], A. Paul Alivisatos[1,2] and Ting Xu[1,1]; [1]University of California, Berkeley, United States; [2]The University of Chicago, United States

Polymer-grafted nanoparticles (PGNPs), which consist of an inorganic core and a polymer shell, offer many possibilities to build advanced materials. Expanding our materials library from spherical particles to faceted particles opens up a whole new space of self-assembled materials that can exhibit emergent properties, with self-assembly driving forces unique to their shape and the polymer conformation on the surface. This work aims to understand the self-assembly behavior of faceted PGNPs, by investigating the interplay of the nanoparticle geometry and contributions from the surface ligands on the self-assembly of nanocubes, including the structural and orientational order of the superlattices.

Monodisperse and shape-pure iron oxide nanocubes were self-assembled at the air-liquid interface, and their superlattice structure was studied with TEM and scattering experiments. In the absence of a polymer shell, the superlattice structure is predominantly determined by the shape parameter of the nanocubes, which we can consider as the *hard* roundness of the particles. This *hard* roundness does not alter the orientational order of the superlattice, and therefore all the nanocubes are aligned inside the superlattice. Hower, when introducing a polymeric ligand onto the surface of the particles, we alter the *soft* roundness of the particles. This influences the superlattice structure similarly to the *hard* roundness, however it also alters the orientational order between the particles, where increasing the *soft* roundness decreases the lateral orientational order in the nanocube superlattice. We demonstrate that this separate control of nanoparticle shape and polymeric ligand can be utilized to achieve control of the structural and orientational order of the nanocubes.

Our research shows that small changes can be used to guide the self-assembly of faceted particles, opening up avenues for the design of new advanced materials. Additionally, the structure and orientation dependent properties of these materials can be studied.

5:00 PM SF05.10.18
Revealing the Relationships Between System Design and Imperfections in DNA-Assembled Nanoparticle Lattices Eric Shen and Aaron Michelson; Columbia University, United States

A defining quality of nanoscale materials is the ability to fine-tune their properties by adjusting the system architecture and constituent elements. DNA origami – customizable wire-frame voxels – afford us a bottom-up fabrication platform with a high degree of control over the self-assembly of nanoscale crystalline frameworks and the organization of cargo such as nanoparticles and proteins within those assemblies. This methodology lets us fabricate complex, multifunctional lattices with varying symmetries. One of the core challenges is the development of methods to understand the relationships between prescribed structures and the resultant properties of nanomaterials.

In studying the defects and imperfections in engineered nanoscale systems, we can probe the average for a population of assemblies or the intricacies of a single sample. Small angle x-ray scattering (SAXS) and x-ray tomography correspondingly examine these two modes of nanoscale lattices. We used hard x-ray nanoprobe (HXN) tomography to investigate the 3D organization of nanoparticle superlattices supported by inorganically templated DNA-voxel frameworks. We simultaneously collected transmission ptychography data and fluorescence data to reconstruct a volumetric map of individual gold nanoparticles throughout a nanoscale lattice with 7-nanometer resolution. In addition, this allowed us to pinpoint and detail the presence of point vacancies and interstices, screw dislocations, and grain boundaries. Because the presented approach is non-destructive, we coupled it with synchrotron-based small angle x-ray scattering (SAXS) on the same sample to gain insight into the ordering and structure of the global population of nanoparticle lattices. Together, these methods explain the role system design parameters, such as frame geometry and bond design, have on the defects and imperfections found in engineered nanoscale lattices.

Kinetically Controlled Phases in Complexed Block Copolymers Boyce Chang; Iowa State University, United States

Block copolymers (BCPs) are macromolecules with well-defined architecture and can self-assemble into intricate nanostructures. Feature sizes of BCPs are molecularly defined and could range from optical wavelengths down to sub-10nm. Thus, they have been utilized for the fabrication of photonic crystals, selective membranes, and semiconductor patterning. The nanostructure formed by BCPs depend on its molecular weight and fraction of each block. More recently, it has been shown that BCP morphology can be similarly altered using selective continuous flow solvent vapor annealing (SVA) (Figure 1). Here, we demonstrate the effect of SVA conditions on the morphology of thin film complexed BCP. Solvent activity, quenching and affinity are systematically investigated through a flow controlled system.

Unassisted Hydrogen Peroxide Production via Buckypaper-Integrated Perovskite Photocathode—Passivation Strategy for Stable Aqueous Electrolysis Dongrak Oh, Rashmi Mehrotra and Ji-Wook Jang; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Hydrogen peroxide (H_2O_2), one of top 100 chemicals, is a representative eco-friendly oxidizing agent serving as wide range of applications such as wastewater treatment, the paper industry, and pulp bleaching etc. In addition, H_2O_2 is a promising eco-friendly energy carrier together with H_2, because it possesses similar energy density (3.0 MJ L^{-1} at 60%) to compressed H_2 (2.8 MJ L^{-1} at 35 MPa), and ease to store and transport as it is liquid phase unlike gas phase of H_2. On the other hand, currently more than 95% of H_2O_2 is industrially produced by the anthraquinone oxidation process, which requires complicated multi-step, hazardous organic chemicals consuming much fossil fuels and producing large amount of CO_2. Thus, development eco-friendly technology for H_2O_2 production is very essential.

In this point, solar H_2O_2 production via the single-step $2e^-$ oxygen reduction reaction (ORR) offers a simple, safe, and sustainable way. Current solar H_2O_2 production applications, however, only utilize inorganic-based photoelectrodes. Such electrodes intrinsically show poor charge transfer characteristics and thus result in low performances. On the other hand, perovskite (PSK) photoabsorbers offer many benefits over inorganic-based photoelectrodes such as a longer charge carrier diffusion, band tunability, and an excellent light absorption coefficient. However, despite of these better features, PSK materials have not attracted much attention because of their poor stability in aqueous solution.

Herein, we introduce an unassisted hydrogen peroxide production system in an aqueous electrolyte with oxidized buckypaper (O-BP)-integrated perovskite photocathode. The technical strategy building proper junction between active surface catalyst and photoabsorber serves as critical role to enhance the stability of perovskite electrode. First, O-BP which is self-cross-linked by oxidized carbon nanotubes is fabricated for the efficient $2e^-$ ORR. Experimental measurements demostrates conspicuous advantages of such sheet type carbon compared to powder in terms of physical stability on photoelectrode, while it still shows 100% of Fradaic efficiency and excellent stability. Next, highly efficient inorganic–organic methylammonium lead triiodide ($MAPbI_3$)-based photocathode is synthesized to utilize solar energy. Finally, Field's metal (FM) is used as interlayer between O-BP surface catalyst and perovskite photoabsorber. FM melts at ~65 °C and solidifies at ambient temperature, which easily control their state and thus results in formation of tight attachment facilitating charge transfer and perfect protection from aqueous electrolyte invasion when it's liquid and solid, respectively. From the fusion of three part technically, the stable O-BP-integrated pervoskite photocathode shows better stability (for 45 h) compared to that of the non-passivated PSK layer (for few minutes) in no external bias system with famous a-$NiFeO_x$ oxygen evolution electrode. Moreover, a H_2O_2 production rate of ~0.751 μmol min^{-1} cm^{-2} and ~1.463% of solar-to-chemical conversion efficiency (SCC) was achieved. This work presents importance of engineering skill by utilizing only well-known catalysts and photoabsorber, demonstrating significant increase of SCC compared to previous works.

5:00 PM SF05.10.22
Electrophoretic Formation of Colloidal Crystals and Their Inverse Opals in Large Areas Shun-Yu Tsai, Yun-Cheng Huang, Wai-Hong Cheang and Puwei Wu; National Yang Ming Chiao Tung University, Taiwan

We demonstrate the use of a variety of electrophoresis techniques to fabricate colloidal crystals (polystyrene microspheres, SiO2 microspheres, core-shell microspheres) and their relevant inverse opaline structures. The electrophoresis involves the suspension of those microspheres and the imposition of electrical fields to direct their packing into ordered structures in large-area. An example of our recent work is the formation of monolayered polystyrene microspheres on a two-inch GaN wafer, with a half-layered ZnO occupying the interstitial voids among the neighboring polystyrene microspheres. This structure serves as the gradient refractive index layer that faciliates the transmission of light from the GaN. Lastly, we will discuss the possibility of combining dielectrophoresis and electrophoresis for assemblying microspheres.

5:00 PM SF05.10.23
Evaluation of Strength of Sintered Porous Titanium Containing Biodegradable Polymer Chuen Kum Lee[1], Naritoshi Aoyagi[2] and Mari Miyata[2]; [1]Nanyang Polytechnic, Singapore; [2]Nagaoka College NIT, Japan

Introduction: Ti6Al4V alloy is widely used as a biomedical material due to its excellentcorrosion resistance and mechanical properties. On the other hand, bio-based polymers have an excellentbiocompatibility and biodegradability. By impregnating a bio-based polymer into a porous titanium surface, it may be applicable as a new biomedical material with excellent mechanical properties and biocompatibility. In this study, four types of bio-based polymers were used: cellulose derivative (hereinafter, BP1), PLA (BP2),chitosan (BP3), and chitosan derivative (BP4). The purpose of this study is to clarify the structure, compressive strength and bending characteristics of porous titanium materials and its composites.
Methods: Commercial Ti6Al4V powder with 45μm was used as raw material for porous titanium. Porous titanium was produced by spark plasma sintering method at 30MPa pressure with a temperature of 750degree. It has 20mm diameter and 10mm height with a porosity of 27%. After polishing the surface to 0.1μm,compression test specimens were obtained by wire cutting. These specimens are 5mm in diameter and 10mm height. These specimens were impregnated with four types of bio-based polymers. Firstly, these bio-based polymers were dissolved in chloroform, and then soaked in the solution for 2 hours, degassed for 1 hour and impregnated. Microstructures and sintered surface morphology were observed with a scanning electronmicroscope (SEM). Compression tests were performed at a compression rate of 1mm/min, with no lubrication.Compressive proof stress was obtained from stress-strain curves. Three-point bending strength was also measured for porous titanium by ASTM standard. These are 25mm in length, 12.5 mm width and 6 mm thickness.
Results: SEM images were taken at the cross sections of porous titanium and its composites. Polymer impregnation was confirmed by these surface observation and elemental analysis. Compressive proof stress and standard deviation were also obtained.
Proof stress of BP1 composites has 258 MPa. This is lower than porous titanium, 291MPa. Other proof stresses of composites with BP2, BP3 or BP4 showed 345, 348 and 346MPa respectively.
Discussions and conclusions: Composites proof stress is higher than human bone. Standard deviation results show that scattering in stress values tend to be suppressed when polymer was impregnated. Fracture occurs by cracking and propagation. It is considered that cracks firstly initiate into polymer. These cracks are connected with increasing stress. The Gibson-Ashby equation of the form $(\sigma/\sigma_s) = A(\rho/\rho_s)^B$
was used to model the compression stress for this type of open cell material. The parameters σ and σ_s
refer to the compressive stresses of the titanium composites and the theoretical compressive stress of zero porosity titanium respectively. Similarly, the parameters ρ and ρ_s refer to the densities of the titanium composites and zero porosity titanium respectively The coefficients A and B were calculated and will be presented in this work.

5:00 PM SF05.10.24
Logarithmic Correlation and Dispersion of Surfactant-Capped WC/Co Nanoparticle Measured by Atomic Force Microscopy and Dynamic Light Scattering Chengmin Zhang and Byung Yang Lee; Korea University, Korea (the Republic of)

This work reveals a logarithmic correlation between AFM and DLS measured mean particle size according to the relative standard deviation (RSD) using surfactant-modified WC/Co nanoparticles. The ratio of AFM and DLS measurement results is 1 with a 0.07 RSD according to nonlinear regression analysis. The aggregation of WC/Co nanoparticles in aqueous media is a serious problem during the sintering process, which reduces their mechanical properties due to local overheating. Here, cationic, anionic, and nonionic surfactants with different concentrations are added into WC/Co NPs suspension. Mean diameter and particle size distribution reported by DLS and AFM indicate that 20 mg/L concentration hexadecyltrimethylammonium bromide (CTAB) supplies an optimum dispersion effect due to the electrostatic and steric repulsion force. The zeta-potential, FT-IR, and XRD were carried out to investigate the capping behavior of CTAB on WC/Co nanoparticle surfaces. We hope this report could help to solve the aggregation phenomenon that exists in industry products based on WC/Co nanoparticles and supply a comparison protocol between AFM and DLS on polydisperse nanoparticle size characterization.

5:00 PM
Versatile Metal Organic Frameworks-Based Chitosan Air Filters for Efficient NO and Particular Matter Removal Jooran Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

Chitosan, a naturally abundant and sustainable organic biopolymer, is a linear polysaccharide composed of β-(1–4) glucosamine and *N*-acetyl glucosamine. It is the second most plentiful polysaccharide after cellulose and is useful for an extensive range of applications because of its abundance, low cost, excellent biodegradability, and renewability. Many researchers have successfully synthesized numerous metal organic frameworks (MOFs) and demonstrated their gas adsorption ability, MOFs are difficult to use because of their fragility, nanoscale size, and handling problems. To solve these problems, the *in situ* growth of MOFs on fibers is the most favorable method for the development of air filters, and it can lead to good gas adsorption performances. However, research on chitosan-based MOF filters for NO gas adsorption is very limited. In this study, MOFs (CuBTC or ZIF67) were grown on the chitosan fibers *in situ,* and NO gas adsorption performance was investigated using a real-time gas monitoring system. Further, the PMs filtration efficiency and antibacterial properties of the fabricated materials against *E. coli* and *S. epidermidis* were examined.
ZIF67- or CuBTC-based chitosan fibers grown *in situ* on fibers can be used in the development of effective air filters. In this context, metal–organic frameworks (ZIF67 or CuBTC) are grown *in situ* on chitosan fibers (denoted as C-ZIF67 or C-CuBTC), and the NO gas adsorption performance, particular matter filtration efficiency, and antibacterial properties of the fabricated materials against *E. coli* and *S. epidermidis* are investigated. The specific surface areas of C-ZIF67 and C-CuBTC are 311.9 and 140.1 $m^2\,g^{-1}$, respectively, whereas that of the untreated chitosan fibers is 0.1 $m^2\,g^{-1}$. For C-ZIF67, the NO adsorption efficiency rapidly increases up to 78%; specifically, 70% adsorption is maintained for 65 min. For C-CuBTC, the NO adsorption efficiency rapidly increases up to 54% initially and substantially decreases to 41% after 10 min. Furthermore, C-ZIF67 exhibits a 3.4 times higher NO adsorption capacity than that of C-CuBTC. For C-ZIF67 and C-CuBTC, the filtration efficiencies against PMs were higher than 99%. However, C-CuBTC shows a higher antibacterial activity (99.99%) against *E. coli* and *S. epidermidis* compared to C-ZIF67. The C-ZIF67 and C-CuBTC, derived from renewable resources, can be good alternatives for commercial synthetic air filters because they are biodegradable, cost-effective, and environment-friendly.

SESSION SF05.11: Application of Assembled Materials II

8:30 AM SF05.11.01
Ultrahigh Porous Aramid Nanofiber Separators by Phase Separation–Controlled Self-Assembly for High-Speed Lithium-Metal Batteries Bongjun Yeom[1], Arum Jung[1] and Jeong Gon Son[2]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Aramid nanofibrils (ANFs) prepared from poly(*p*-phenylene terephthalamide) fibers have showed excellent mechanical properties and electrochemical stabilities with nanoporous structures, that can be promising candidates as advanced separators for Li-metal batteries. However, the ANFs exhibited limited performances in the electrochemical properties and battery performances due to limits in control of porous structures. Herein, we report hierarchically porous aramid nanofiber separators with maximized porosities >95%, that are capable of effectively suppressing the Li dendrite growth while maintaining highly stable cycle performances at high charge/discharge rates. A two-step solvent exchange process combined with reprotonation-mediated self-assembly is utilized to control the bimodal porous structure of the separators. The first solvent exchange step has a critical role in determination of degree of partial assembly of the aramid nanoseed sols into fibrillar forms. pKa-dependent partial assembly of the aramids results in formations of macroporous structures with a few micron diameters inside the separators. Nanofibrillar assembly are completed at the second stage of the solvent exchange with water. Resultant films show hierarchical porous structures containing nanopores in macroporous polymer frameworks to yield a mechanically stable membrane with high porosity of 95% or more. The optimized samples exhibit high ionic conductivities of 1.9–4.0 mS cm^{-1} and high Li-ion transference numbers of around 0.8 because of the ultrahigh porosity and selective affinity to anions. Formation of Li dendrites are effectively suppressed via fast ionic transports and delocalized distributions of Li ions that can be attributed to marcropores and nanopores, respectively. In addition, the $LiFePO_4$/Li full cell retains around 80% of its capacity after 1000 cycles at charge rates of >10 C. The design and control of porous structures at the micro and nanoscales can be an ideal and promising approach for application as separators in Li-metal batteries to achieve excellent cycling performance at high charge/discharge rates.

8:45 AM SF05.11.02
Self-Healing Advanced Microvascular Diaphragms in Gas Transmission Md Mahfujjul H. Khan and Michael Keller; The University of Tulsa, United States

Using a microvascular approach, this study analyzes polymer-based diaphragm materials for their self-healing characteristics. A self-healing diaphragm system was manufactured using Silicone rubber or Polyurethane that can be installed in a commercially available pneumatic controller in gas transmission. Pressure differential tests are conducted up to 25 psi for the manufactured QM280 PDMS lab-scale membrane materials incorporated with self-healing microvascular channels. The Diaphragm performed well up to 15 psi and failed around 25 psi. A fabric reinforcement was designed to improve the performance. FEA study by ANSYS 2021 R2 with Endurica plugin revealed the stress concentration and fatigue life analysis. Three different orientations for microvascular 1 mm diameter channels were considered: Radially oriented 24 and 52 channels and Spirally oriented channels. Diaphragm experiences minimum deformation at the peripheral surface due to the fixed support boundary condition for all cases. Conversely, Maximum deformation occurred at the center for Radially oriented channels Diaphragm. It is worth noting that in the spiral channels diaphragm, the maximum deformation occurs slightly off-center with an indication of bending in one direction. This phenomenon is attributed to the highest density of spiral channels on that side of the Diaphragm. A variable stress field was observed between the sharp joint of the Diaphragm and the stainless-steel plate assembly. The equivalent Von-Mises stress was the maximum of 27.49 MPa for the Radial 24 channels diaphragm, while 48.63 MPa for the Radial 52 channels and 29.28 MPa for Spiral in the TPU-Plate assembly. The variable through-thickness stress experienced by the Diaphragm is attributed to the presence of the stress riser zones around the 1 mm channels. The principal elastic strains obtained from Ansys static structural results were used as the input for the fatigue analysis with Neo Hookean elasticity stress-strain behavior and the simplest Thomas fatigue model. The results revealed minimum fatigue life for Spiral Diaphragm whereas a maximum for the Radial 52 channel. The predicted minimum fatigue life portrayed the edge of the Diaphragm as the weakest zone subjected to fatigue loading. It was evident that the Spiral channel diaphragm sustained 50% reduced fatigue life compared to the radial channel diaphragm. This reduced fatigue life is attributed to the bending stress generation in spirally oriented channels Diaphragm.

9:00 AM SF05.11.03
Self-Assembled Inverse Opal Photonic Crystals as Diagnostic Sensors Natalie Nicolas; Harvard University, United States

Inverse opals are self-assembled porous 3D photonic crystals whose geometry can be controlled by the size of colloidal particles and concentration of ceramic precursor used during deposition. These structures have a unique potential for colorimetric diagnostic sensing of both soluble biomarkers and viral particles. Changes their structural color due to the selective wetting of pores and subsequent change in effective refractive index can be used to distinguish between fluids with different physical properties, which can be indicative of disease states, or to determine the presence of bound particles. The colorimetric differentiation of fluids with nanomolar to micromolar concentrations of surfactants including bile salts is made possible by patterning the surface chemistry of an inverse opal with a self-assembled monolayer of silanes with several different hydrophobicities. The label-free detection of viruses with an optical microscope has been enabled by observing the change in the wetting of a test solution into the inverse opal due to the binding of a virus to the pore wall. By understanding how to better control pore geometry and surface chemistry and their contributions to the interactions between inverse opals and fluids, we can more effectively utilize these structured materials for diagnostic sensing.

9:15 AM SF05.11.04
Metal-Organic Framework-Based Composite Materials for Chemical Sensor Applications Joon-Seok Lee, Seung-Ho Choi, Won-Jun Choi and Seon-Jin Choi; Hanyang University, Korea (the Republic of)

Metal-organic frameworks (MOFs) consisting of metal ions and organic linkers are promising materials considering their large surface area and high porosity for applications in filtration and sensors. So far, various MOFs have been synthesized and demonstrated as chemical sensing layers.[1-4] Nevertheless, the insulative properties of conventional 3D MOFs limit their applications in electrochemical sensing materials. To address these issues, MOFs were incorporated with conductive materials such as carbon nanotubes (CNTs) and graphene and demonstrated in electrochemical sensing layers for gas and ion detections.

In this presentation, we present the electrochemical sensing properties of MOF-based composites. To obtain electrical conductivity, carbon nanotubes (CNTs) were incorporated with MOFs (e.g., MOF-8 and UiO-66) by in-situ growth on the defective surface of CNTs. The chemical sensing properties of the composite materials were investigated by two different types of transduction techniques; i) chemiresistive-type and ii) cyclic voltammetry-type. In terms of chemiresistive-type sensors, we investigated the role of metal nodes and organic linkers in MOFs upon the injection of reactive gas species such as H_2S by spectroscopy analysis. In the case of the cyclic voltammetry sensor, the detection capability of various heavy metal ions such as Hg^{2+}, Cd^{2+}, and Pb^{2+} was investigated using CNT-ZIF-8 composite via redox reactions. The chemiresistive sensor was integrated with a wireless sensing module for application in real-time wireless detection of chemical species. The proposed MOF-based composites as sensing layers can be applied in various fields such as environmental monitoring and healthcare.

Formation of Pseudo-Facets on Polymer Grafted Nanoparticles Induced by Low Surface Curvature Tiffany Chen, Emma Vargo, Junpyo Kwon, Yiwen Qian and Ting Xu; University Of California Berkeley, United States

Polymer chain conformation on polymer grafted nanoparticles (PGNPs) is a versatile handle to modulate PGNP assembly and properties of single component composites (SCCs). Despite the obvious effect of curvature on chain conformation, interfacial width, and particle assembly, only the two extremes have been explored—flat and highly curved surfaces. How polymer chains behave on a lowly curved surface (i.e. large particle), neither faceted nor highly curved, is not extensively studied. This leads to the question of to what extent (e,g, distance from core, surface curvature and grafting density) will the behavior of polymer on lowly curved surface be influenced by neighboring molecules and nanoparticles. It remains unknown whether the polymer chains will behave like on a curved surface or on a flat surface, or they will have emerging behavior of the two systems.

As the surface transition from a small nanoparticle to a flat surface, we hypothesize that the grafted polymer chains may locally organize in the lateral direction. In the size regime where the ratio of particle diameter to polymer radius of gyration is one to two orders of magnitude, polymer brush on nanoparticle can locally rearrange to form faceted polymer grafted nanoparticles that have similar organization as those on faceted particles. Here we tested the hypothesis using polystyrene grafted silica particles, with the particle core size of 100, 150 and 380 nm, polymer molecular weight ranges from 40k to 100k g/mol and grafting density of 0.1 – 0.2 chains/nm^2. Image analysis showed increasing interparticle distance with increasing polymer chain length and 60° interparticle angle of the self-assembled 2D monolayer film, confirming hexagonal packing. Deformations of 2D PGNP monolayer reveals uneven mechanical strength around the core, suggesting different types of chain interactions. Polymer brush form aligned nanofibrils and generate voids in between the particles, while polymer brush at the interstitial sites are intact and less resistant to deformation. We speculate the polymer brush are mobile and can locally rearrange to form pseudo-facets during self-assembly, resulting in weaker mechanical response due to chain interdigitation instead of chain entanglement between the neighboring particles. The width of the voids corresponds to the size of facet, which is consistent with 30° degree vector. Despite the isotropic spherical core, polymer brush can adopt anisotropic organizations. This work utilizes qualitative information to elucidate how energy is absorbed and dissipated across the PGNP system to understand polymer chain conformation. This study also introduces a new parameter of lateral heterogeneity in chain conformation on nanoparticles, subsequently, modulating how PGNPs assemble and the properties of PGNP-based SCCs.

Structuring Liquids With Chemically Fueled Interfacial Assemblies Sarah Gleeson[1], Paul Ashby[1], Thomas Russell[2,1,3] and Brett A. Helms[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of Massachusetts Amherst, United States; [3]World Premier Institute–Advanced Institute for Materials Research, Tohoku University, Japan

Nature uses molecular aggregation to spatiotemporally organize compartments, resulting in precise control over liquid-phase chemistries. Structured liquids are able to partially replicate this natural behavior, using particle and molecular assembly at interfaces to lock unique liquid geometries in place. By adding an internal clock to structured liquids, the ability to control chemical systems in both space and time will enable life-like behavior in liquid materials. Currently, jammed interfaces are energetically trapped into their assembled state and require a stimulus to disrupt their binding to allow for reconfiguration. Here, we show that interfacial assemblies can be transiently energized into an out-of-equilibrium assembly, allowing for a structured liquid interface with a pre-programmed lifetime. We add chemical fuel to convert hydrophilic moieties on a water-soluble polymer into hydrophobic anhydrides, driving the formation of colloidal aggregates in solution and leading to polymer adsorption at an oil-water interface. While the fuel is present, the liquid interface is stabilized by a solid-like film, but over time the fuel is depleted, leading to anhydride hydrolysis and desorption of material from the interface. The result is a transient structured liquid: non-equilibrium liquid compartmentalized geometries that are locked in place for a predetermined amount of time before weakening of the interfacial assembly leads to unjamming and spatial reconfiguration. This provides unprecedented temporal control over structured liquids and a means to design all-liquid chemical systems that autonomously change over time, opening the door to future advances in chemical reactors, timed release, and adaptive membranes.

10:30 AM SF05.11.09
Spontaneous Mirror Symmetry Broken Patterns for Physically Unclonable Anti-Counterfeiting Labels Geonhyeong Park[1], Hyewon Park[1], Joanna M. Wolska[2], Jesse G. Park[1] and Dong Ki Yoon[1]; [1]KAIST, Korea (the Republic of); [2]University of Warsaw, Poland

Advances in technology improve our daily lives. At the same time, however, evolving counterfeit technologies bring enormous challenges. Accordingly, the demand for security systems to protect personal information has been increased. Anti-counterfeiting labels based on physical unclonable function (PUF) are in the spotlight because of their natural randomness, making them difficult to forge. Here, a new concept of PUF is introduced using spontaneous mirror- symmetry breaking facilitated by directed self-assembly of achiral bent-shaped molecules. Statistical analysis of the chiroptical responses shows that this PUF with mirror-symmetry breaking have excellent performances such as uniqueness, reproducibility, stability, and reconfigurability. Furthermore, high-level security tags that embed chiral random patterns in deterministic codes can be fabricated with selective light exposure. Our strategy of incorporating the randomness of nature into artificial devices is expected to serve as a cornerstone for applying various natural phenomena to high-level security systems.

10:45 AM SF05.11.11
3D Printing of Structurally-Colored Architectures Using Bingham Colloidal Inks Jong Bin Kim[1], Su Yeon Lee[2] and Shin-Hyun Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Nature has adopted spectacular nanoscience in exhibiting structural colors on epidermal skins of organisms or gems. Researchers have endeavored to fabricate artificial structural colors, which are non-toxic, nonfading, and stimulus-responsive. There has been a recent surge of interest in the 3D printing of nanomaterials to form smart interfaces or functional devices. However, nanomaterials with structural colors have rarely been 3D-printed as they should accompany the periodicity in the colloidal arrangement as well as the structural fixation in a three-dimensional space. Recently, 3D printing of colloidal crystals was reported using digital light processing (DLP), but direct writing is still required for more time-efficient and colloid-saving strategies. There are previous studies in direct-writing of colloidal crystals and glasses, but the well-controlled evaporation of the solvent is necessitated so that structural shrinkage occurs and the process is time-consuming.

Here, we fabricated Bingham fluid using the particle aggregation in the repulsive colloidal system, which does not accompany any structural shrinkage after crosslinking and coloration. A novel idea has been applied to make Bingham colloidal inks; hydrophilic nanoparticles dispersed in hydrophobic resin by forming hydrogen bonds are repulsive by steric hindrance, but become linked after the enforced dispersion of hydrophilic solvent which destroys the solvation layer around nanoparticles. Furthermore, the optimal composition has been uncovered by using both the cosolvent which dissolves particles and resin together, and the specific solvent which selectively dissolves into nanoparticles. Both kinds of solvents are found to be crucial in terms of the high modulus of the Bingham ink and ink extrudability without nozzle blockage. In addition, coloration by the well-defined periodicity in a short-range order is adjusted by the mixing ratio of the solvent.

The ink system is composed of silica particles dispersed in urethane acrylate, where the hydrogen bonds between the two form so-called solvation layers around particles where their overlap brings about interparticle repulsion, inducing colloidal crystallization. The linkage between particles occurs after the dispersion of ethanol due to the destruction of solvation layers. Ethanol is penetrated into the voids of particles and refractive indices are matched, hence making the ink transparent. The index match impedes the formation of large aggregations on the ground of minimized van der Waals force. The particle linkage occurs in nanoscale so that the printing resolution is not compromised with Bingham property. The additional dispersion of water more selectively binds the colloidal linkage, resulting in higher modulus and yield stress of the ink. The values are among the highest in the previous reports.

The high modulus and yield stress enable the printing of a sphere, upright tower, tilted tower, and even buildings or insects. UV crosslinking fixes the structures right after the extrusion without any shrinkage from solvent evaporation, where the evaporation only endows them with structural colors by increasing the index contrast. Ethanol dispersion renders the interparticle distance to decrease as it dismantles the solvation layers around particles. Interestingly, water dispersion further decreases the gap between particles as it is selectively dispersed into nanoparticles, thus breaking down the solvation layer further. The optical properties resultingly show the blueshift of the photonic bandgap. The optimal range of mixture dispersion is explored as an excess amount of solvent impairs even the periodicity in a short-range order. This strategy successfully prints customizable 3D objects with structural colors in terms of colors, design, and high-resolution printing. It will open a new avenue in the 3D printing of soft robots and sensors with nonfading and stimulus-responsive structural colors.

SESSION SF05.12: Building Advanced Materials via Aggregation and Self-assembly

New Avenues for Anticounterfeiting by Phase Selection and Plasmonic Shifts in Binary Plasmonic Alloy Nanoclusters Stephan V. Roth[1,2], Matthias Schwartzkopf[1], Niko Carstens[3], Thomas Strunskus[3], Peter Muller-Buschbaum[4] and Franz Faupel[3]; [1]Deutsches Elektronen-Synchrotron DESY, Germany; [2]KTH Royal Institute of Technology, Sweden; [3]Christian Albrechts-Universität zu Kiel, Germany; [4]Technical University of Munich, Germany

Anticounterfeiting decisively relies on tailoring structural colors based on plasmon resonances. The structural color is uniquely determined by the plasmon resonances' spectral shape and position [1]. For the first time, we are able to directly observe in situ and quantify the onset of different phases and compositional changes in binary alloy plasmon-active silver (Ag)-copper (Cu) nanoclusters due to spinodal decomposition [2]. We are able to tune and establish an advanced Cu-rich core and Ag-rich shell morphology for the alloy clusters in a high-density nanocluster plasmonic multilayer device during sputter deposition of the alloy. In this ground-breaking study we are able to quantify effective diffusion coefficients and to clearly corroborate theoretical assumptions on the phase separation process on the nanoscale in complex alloy self-assembled nanocluster devices: With Cu being the structure-defining component and Ag predominantly in the shell, our findings offer the potential to partially decouple structural (distance) effects and size- and composition-related influences on the plasmon resonance in directly deposited, high-density, organic shell-free cluster layers. With scale effects coming into play, we are thus able to uniquely correlate cluster morphology and composition with the changing optoelectronic properties. Such tunable, plasmon resonance-based structural color paves an unprecedented way for advanced for high-density nanocluster-based anti-counterfeiting.

1:45 PM SF05.12.03
Multifunctional Materials by Self-Assembly of Perovskite Nanocrystals Alberto Sanzde leon, Miriam Herrera and Sergio I. Molina; Universidad de Cádiz, Spain

Metal halide perovskite nanocrystals (NCs) have gained much attention in the last years due to their unique optical properties. In particular, cesium lead halide NCs ($CsPbX_3$, X = Br, Cl and I) present excellent photoluminescence quantum yields and narrow emission line widths. However, $CsPbX_3$ tend to be unstable under environmental conditions (humidity, UV radiation, water, oxygen, heat, polar solvents...), which limits their viability in long-term applications on an industrial scale. Embedding the $CsPbX_3$ NCs in a polymer matrix improves their stability while maintaining their optoelectronic properties. In addition, the possibility of creating a micropattern with the polymer matrix allows the development of multifunctional materials, expanding the number of potential applications.[1,2]

In this context, breath figures (BF) is a bioinspired, bottom-up approach that allows the creation of honeycomb-patterned porous surfaces with controlled topography and composition in one single step by solvent casting. The surfaces are formed by condensation of micron-sized water droplets and self-assembly of amphiphilic compounds (e.g. block copolymers or surfactants), which migrate towards the interface between the water droplets and the organic polymeric solution. When the experimental conditions are optimized, the surface porosity after the BF approach also provides self-cleaning properties to the material, in agreement with the Cassie-Baxter model.[3,4]

We report on the development of a method to prepare nanocomposites by embedding $CsPbBr_3$ NCs in a polystyrene matrix by BF. As a result, a hierarchically structured, hybrid film with double functionality is obtained in one single step within few seconds: the formation of a well-arranged, honeycomb-patterned porous structure confers the hybrid film with self-cleaning properties while the $CsPbBr_3$ NCs keep their luminescent behavior within the polymer. This allows to have a film with controlled composition and topography, being an interesting alternative to top-down techniques as lithography, which are more time consuming and require expensive equipment.

This approach has also been applied onto LED lenses demonstrating its applicability in real-life applications. The strategy herein proposed can potentially be extended to other perovskite NCs and other nanomaterials in order to obtain new hybrid coatings with different functionalities, paving the way to multifunctional materials with self-cleaning properties with potential applications in optoelectronics or photovoltaics.

Multiscale Structural Control of Thiostannate Chalcogels with Two-Dimensional Crystalline Constituents Heehyeon Lee[1,2], Thanh Duy C. Ha[3], Youngtak Oh[1] and Myung-Gil Kim[3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Chalcogenide aerogels (chalcogels) are amorphous structures widely known for their lack of localized structural control. This study, however, demonstrates a precise multiscale structural control through a thiostannate motif ($[Sn_2S_6]^{4-}$)-transformation-induced self-assembly, yielding Na-Mn-Sn-S, Na-Mg-Sn-S, and Na-Sn(II)-Sn(IV)-S aerogels. The aerogels exhibited $[Sn_2S_6]^{4-}$:Mn^{2+} stoichiometric-variation-induced-control of average specific surface areas (95–226 $m^2\ g^{-1}$), thiostannate coordination networks (octahedral to tetrahedral), phase crystallinity (crystalline to amorphous), and hierarchical porous structures (micropore-intensive to mixed-pore state). In addition, these chalcogels successfully adopted the structural motifs and ion-exchange principles of two-dimensional layered metal sulfides ($K_{2x}Mn_xSn_{3-x}S_6$, KMS-1), featuring a layer-by-layer stacking structure and effective radionuclide (Cs^+, Sr^{2+})-control functionality. The thiostannate cluster-based gelation principle can be extended to afford Na-Mg-Sn-S and Na-Sn(II)-Sn(IV)-S chalcogels with the same structural features as the Na-Mn-Sn-S chalcogels (NMSCs). The study of NMSCs and their chalcogel family proves that the self-assembly principle of twodimensional chalcogenide clusters can be used to design unique chalcogels with unprecedented structural hierarchy.

Rising From the Flatland—A Strategy to Achieve Solid-State Emission and Circularly Polarized Luminescence Zijie Qiu; The Chinese University of Hong Kong, China

Aggregation-induced emission (AIE) describes a photophysical phenomenon in which molecular aggregates exhibit stronger emission than single molecules, thus the AIE luminogens (AIEgens) are promising solid-state emitters. One of the common features of AIEgens is the non-planar molecular structure, which prevents severe π-π interactions in the aggregated and solid states. Rising from the flatland is therefore a general strategy to achieve solid-state emission for various high-tech applications. Chirality and circularly polarized luminescence can also be obtained from non-planar structures. In this talk, I will present several works about the precise synthesis, amplified properties, as well as high-tech applications of organic functional materials with non-planar molecular structures.

2:30 PM SF05.12.06
Surface Assembly of Ionic Liquid Functionalities on Mesoporous Silica to Enhance Paraffin Affinity and Induce Reverse Selectivity for Ethane/Ethylene Separation Fahmi Anwar[1,1], K Suresh Kumar Reddy[1,1], Anish M. Varghese[1,1], Maryam Khaleel[1,1,1], Kean Wang[1,1] and Georgios Karanikolos[1,1,2]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]University of Patras, Greece

Low molecular weight olefins, such as ethylene, constitute an important feedstock not only in polymer production but also as reactants for the synthesis of several compounds, with a global production rate of over 200 million tons per year. Ethylene is mainly produced by steam cracking of naphtha, and, depending on its final application, it can be obtained in different grades. For example, a high-purity grade (>99.5%) is required for polymer production. To obtain polymer-grade olefins, it is imperative to separate light olefins from paraffins. The state-of-the-art technology for light olefin/paraffin separation is cryogenic distillation, yet because of the similar sizes and close volatilities of the C_2H_4/C_2H_6 molecules, the process is energy-intensive, such that even subtle improvements in the quality of separation can significantly affect the operating cost.
Adsorptive separations based on porous adsorbents exhibit high potential for light-olefin/paraffin separation. As the industrial feed is rich in olefins, developing a paraffin-selective adsorbent is energetically favorable. In this study, we developed surface-functionalized silica-based adsorbents for C_2H_4/C_2H_6 separation which selectively take up ethane because of their enhanced van der Waal's interactions with ethane molecules. Fluorine-containing anions for instance, have been reported to have stronger interactions with C_2H_6 molecules, attributed to the C–H—F van der Waal's forces between the six hydrogen atoms of the C_2H_6 molecule and the fluorine atoms. Therefore, in our work, a fluorine-based ionic liquid (IL) with longer alkyl chains, 1-propyl-3-methyl-imidazolium bis(tri-fluoro-methyl-sulfonyl) imide was selected as the primary IL for grafting on MCM-41 surface *via* silanization to develop a reverse-selective adsorbent.
To study the effect of the type of anion and cation on adsorbent performance, anions such as dicyanamide and stearate were also investigated by switching the anions of the primary IL. In addition, the effect of the cation on the selectivity was investigated by swapping the imidazolium-based cation with a phosphonium-based cation. These novel functionalized adsorbents were observed to switch selectivity after IL modification and exhibited reverse selectivity. The developed adsorbents exhibited also low enthalpies of adsorption, i.e., 12 kJ/mol and 9 kJ/mol for C_2H_6 and C_2H_4, respectively, which implies facile regeneration with reduced energy consumption.

Growth of Mesoscale Ordered Two-Dimensional Hydrogen-Bond Organic Framework with the Observation of Flat Band Feng Liu[1], Minghu Pan[2] and Fangsen Li[3]; [1]University of Utah, United States; [2]Shaanxi Normal University, China; [3]Chinese Academy of Sciences, China

Flat bands (FBs), presenting a strongly interacting quantum system, have drawn increasing interest recently. However, experimental growth and synthesis of FB materials have been challenging and remained elusive for the ideal form of monolayer materials where the FB arises from destructive quantum interference as predicted in 2D lattice models. Here, we report surface growth of self-assembled monolayer of 2D hydrogen-bond (H-bond) organic frameworks (HOFs) of 1,3,5-tris(4-hydroxyphenyl)benzene (THPB) on Au(111) substrate and the observation of FB. High-resolution scanning tunneling microscopy/spectroscopy (STM/STS) shows mesoscale, highly-ordered and uniform THPB-HOF domains, while angle-resolved photoemission spectroscopy (ARPES) highlights a FB over the whole Brillouin zone (BZ). Density-functional-theory (DFT) calculations and analyses reveal that the observed topological FB arises from a hidden *electronic* breathing-Kagome lattice without *atomically* breathing bonds. Our findings demonstrate that self-assembly of HOFs provides a viable approach for synthesis of 2D organic topological materials, paving the way to explore many-body quantum states of topological FBs.

Self-Assembled Magnetic-Fluorescent Nanocluster for Highly Sensitive Rotavirus Detection Hong En Fu and Young Keun Kim; Korea University, Korea (the Republic of)

Rotaviruses are well-known pathogenic agents of severe gastroenteritis responsible for acute diarrhea and vomiting, leading to dehydration and death in young children. The appropriate treatment can avoid the death of patients; however, due to late diagnosis, morbidity is still increasing. Point-of-care testing, especially lateral flow assay (LFA), has received much attention because of its rapid, simple, and inexpensive detection method [1]. Unfortunately, the present LFA kits have poor sensitivities and specificities compared to other immunoassay methods. Recently, magnetic antigen enrichment incorporating both magnetic and fluorescent nanoparticles has dramatically enhanced the sensitivity of the target antigens [2]. However, a significant challenge is the creation of a magnetic-fluorescent nanoconstruct with high magnetic responsivity, strong light emission, and structural uniformity [3]. Here, we developed a facile strategy to synthesize magnetic-fluorescent CdSe-CdS/Fe_3O_4 nanoclusters (CFNCs) for highly sensitive and specific rotavirus detection. The interparticle distance between nanoclusters can be enlarged by regulating solvent polarity, allowing other nanoparticles to penetrate the nanoclusters. We coupled quantum dots to as-synthesized Fe_3O_4 nanoclusters by the above method. Massive CdSe-CdS integration allows for reducing the fluorescent quenching effect. Furthermore, we functionalized CFNCs with biocompatible poly(acrylate sodium salt) on the surface to improve water dispersity and facilitate antibody conjugation. Finally, we evaluated the CFNCs-based LFA performance by detecting the rotavirus as a target antigen, comparing the unconcentrated condition and the magnetic enrichment in fluorescence intensity and detection limit.

Physical Supercritical Fluid Deposition—A Scalable Process for Controlling Polymer Self-Assembly on Surfaces Loren G. Kaake; Simon Fraser University, Canada

Controlling materials self-assembly over a wide range of length scales is vital to advanced applications in a wide variety of fields. The key challenge in developing a fabrication technique is not only to form nanoscale structures reproducibly and robustly, but to direct their placement to form mesoscale and even macroscale structures. To this end, we are investigating self-assembly processes in supercritical fluids. In a correctly chosen solvent system, a solute can exhibit a peak in its saturation solubility with respect to temperature. By holding the solvent at the temperature of the peak and heating the substrate, the solute can be precipitated from the supercritical solvent onto the substrate. The location of the deposition can be controlled by locally heating the substrate, for example, by passing current through lithographically patterned conductive traces. This coupling of solution phase self-assembly and photolithography gives physical supercritical fluid deposition the potential to control material deposition at all length scales. The unique deposition conditions also provide additional means of controlling the nanoscale structure of materials resulting in uncommon morphologies for polymer semiconductors. The self-assembly process takes place in several steps including a solution phase pre-aggregation step that is sensitive to the Rayleigh number of the solution. Following deposition onto the substrate, the presence of solvent additives can facilitate the formation of larger scale structures by increasing the surface mobility of the deposited material.

Effective and Sustainable Cs^+ Remediation via Exchangeable Sodium-Ion Sites in Graphene Oxide Fibers Youngtak Oh[1] and Heehyeon Lee[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

The uncontrolled release of radionuclides following the Fukusima incident has prompted the need for rapid, stable, and sustainable radionuclide-capturing materials. If the intrinsic problems related to the slow adsorption, low capacity, and complexity of surface modulation methods are solved, graphene oxide (GO) structures can be utilized for effective cesium (Cs^+) remediation. This study presents sodium-infused GO fibers with a highly efficient Cs^+ capture ability (150–220 mg g^{-1} capacity within a 30-min saturation time) and consistent regeneration ability. The crucial role of sodium in GO colloid assemblies and the highly efficient and sustainable Cs^+ remediation functionality is investigated.

Reformulated FeOOH Acetate Nanoplatelet for Heavy Metal Immobilization DaeBeom Lee, Yun-Sik Lee, Bum Chul Park, Kijong Cho and Young Keun Kim; Korea University, Korea (the Republic of)

Arsenic is a heavy metal that contaminates the ecosystem and originates global damage to a sustainable environment.[1] The attempt to immobilize arsenic using neither nanostructure-engineered material nor natural nanomaterials is suggested due to its productivity and potential to harm the ecosystem in the soil.[2]

Here, we suggest a method to enhance the arsenic immobilization via using sustainable nanomaterial amendment, reformulated FeOOH-acetate nanoplatelets (FAN). Iron oxyhydroxide is a clay mineral that is abundant in the earth's crust and is a sustainable natural material.[3] FAN is synthesized either by reformulating the natural iron oxyhydroxide form or by the particle attachment-based synthesis, both in an expandable scale. In the crystallization process of FAN, acetate anions are coordinated to the iron atom with bidentate bridging, inducing a stacking of FeO_6 octahedron layers with a large spacing. It has an inorganic-organic hybrid structure with an extended lepidocrocite layered structure with a basal spacing of 1.14 nm. FAN immobilizes arsenic by two mechanisms, electrostatic intercalation with a large interlayer spacing and chemical adsorption on the surface of layers. This synergetic adsorption mechanism enables FAN to enhance the adsorption capacity of arsenic species acting as sustainable engineered nano-amendments. The ability to immobilize the bioavailable arsenic is confirmed with the bioassay of collembolan and plant reproduction, and arsenic adsorption results in arsenic-contaminated artificial soil and mine soil. This research will be the basis for crystallization-based engineering of natural materials for a sustainable environment.

Polymerized Ionic Liquid-Enabled Heterostructured Carbon MesoNetworks by Electrospinning Qi Li[1], Feng Yan[1] and John Texter[1,2,3]; [1]Soochow University, China; [2]Eastern Michigan University, United States; [3]Strider Research Corporation, United States

This paper illustrates symmetry-breaking heterostructured network coatings prepared by electrospinning using (1) graphene and (2) MWCNT building blocks. Aqueous thermodynamically-stable dispersions of carbon nanotubes and graphene, respectively, at 6-17% by weight, are prepared liquid phase exfoliation using polymerized (surfactant) ionic liquid stabilizers. These dispersions provide ultra-high thermal conductivity and heterostructured and high specific surface area coatings. Such advanced coatings enable development of a platform for catalytic membranes and electrocatalytic electrodes derived by electrospinning (ES) and further extend the utility and potential of 2D materials and advanced composites based on 2D materials. We demonstrate how networks made by ES can be grown beyond inherent 1D fibers to provide 2D-heterostructured networks as supports and electrodes. Two classes of such networks are presented: (1) randomly oriented graphene flakes connected by nanofibers; (2) 2D-microscale membranes composing mesoscale networks of MWCNTs connected by nanofibers. These MWCNT mesoscale networks exhibit a 0D+1D=2D self-assembly phenomenon that appears driven by (a) polymer bead-necklace connectivity and (b) capillary-force-driven 2D assembly of MWCNT out of a highly electrically polarized columnar fluid stream. **These free-standing 2D heterostructured micro-films have no 2D constituents.** Morphology tuning and densification, and modulation of ionic and electrical conductivities by chemical doping, chemical deposition, and anion exchange are described. Applications of such coatings to catalysis, electrocatalysis, and energy devices (batteries, fuel cells, and dye-sensitized solar cells) are discussed.

Tetraphenylbenzene-Based AIEgens—Preparation and OLED Application Anjun Qin; South China University of Technology, China

Aggregation-induced emitting (AIE), a scientific concept coined by Tang et al. in 2001, refers to a unique phenomenon that molecules that emit weakly or non-luminously in solutions are induced to emit intensely in the aggregate and solid states. Currently, the AIE luminogens (AIEgens) have been widely applied in diverse areas, and advantages over traditaional fluorophores have been well demonstrated. To further expand the research fields of AIE, more AIE cores besides tetraphenylethene, silole, and 9,10-distyrylanthrance, need to be designed and synthesized.
In this talk, I will report our recent efforts on development of tetraphenylbenzene-based AIEgens under the guidance of restrictiction of intramolecular rotation. At the same time, the application of them in blue/deep blue nondoped OLED will be discussed.

9:30 AM *SF05.13.02
Redox-Based Study Opportunities with AIEgens Towards Microalgae-Derived Health Supplements Youhong Tang; Flinders University, Australia

Reactive oxygen species (ROS) are oxygen derivatives comprised of hydrogen peroxide (H_2O_2), hydroxyl ions (OH^-), superoxide anions (O_2^-), and their secondary reaction products, produced by the metabolic redox reactions in living cells. ROS can be produced in chloroplasts, mitochondria, and several other subcellular compartments in photosynthetic organisms. Among the photosynthetic organisms, microalgae are a large group of unicellular organisms in marine and freshwater environments. These organisms possess a wide range of polysaccharides, lipids, proteins, antioxidants, vitamins, and pigments that could be exploited as sustainable nutritional and therapeutic supplements. These biomolecules synthesizing machineries could be triggered by altering the environmental conditions, such as nutrients or stress conditions. ROS formation often accompanies the stress-based strategies as an essential cellular component of responding to stress factors. In order to upstream the yield of the beneficiary biomolecules from microalgae, a further realization of the ROS interventions during their bioaccumulation processes could radically improve the production of these health supplements.
Recent advancements of aggregation-induced emission luminogens (AIEgens) offer remunerative sensing applications with strong photo-bleaching resistance, high signal-to-noise ratio, and large Stokes' shift. The photophysical properties of these AIEgens could be utilized in algal research for growth induction and essential biomolecules production through altering the ROS signalling pathways and light wavelength in favourable regime to improve their association in the biological application and health supplements from microalgae. However, photosynthetic organisms contain different biomolecules with their autofluorescence properties, selecting appropriate probes for the studies is very challenging and in demand. This could lead to the optical engineering of suitable photosensitizers to maximize the availability of the essential biomolecules in microalgae. Thus, utilizing organic luminogenic aggregates could provide us with a promising opportunity to develop algal technology for more significant health benefits.

10:00 AM *SF05.13.03
The Assembly of Inorganic Ionic Oligomers for Advanced Material Preparation Zhaoming Liu and Ruikang Tang; Zhejiang University, China

Polymerization and crosslinking of organic monomers or oligomers have made diverse bulk polymeric materials with advanced functions. Yet, it is hardly been achieved on inorganic ionic species for bulk materials preparation due to the different behavior of covalent and ionic bonds. Our recent works revealed that the inorganic ions can be assembled into inorganic ionic oligomers, which could act as precursors for bulk material synthesis *via* inorganic ionic polymerization and crosslinking. (Nature, 2019, 574, 394). In this way, the inorganic bulks could be moldable constructed as we making organic polymers. The inorganic ionic polymerization and crosslinking enabled multiple advanced structures preparation, such as biomimetic continuous amorphous-crystalline interface, biomimetic flexible mineral phase, biomimetic organic-inorganic interface, periodic mineral defects etc.. Based on such structures, we realized the moldable construction of hard minerals by particle fusion (Science, 2021, 372, 1466), regrowth of tooth enamel (Sci. Adv., 2019, 5, eaaw9569), fast (within 5 min) remineralization of human dentin (Adv. Healthc. Mater., 2022, 2201161), production of biomimetic unltra-tough materials (Angew. Chem. Int. Ed., 2020, 59, 2071; ACS Nano, 2022, 16, 7926), biomimetic humidity sensor (Adv. Funct. Mater., 2021, 2101291) and hybrid minerals as a new plastic substitute (Adv. Mater. 2022, 34, 2107523). Our works present the inorganic ionic oligomers as new precursors for advanced material preparation, shedding light on an alternative strategy to make marvelous inorganic and hybrid materials. It also emphasizes the unique and important role of making materials by aggregation and assembly of clusters through non-classical crystallization pathway.

10:30 AM SF05.13.04
Programmable Patterning of Cholesteric Liquid Crystals by Self-Assembly Lang Qin and Yanlei Yu; Fudan University, China

Responsive photonic crystals are widely employed to construct rewritable paper, where patterns are written and erased repeatedly via color switching. The working principle mainly lies in the changes on the lattice constant of periodic structures, which, however, restricts the localized color tuning of the recorded patterns and thus limits multicolor information transfer. Herein, a novel strategy is reported to write, erase, and importantly to tune the colors by developing unique light-driven cholesteric liquid crystals (CLCs) that possess self-organized helical superstructures with two structural elements of pitch lengths (lattice constant) and helical axes (reconfiguration). Reconfiguration of the helical axes provides two high-contrast optical states for writing and erasing by pressure and electricity, whereas precise photocontrol of the pitch lengths contributes to localized color tuning. These features primarily capitalize on the light-driven CLC with diverse photostationary colors, which is induced by a newly designed binary chiral system and confined in the polymer dispersed liquid crystal layer. Distinct multicolor patterns are mechanically written, optically tuned, and electrically erased on the rewritable photonic paper in a programmable manner. Such photonic paper has potential to record, program, and remember optically addressed images in visualized color information and user-interactive display technologies.

10:45 AM SF05.13.05
One Step Method to Simultaneously Growth TiO_2 Compact and Porous Layers for DSSC Photoelectrodes Arturo I. Espinoza[1], Ana L. Leal[2], Alicia Vera[2], Carlos Zúñiga[1] and Josue Aguilar[3]; [1]Instituto Nacional de Astrofísica, Óptica y Electrónica, Mexico; [2]Universidad de Sonora, Mexico; [3]Universidad Autónoma de Nuevo León, Mexico

Titanium dioxide (TiO_2) interest has increased considerably in recent years, owing to its exceptional optoelectronic properties and potential applications in electronic devices, such as photodetectors and DSSCs. In DSSCs, photoelectrodes play an important role. Typically, photoelectrodes must have a blocking and a porous layer of oxides to avoid electron leakage and to improve conversión efficiency. Typically, those layers are fabricated through different techniques or processes. In the present work, a one-step method for simultaneous fabrication of TiO_2 blocking and porous layers at relatively low temperatures is presented. In addition, samples with TiO_2 blocking and porous layers were characterized by FESEM/EDS, XRD, and UV-visible spectroscopy techniques with the purpose of determining their structural characteristics, morphology, optical behavior, and bandgap. As result, crystalline TiO_2 blocking and porous layers were successfully obtained and tested as photoelectrodes for DSSCs. The best oxide materials obtained by the developed process correspond to the Anatase phase, which is formed by a TiO_2 compact layer and a porous layer of particles of 100-200 nm, the optical band gap of 3.30 eV, and optical bandwidth comprises the visible range with applications in DSSC photoelectrodes.

SESSION SF05.14: Virtual Session II: Building Advanced Materials via Aggregation and Self-Assembly

10:30 AM SF05.14.01
Lightweight High-Strength Nano-Architecture Silica Templated from 3D DNA Frameworks Aaron N. Michelson[1], Tyler Flanagan[2], Seok-Woo Lee[2] and Oleg Gang[3,1]; [1]Brookhaven National Laboratory, United States; [2]University of Connecticut, United States; [3]Columbia University, United States

Nanolattices are an emerging class of mechanical metamaterials highly attractive due to their superior strength-to-weight ratios which originate from their complex spatial architectures and the nanoscale-sized elements that usually possess near-theoretical strength. Despite much interest, rational design and fabrication of nanolattices remains challenging, particularly when the dimension of element is less than 50 nm, because it is extremely difficult to arrange such small elements into complexly designed three-dimensional structures. In this study, we solved this problem and successfully fabricated silica nanolattices with ~4-20nm thick elements using self-assembly and silica templating of DNA origami ordered frameworks. In-situ micro-compression testing was performed to examine the mechanical properties. We observed the strong effects of lattice dimensions on yield strength and failure mode. Nonetheless, all silica nanolattices were found to exhibit yield strengths much higher than those of any known engineering materials with the similar mass density. The robust octahedron coordination of the extremely thin silica elements with ultrahigh strength leads to the excellent combination of light-weight and high-strength. Our results show that DNA-based self-assembly offer an effective approach for a fabrication nano-architectured lattices with superior mechanical properties.

10:45 AM SF05.14.02
Thermal-Responsive Poly (N-isopropyl acrylamide)/Divalent Cation Alginate Hydrogels Chenyan Zhao, Jiusi Chen and Zhaowei Yuan; National University of Singapore, Singapore

Temperature-responsive hydrogels with enhanced mechanical properties are desirable in intelligent device area including artificial electronic skin and soft robotics. In this contribution, poly(N-isopropyl acrylamide)/sodium alginate (PNIPAM/Ca-alginate) and PNIPAM/Fe^{2+}-alginate hydrogels were prepared by a two-step strategy, obtaining hydrogels with two kinds of cross-linking: chemical cross-linking and ionic cross-linking. Maintaining the excellent water harvesting ability, the hydrogels exhibited improved mechanical properties compared with that of the PNIPAM/Alg hydrogel and the compressive strength of 2 hydrogels depended significantly on the cross-linking density. Meanwhile, compared with the traditional single network, the ‘egg-box’ structure of these hydrogels performed better stability with the formation of channels from which water diffuses easily during swelling and deswelling.

10:50 AM *SF05.14.05
Luminescent Aggregate Materials Based on Excited-State Molecular Motion Regulation Zheng Zhao; The Chinese University of Hong Kong, Shenzhen, China

Aggregates include powder, nanoparticles and film serve as a particularly useful form of materials that often display new properties compared to their molecular components. Aggregation-induced emission is one of the most representative examples of aggregate materials. In the following presentation, we will introduce our research development in regulating excited molecular motion of AIE materials and our exploration in utilizing excited state molecular motion regulation to achieve addition function of AIE materials besides luminescent property. The involve contents include luminescence mechanism study, new structure design and application exploration. What we want to claim is that molecular structure design is much significant for materials science, however, from molecules to solid state materials, a lot of things happen during the aggregation process, which may endow molecules with many new properties and functions. Elucidating the new emerging properties and the underlying mechanism is of great significance. We have coined this as aggregate science

11:20 AM SF05.14.06
Magnesium Hydroxy Carbonate Hydrates—Nature-Inspired Water Filters for Heavy Metal Sequestration Anton Sednev-Lugovets[1], Yang Lu[1], Ørnulv Vistad[2], Håkon Austrheim[1], Henrik Friis[1], Patricia Carvalho[2] and Matylda Guzik[1]; [1]University of Oslo, Norway; [2]SINTEF Industry, Norway

The climate change, growing world population, together with a widespread use of chemicals in industry and our everyday life, are projected to reduce water availability in sufficient quantity and quality. Heavy metal contaminations have a seriously damaging impact on the quality of water bodies, imposing a great burden on downstream users and ecosystems. Although, natural materials, such as charcoal, sand and diatomaceous earth, have been already incorporated into modern water filtration systems (1), there is still a great need for highly efficient and environmentally sustainable sorbents.

Motivated by this challenge, we focus our research on investigation of nature-inspired sustainable functional materials and their application in water filter technologies.

Magnesium hydroxy carbonate hydrates are a relatively small group of naturally formed minerals that have been widely investigated for large-scale CO_2 sequestration. However, our recent study has shown that these compounds can also effectively remove heavy metals (e.g., Cr, Cd, Cu, Pb, Ni (2)) from water and act as water filters (3,4). Two members of this mineral family: ***1)*** dypingite (named in ’70s by Gunnar Raade, after the Dypingdal serpentine-magnesite deposit in Norway), and yet ***2)*** unnamed compound (hereafter referred to as UPh, a new crystalline phase identified by us while studying dypingite samples), deserve particular attention due to their unique desert rose morphology. The term “desert rose” designates self-assembled microstructures with clusters organized into fanning platelets. These 3D configurations exhibit hierarchical features that span across multiple length scales and present high specific surface area, which are crucial for many applications including sorption. Despite the remarkable sorption performance, information about the dypingite and UPh structural properties is surprisingly limited. Even though, the naturally occurring dypingite was a subject of several investigations (5,6), the available data on the material chemical composition, in particular

water content, and structural features are inconsistent. The synthetic dypingite minerals has also been obtained but none of the applied approaches resulted in the formation of desert rose-like microstructures, occurring exclusively in naturally formed compounds. For better understanding of phenomena behind the physical & chemical performance of both minerals, the systematic and detailed material analysis is indispensable.

To partly fill this gap, we have been performing comprehensive structural, microstructural and functional studies on natural and synthetic samples of both minerals that allow us: ***i)*** to define optimum synthesis conditions for the formation of materials with desert rose morphologies, ***ii)*** to determine relationship between the material structural/microstructural characteristics and its heavy metal sorption capacity, ***iii)*** to define the compound stability range, and ***iv)*** to identify unique powder X-ray diffraction patterns of both phases, in order to solve their crystal structures.
