Easy-generation of stable charge carriers in organic semiconductors is a key challenge towards modern high-performance devices for electronics, photovoltaics, spintronics, sensing, and catalysis applications. In recent years, covalently tethering an appropriate dopant to a semiconductor of interest to achieve self-doping by charge transfer upon simple photoexcitation has emerged as a promising attractive strategy. In the case of self-n-doping, perylene bisimide (PBI) derivatives have garnered the most attention due to their high electron affinity and strong absorption in the visible range, as well as their good chemical robustness and excellent photostability. Several studies described the photogeneration of anions in amine or ammonium-functionalized PBIs. However, in these few examples, only charge lifetimes of tens of minutes, at best, were reported. Additionally, the role of the chromophores arrangement in this photo-n-doping process remains unclear, and a more thorough understanding is required to design efficient self-n-doped materials. Our laboratory has previously revealed the formation of unusually long-lived positive photo-charges in self-assembled nanowires from electron-rich semiconductor molecules substituted with chiral oligopeptide-polymer side chains. The doping was attributed to a photo-induced electron transfer to the lateral amide bond acting as an acceptor and it was demonstrated that the formation of well-defined helical, one-dimensional aggregates is one decisive prerequisite for its occurrence. Recently, we discovered that the same molecular architecture and self-assembly strategy can also lead to self-n-doping of supramolecular nanowires based on well-chosen electron-poor chromophores. Dicyanoperylene bisimide (CN2-PBI) along with tetrachloroperylene bisimide (Cl4-PBI) were substituted with oligopeptide-polymer side chains and their supramolecular aggregates were investigated by a combination of spectroscopies as well as atomic force microscopy and X-ray scattering. While Cl4-PBI aggregates show no photo-doping, illumination of the CN2-PBI nanowires leads to the formation of air-stable radical anions with extraordinarily long lifetimes on the order of hours that can accumulate to concentrations of up to 7 mol%. In addition, devices prepared from these aggregates exhibit macroscopic transport properties typical for a strongly doped electron conductor with a highly persistent photocurrent. The comparison of these two systems reveals that the formation of mixed Frenkel/Charge-Transfer excitons in the aggregates plays an essential role in the efficiency of the photo-n-doping. Moreover, this conclusion was further confirmed to be a universal condition by the study of two additional self-p-doping systems. These results prove that the macroscopic electronic properties are not only inherent to the employed molecular structure, there are an “emerging property” that is strongly affected by the intermolecular chromophore arrangement which thus needs to be carefully designed as well in self-doped organic electronic materials.

What Can We Learn from the Chiral Induced Spin Selectivity Effect on Electron Transfer? Ron Naaman; Weizmann Inst, Israel

The chiral induced spin selectivity (CISS) effect means that electron transport through chiral systems is spin dependent. The effect was found to exist not only on molecular scale but also in crystals when the scale of the spin transport exceeds microns. In addition, in many cases, the effect was found to increase with increasing temperatures. Recent studies on electron transfer (ET) through proteins established that the effect is indeed long range and with extremely high spin selectivity, reaching 100%.
Experimental results obtained on long range CISS effect will be presented and the dilemma they present will be discussed. Since the CISS effect involves also charge transfer, its mechanism must reflect the ET process. The observations obtained regarding the long range CISS effect, are not consistent with hopping or mechanism. A new insight on the ET mechanisms will be presented that is consistent with many experimental observations that could not explained by the “conventional” models.
It will be shown that within the modified scheme both the ET and the CISS effect can be explained in principle, although the real first principle calculations remain a major challenge.

Spinterface Mechanism for the Chirality-Induced Spin Filtering - From Transport to Photoexcitation Yonatan Dubi; Ben-Gurion University, Israel

When electrons are injected through a chiral molecule, the resulting current may become spin polarized. This effect, known as the chirality-induced spin-selectivity (CISS) effect, has been suggested to emerge due to the interplay between spin–orbit interactions and the chirality within the molecule. However, such explanations require unrealistically large values for the molecular spin–orbit interaction without any physical justification. Put simply, to date, the physical origin of the CISS effect is unknown.
Here, we present the “spinterface mechanism” for the CISS effect, based on the interplay between spin–orbit interactions in the electrode, the chirality of the molecule (which induces a solenoid field), and spin-transfer torque at the molecule–electrode interface. The spinterface mechanism has already been shown to allow remarkable fit between theory and data for numerous experiment. We will provide new examples for such fits, further corroborating the mechanism. We will describe a set of experiments which can be used as a “smoking gun” for differentiating this mechanisms from other theoretical explanations. Finally, we will describe a spinterface mechanism for the CISS effect in photo-excited electrons scattered off a layer of chiral molecules.

Experiment and Hope—Evidence for Quantum Solid-State Electronic Conduction Across Proteins David Cahen; Weizmann Institute of Science, Israel

Electron Transport (ETp), *electronic* conduction, across ultra-thin protein films as active layer in a solid-state junction, can be surprisingly efficient. Length-normalized ETp efficiency can be similar to, or even exceed that of conjugated molecules; moreover, it can be temperature-independent down to at least 4K. If intra-protein transport dominates (contacts are not limiting; a challenge as proteins are poly-electrolytes), no significant transport barrier is measured, challenging the simplest explanation for this transport, hopping conduction.
Such results have, nowadays, the banner “quantum” all over them, as they seem consistent with quantum tunneling; one of the problems with such an explanation. While recently the first golden standard evidence, with alkyl-thiol molecule films, for such, interference, was reported, it is still lacking for proteins. In truth, coherent transport through proteins, non-periodic systems that are dynamic, even at low temperatures, is not at all obvious. Still there are some results that are
surprising in this context:
- the above-noted temperature independence, which we have now found for up to ~ 20 nm (multilayers of bacteriorhodopsin, bR)
- the inability to fit, small, short proteins (Azurin, Az) data to any reasonable hopping model
- the possibility to bring short proteins (Az, Cytochrome C) in and out of resonance by applied bias
- clear inelastic electron tunneling spectra for Az (and their absence for larger proteins).

Unraveling the transport mechanism is, apart from scientific curiosity, of interest, as understanding ETp may have relevance for ET (replace coupling to contacts by electron injection / extraction). I will discuss our recent experimental data and their analyses, and try to put them in perspective also with reports from other groups. The aim is to separate expectation and anticipation from experimental observables, to define the puzzle that we try to solve3, even if it starts to resemble the ‘duck test”.

Large Cooperative and Dielectric Effects on the Tunneling Rates Across Molecular Tunnel Junctions Christian A. Nijhuis; University of Twente, Singapore

The measured tunneling rates are in molecular junctions are often large over surprisingly large distances.[1] In addition, often the temperature dependency (or lack thereof) is still poorly understood. We are investigating the mechanisms of charge transport across junctions of the form metal—molecules—metal where the molecules are present in the form of self-assembled monolayers (SAMs). I will give a brief summary of our effects to elucidate charge transport mechanisms in molecular tunneling junctions by measurements of dielectic constast coupled with temperature dependent measurements.[2] We find that charge transport increases with dielectric contstant, with increasing dielectric constant the tempersature dependency (or activation energy increases).[3] In mixed monolayers, we find a soft atom induces positive cooperative effect on electron transfer rates.[4,5] These studies as group highlight the complex interplay between several intertwined factors (molecular structure, molecular organization, dielectric properties and interfaces) in the mechanism of charge transport across molecular junctions.

Long-Range Charge Transport Through Bacteriorhodopsin Multilayers Domenikos Chryssikos[1,2], Jerry A. Fereiro[1,3], Jonathan Rojas[1], Mordechai Sheves[4], David Cahen[4] and Marc Tornow[1,2]; [1]Technical University of Munich, Germany; [2]Fraunhofer Research Institution for Microsystems and Solid State Technologies, Germany; [3]Indian Institute of Science Education and Research Thiruvananthapuram, India; [4]Weizmann Institute of Science, Israel

Proteins are ubiquitous in the vital functions of the cell, many of which rely on charge transfer, such as respiration and photosynthesis. Recent research has revealed that certain proteins maintain their structure, as well as their conductive properties, even in the unnatural "dry" state (with only some structural water retained). [1, 2] As a result, researchers have strived to exploit the electronic properties of proteins in the context of hybrid solid-state devices, such as protein-inspired sensing, photovoltaics and memory devices. [3] To this end, understanding the nanoscopic charge transport mechanisms inside dry proteins is crucial. In this study, we focus on bacteriorhodopsin (bR), a proton pump in the purple membrane of *Halobacterium salinarum*. bR is a promising candidate for solid-state devices due to its thermal stability and photoactivity. [4] While the self-assembly and electrical characterization of bacteriorhodopsin-rich layers is well-established, [5] the controlled preparation of multilayers remains challenging for structural and electrostatic reasons. Here, we present a technique for the preparation of multilayers of octylthioglucoside-treated bR (OTG-bR) embedded in protein-lipid vesicles, on amino-terminated TiN substrates. The technique employs the cationic polymer polydiallyldimethylammonium (PDDA) as an electrostatic linker between the protein layers. Our analysis using atomic force microscopy (AFM) revealed the successful preparation of stacked films of OTG-bR, with heights 8.2, 13.0, and 16.2 nm for one, two, and three OTG-bR layers, respectively. X-ray photoelectron spectroscopy (XPS) verified the relatively high macroscopic surface coverage of approximately 90% for the triple layer. DC current-voltage measurements where performed in a vertical configuration using the TiN substrate as bottom, and eutectic gallium-indium or evaporated Ti/Au as top contacts. We observed an exponential attenuation of the current as a function of layer thickness, with attenuation coefficients of $0.7 - 1.0$ Å^{-1}. These values are somewhat smaller than previously reported [2, 6] and in addition, show a small yet intriguing increase with increasing voltage bias. Variable-temperature measurements revealed temperature independence below $T \approx 50$ K, and Arrhenius-like temperature dependence with activation energies of roughly 50 meV above this temperature. Considering the above findings, we propose a possible multistep charge transport mechanism, which would combine both, off-resonant and resonant charge carrier tunneling, as well as thermally activated hopping processes.

Seeing Directly How Picocavity Adatoms Control Molecule-Metal Coupling Jeremy J. Baumberg; University of Cambridge, United Kingdom

Our ability to trap light into extreme nanoscale gaps between coinage metals using plasmonics has enabled routine vibrational measurements of molecular monolayers, even within active molecular electronics devices [1]. We recently showed that single metal atoms can be pulled out of the interface by light [2] (or electric fields), and that coordination bonds with individual molecules can be tracked in real time [3-6], or their redox state observed [7]. We discuss new observations for the thousand-fold enhanced optical forces in such nanogaps.
Such spectroscopy reveals a wealth of information: from how applying voltages can twist the conducting molecules in a gap [8], to how solvated charge is able to penetrate self-assembled monolayers [9]. The robust and precise self-assembly of the nanoparticle-on-mirror geometry is ideal for tunnelling photocurrent devices [10], and shows that asymmetry is created in the junction, likely by such picocavities. We also discuss the dynamics of the picocavity formation [11], and how this may be now controlled.

4:00 PM *EL10.06.02
In-situ Spectro-Electrochemistry of Conductive Polymers Using Plasmonics to Reveal Doping Mechanisms Ivana Qianqi Lin[1,2], Jialong Peng[2], Tamás Földes[3], Hyeon-Ho Jeong[2], Yuling Xiong[2], Charalampos Pitsalidis[2], George G. Malliaras[2], Edina Rosta[3] and Jeremy J. Baumberg[2]; [1]University of Twente, Netherlands; [2]University of Cambridge, United Kingdom; [3]University College London, United Kingdom

Conducting polymers are a key component for wearable organic electronics due to their low-cost fabrication compared to silicon counterparts, and their mechanical flexibility compatible with foldable devices. The reversible doping/dedoping of conductive polymers is the basis of organic thin-film transistors, sensors, and displays.

Doping transfers electrons in/out (i.e., reduction/oxidation) of the neutral conductive polymers, creating negative/positive charge carriers. Two-electron transfers are involved in generating polarons or bipolarons. The former contains mono-radical ions, and the latter contains di-anions/cations. Although many techniques have been used to characterize the doping/redox process, conflicting conclusions often arise from the **difficulty in obtaining well-defined electrochemical response from the polymers**, and **it is unclear why short-lived polaron intermediates are sometimes observed but sometimes not.** Understanding of the doping/redox mechanism is thus scarce, limiting development of widespread polymer-based applications.

In this work [1], we present an in-situ spectro-electrochemical technique to address this challenge. Using nanoparticles encapsulated by thin shells of conductive polymers, their redox dynamics can be interrogated. By drop-casting the core-shell nanoparticles onto a gold substrate, an electrochromic nanoparticle-on-mirror (*e*NPoM [2,3]) geometry is formed giving well-defined electrochemical response, as well as actively-tuned scattering color through switching their refractive index. More importantly, the plasmonic hotspots formed in the *e*NPoM geometry confine light into nanocavities at the volume of < 100 nm^3, enabling vibrational Raman scattering enhancement of $>10^4$ and high signal-to-noise ratios. Surface-enhanced Raman spectroscopy (SERS), in combination with cyclic voltammetry, uncover structural fingerprints at the few-molecule level during redox transitions. Our data intriguingly show that the **doping mechanism varies with polymer conductivity: a disproportionation mechanism dominates in more conductive polymers, while sequential electron transfer prevails in less conductive polymers**. This technique thus allows in-situ study of the thin-film conductive polymer redox in real-time to reveal new features in the doping mechanism.

4:30 PM *EL10.06.03
Combining Single-Molecule Raman with Molecular Conductance Measurements Josh Hihath; Arizona State University, United States

The ability to manipulate and characterize individual molecules with atomic-level precision is necessary to develop a thorough understanding of the intricacies of the effects of changes in molecular structure on a range of phenomena such as reaction mechanisms, catalysis, local effective temperatures, surface interactions, and charge transport. Along these lines, the field of molecular-scale electronics has evolved tremendously in recent years: from the initial experiments claiming single-molecule conductance measurements to the development of platforms that provide a detailed understanding of the charge transport properties of these systems. It has now become possible to probe the chemical, structural, mechanical, and electrical properties of single-molecule devices and explore unique functional paradigms for applications. However, continued advances in *in situ* characterization of a molecular junction are needed to provide detailed information about the molecular configuration and its impact on the charge transport, reactions, and device behavior. Single-molecule conductance and Raman spectroscopies each provide unique perspectives into the behavior of molecular systems and reactions at the single-molecule level. In this talk we will discuss the development and implementation of system designed to simultaneously obtain conductance information and Raman spectra from a molecular junction to provide direct structural and chemical information about a single-molecule junction.

This multi-dimensional information yields repeatable, self-consistent, verification of single-molecule resolution, and allows for detailed analysis of structural and configurational changes of the molecule *in situ*, and provides new opportunities for identifying molecular substituents, conformations, and the impact of these changes on the transport properties of the molecular systems. We will discuss the correlation between single-molecule binding events and changes in Raman spectra (intensity, modes, etc.) and conductance to explore the possibility of obtaining single-molecule spectra from the molecule bound between two electrodes. We will further explore the utility of this system for *in situ* characterization of single-molecule devices including electrically-active single-molecule switches, memory devices, and biomolecules.

SESSION EL10.07: Poster Session

5:00 PM EL10.07.02
Beyond Fermi-Level Pinning: Control over Energy Level Alignment at Molecule-Electrode Interfaces via Proton-Coupled Electron Transfer Fuad Alami, Georgios Katsoukis and Christian A. Nijhuis; University of Twente, Netherlands

Intelligent design of energy level alignment for molecular electronics is crucial for developing complex charge transfer systems. The majority of approaches for energy level alignment pertain to chemical modification. However, molecule-electrode interactions can also present a means of modulating alignment within the junction via interactions such as push-back effects[1] and Fermi level pinning[2]. In addition, substrate-mediated interactions can induce structural, chemical, and electronic changes in self-assembled monolayers.[3] To the best of our knowledge, studies between the coupling of a proton-coupled electron transfer (PCET) system and substrate-mediated interactions have yet to be investigated. In these studies, we examine the influence of substrate choice on the well-known PCET demonstrated in hydroquinone redox reactions. By using 11-mercaptoundecylhydroquinoine (11-MHQ) tethered to platinum or gold, we can differentiate the substrate's influence on the charge transfer mechanism. We believe that the substrate's influence on the charge transfer mechanism induces a variance in the molecular dipole contribution to change in work function. To further understand this phenomena, we investigated whether the substrate influences the redox equilibrium by characterizing the monolayer by Fourier transform infrared spectroscopy (FTIR) and cyclic voltammetry (CV) and X-ray Photoelectron Spectroscopy (XPS). Furthermore, understanding the resulting energy alignment of the system was done through Ultraviolet Photoelectron Spectroscopy (UPS) and the manifestation of such influences on the electronic tunneling behaviors is demonstrated by forming a two-terminal junction composed of metal/11-MHQ/EGaIn (eutectic alloy of gallium and indium). These junctions demonstrated a reversal in rectification only dependent on electrode choice.

Dynamic Molecular Switches Based on HATNA Derivatives for Application in Neuromorphic Computing Alessandro Borrini; University of Twente, Netherlands

Currently, about 5%–15% of the world's energy is spent in some form of data manipulation and this fraction is expected to rapidly increase. Between 20 and 30 MW are estimated for von Neumann type computers to emulate same level of complexity as our brains. Our brain works with 20 W.[1] Neuromorphic computing architecture focuses on building electronic neural processing systems that directly emulate real neurons and synapses. Currently, most approaches to neuromorphic computing rely on high energy consuming silicon materials.[2] An attractive energy efficient solution is given by molecular switches which can potentially simulate synaptic plasticity. However, up to now, molecular switches can only switch between fixed on and off states, hence showing a static rather than dynamic behaviour. The key factor to reproduce synaptic plasticity is coupling different processes each characterised with its own time constant, analogues of action potential coupled to slow diffusion of Ca^{2+} and neurotransmitters in synapses. 5,6,11,12,17,18-hexaazatrinaphthylene (HATNA) in a tunnelling junction is a promising candidate because it can couple a fast electron transfer to slow proton transfer.[3] Synthetic modification of HATNA with diphenylacetylene (DPA) moieties can potentially facilitate tunneling electron transfer rates in the junction while at the same time enhance packing density of molecules on the electrode.[4,5] In this poster we give an overview of the synthesis route to achieve the dynamic switch HATNA-DPA and initial monolayer composition studies.

5:00 PM EL10.07.04
Mechanical Stabilization of Molecular Junctions by Interaction with Polar Media Yoni Langbeheim and Uri Peskin; Technion-Israel Institute of Technology, Israel

The build-up of energy density in nano-scale electronics via inelastic resonant electron transfer is detrimental to chemical bonds' stability and molecular structure's integrity. This effect may be harnessed for control of the electron (hole) current, but on the other hand, accumulation of excess vibrational heat may lead to bond rupture and breaking of the nano junction. Therefore, finding physical conditions at which these junctions can sustain high-voltage resonant transport is of prime importance for experimental application.
We predict that polar media interacting with the transient charging of the molecule may stabilize junctions under resonant transport. The Polaron-like coulomb interaction of polar media with the charged species is lowering the energetic range for discharging events. In highly-polar solvents, this effect tends to favor cooling transport processes over heating ones, stabilizing the overall charge transfer event. A second effect is brought up by the thermally-induced growth of the number of interacting solvent particle configurations. The widening band of emerging virtual states broadens the possibility windows for charge transfers from (or to) the electrode. This thermal broadening also tends to promote the cooling inelastic charge transfer pathways over the heating ones, overall inducing a temperature + polarity dependent transport-induced cooling effect. These findings are added on top of a temperature-dependent electrode cooling process known from previous studies.

5:00 PM EL10.07.05
Synthesis of Oligomers in Molecular Junctions Tal Klein and Oren Tal; Weizmann institute of science, Israel

We use the Ullmann reaction to successfully synthesize individual oligomers in molecular junctions at 4 Kelvin. Our motivation is twofold: first, finding a scheme based on a very general and widespread reaction for in-situ preparation of a single polymeric chain suspended between two electrodes for the study of charge, spin, and heat transport across such quanzi-1D systems. Second, a better understanding of chemical synthesis in very peculiar conditions. We will discuss the role of low-coordination substrates, electric fields, and unusual energy resources, as friction, on the reaction and the resulted single-oligomer junctions.

8:30 AM *EL10.08.01
Distinguishing Tunneling from Hopping—Temperature, Length and Voltage Behavior Ayelet Vilan; Weizmann Institute of Science, Israel

A key question of molecular electronics is how far the charge transport is coherent, which is often coded to '*tunneling*' (coherent) vs. '*hopping*' (incoherent). Although coherent transport is associated with rich quantum mechanical phenomena, coherent electrons are "too-fast" to interact with the molecular medium and therefore yield a rather featureless voltage response. In contrast, incoherent transport involves molecular deformation and environment polarization, which leads to far richer current-voltage characteristics. Traditionally, the lack or existence of *temperature* dependence is taken as a prime criterion for *tunneling* or *hopping*, respectively. However, there are opposite cases of *temperature*-independent *hopping* (as in inverted Marcus regime) or *temperature*-dependent *tunneling* (by temperature broadening of DOS of the contacts). Overall, it undermines the reliability of *temperature* response for *tunneling / hopping* distinction. It is less known, that also the *voltage*-response differs considerably between the two mechanisms: off-resonance *tunneling* is characterized by mild, polynomial *voltage* dependence in contrast to *hopping*, which is characterized by a strong, exponential dependence on *voltage*. The third control-parameter, *length*, has somewhat 'opposite' effect: *tunneling* decays exponentially (strongly) with *length*, and *hopping* is only weakly *length*-dependent. Therefore, it is often argued that *hopping* is typical of long transport distance, exceeding ~4 nm. In contrast, we recently demonstrated transport by *hopping* across a minute distance of merely ~1 nm. Moreover, observing the combined interplay of the three parameters: *temperature*, *voltage* and *length*, reveals behavior that exceed simplistic models, suggesting that the real transport model is yet beyond our conceptualization. My talk will bring various examples of experimental transport traces and suggest possible analytical protocols to elucidate the *tunneling* - *hopping* dilemma.

9:00 AM *EL10.08.02
Molecules in Nano-Conduction-Junctions and Optical Cavities—Electron Transfer and Transmission, Polaritons, Vibrational Strong Coupling and Collective Response Abraham Nitzan[1,2]; [1]University of Pennsylvania, United States; [2]Tel Aviv University, Israel

Transport phenomena involving molecules confined within dielectric or metallic nanostructures involve coupling and energy conversion processes between charge carriers, phonons and photons. From both their scientific aspect and technological potential studies of such phenomena stand at the interface of two important fields: molecular electronics and molecular plasmonics. In this talk I will describe our work on such processes, focusing on phenomena that involve interaction with the radiation field, along several main issues: (a) Transport and spectroscopy in illuminated molecular junctions. (b) Molecular optical response when interacting with confined radiation fields (optical cavities). (c) Molecular electron transfer in optical cavities. (d) Cavity induced vibrational strong coupling and its implications on chemical reactivity.

Theoretical Insight into the Electronic Properties of Switchable Molecular Junctions Jerome N. Cornil; University of Mons, Belgium

In this contribution, we will review some of our recent theoretical works focusing on the electronic properties of switchable molecular junctions. We will describe photoswitches sandwiched between gold or ferromagnetic electrodes in close connection with corresponding experimental data and will illustrate that the design of functional molecules can be strongly hampered by pinning and/or collective electrostatic effects in the junction; a new chemical design will be introduced to enhance the on/off ratio in diarylethene-based molecular junctions. Finally, we will report calculations of magnetoresistance for junctions in the field of molecular spintronics.

Robust Devices Comprising Self-Assembled Bilayers Ryan Chiechi[1,1], Xinkai Qiu[2] and Sumit Kumar[2]; [1]North Carolina State University, United States; [2]University of Cambridge, United Kingdom

In this talk, I will discuss our work on self-assembled ensembles of (bio)molecules that are sufficiently robust to function in arrays capable of memristor-like function, diode logic and binary information storage. When sandwiched between electrodes, these ensembles mitigate charge-transport primarily via non-resonant tunneling, presenting the opportunity to control the flow of charge across interfaces at the quantum level, through self-assembly and synthetic modification. We are developing a new type of self-assembled monolayer that enables the creation of robust molecular ensemble junctions that can be printed, integrated into devices and that are bench-stable for weeks. Using this approach to program the self-assembly of protein complexes that sustain coherent tunneling over distances of 10 nm, we have been able to create simple diode logic and memristor-like devices that read out stochastic information encoded in trains of droplets in microfluidic channels. By optimizing the self-assembly of photo-switches, we have demonstrated the ability to read, write, erase and rewrite binary-encoded. While rudimentary, these devices demonstrate the utility of molecular self-assembly in the fabrication of molecular-electronic circuits using soft materials.

Single-Protein Electronics—Effect of Surface Mutagenesis and Multiheme Redox Cofactors Ismael D Diez Perez[1], Albert Cortijos Aragones[2], Eliseo Ruiz[2], Nuria Aliaga-Alcalde[3] and Christian A. Nijhuis[4]; [1]Kings College London, United Kingdom; [2]Universitat de Barcelona, Spain; [3]Institut de Ciència de Materials de Barcelona, Spain; [4]University of Twente, Netherlands

Bioelectronics is rapidly moving towards designing nanoscale electronic platforms that allow in vivo determinations. Such devices require interfacing a complex biomolecular moiety as the active sensing unit to an electronic platform for signal transduction. Inevitably, a true systematic design goes through a bottom-up understanding of the structurally related electrical signatures of such hybrid biomolecular circuits, which will ultimately lead us to tailor its electrical properties and exploit them as high performance bioelectronic devices with a wide variety of applications in organic electronics, sensing, biomanufacturing, *etc*.

In this contribution, we will present our latest efforts on trying to understand and control charge transport in a single-protein junction. Our approach relies on trapping individual redox proteins in a tunneling junction under electrochemical control to characterize their main electrical signatures. The method can capture very fine details of the charge transport mechanisms across proteins in an aqueous environment [1,2]. Our studies started on a benchmark redox protein model such as a bacterial blue Cu-Azurin. We will show first the main observed electrical signatures of these systems that make them particularly efficient in transporting charge. We then bioengineer the outer protein surface using point-site mutagenesis as a mean to get a more detailed picture of possible electron pathways through the protein backbone [2,3]. Our results suggest that the protein might not use distinct physical electron pathways across its structure, but transport mechanism can be switched upon quenching of particular motions in the protein structure via mutations. We then compare the above model system to a natural molecular wire, a multiheme protein. Multiheme proteins have been recently discovered as the building blocks in highly conducting pili and transmembrane structures of certain species of the so called electrical bacteria [4]. Our results suggest a very efficient charge transport process along the multiheme main axis with a very shallow electron decay constant.

Summing up, the above work shows the potential of electrochemically controlled nanoscale protein junctions to both elucidating charge transport mechanisms in biological systems as well as in enabling a bottom-up design of electrode/protein interfaces for the future generations of bioelectronic devices.

SESSION EL10.10: Analysis Methods and Modeling of Junctions
Session Chairs: Maria El Abbassi and Christian Nijhuis
Friday Afternoon, April 14, 2023
Moscone West, Level 3, Room 3014

1:30 PM *EL10.10.01
Machine Learning Tools for the Measurements and Analysis of Quantum and Molecular Devices Maria El Abbassi, Frederik Van Veen, Luca Ornago and Herre S. van der Zant; TU Delft, Netherlands

A deep understanding of the electrical properties of quantum materials and molecular junctions remains very challenging and is currently limited to a small selection of non-reproducible devices which show large device-to-device fluctuations. Understanding the details of every single device remains difficult, time consuming and impossible to scale up. Fast screening of different materials including molecules, as well as precise understanding and control of their electronic properties will open the way to a large number of applications including quantum computing, sensing, etc. However, one of the main challenges of quantum hardware is the poor understanding and control of the properties of the material and its interfaces/surface.

In this talk, I will share our results on using benchmark systems and large dataset combined with machine learning tools to gain more insights into the understanding of transport properties in molecular devices. By developing high-throughput platforms, we could optimize the fabrication of graphene nanogaps to contact molecules and achieve the first stable and reproducible graphene molecular junction by decoupling the electronic properties of the junction from its mechanical anchoring and stability [1]. Combining large statistics allowed by mechanically controlled break junction and clustering techniques [2,3, we could also unravel several electronic paths through porphyrin molecules [4] as well as benchmark transport properties of alkane molecules [5]. I will conclude the talk with advance on the fabrication and measurements of carbon nanotube based spin qubits.

Molecular Structure and Substrate Effects on Single-Molecule Thermoelectric Properties Tim Albrecht[1] and Joseph M. Hamill[1,2]; [1]University of Birmingham, United Kingdom; [2]University of Copenhagen, Denmark

The ability to tailor the electronic transmission function in molecular materials with the help of chemical design opens exciting prospects towards

optimising their electronic and thermal transport properties as well as the thermopower. For example, it is now well-established that quantum interference effects, the targeted introduction of substituents or even the exchange of individual atoms in a molecular structure are factors that allow for finetuning of the energetic structure of the junction.[1,2] The notion of a "Molecular" Quantum Technology is emerging, here in the context of materials design with increasing evidence that favourable thermoelectric properties at the single-molecule level can be translated to "many molecule" devices.
Employing Scanning Tunnelling Spectroscopy in combination with advanced data analysis tools,[3-5] we have recently started to explore different classes of molecules in this context. Based on a variation of distance-dependent I/V spectroscopy, we have measured the thermopower for simple organic molecules as well as new and more complex molecular designs. Specifically, our results agree well with previously reported values for 1,8-octanedithiol, 4,4'-bipyridine and OPE3,[6] while we also find interesting quantum interference and substrate effects for a series of anthracene-based molecules.[7] To this end, we observe a “pinning effect” for asymmetrically coupled molecules, where the stronger anchor dictates the overall charge transport and thermoelectric behaviour, and inversion of the thermopower for weakly bound molecules in Au/Au vs. Au/Pt junctions. In connection with recent thin-film studies, the latter lend themselves to a detailed comparison of thermoelectric performance at the single-molecule and thin-film levels.[8,9]

Dynamic Disorder Design Rules for Small-Molecule Organic Semiconductors Makena Dettmann[1], Lucas Cavalcante[1], Luke L. Daemen[2] and Adam J. Moule[1]; [1]University of California, Davis, United States; [2]Oak Ridge National Laboratory, United States

Small-molecule organic semiconductors are promising materials for applications ranging from solar cells to medical sensors. Their nearly infinite design space means that, in theory, it is possible to tailor the material to the exact specifications of a particular application. In reality, however, design rules to improve mobility (μ) remain elusive because of the complex calculations required to understand its limiters. Transient localization theory posits that charge carriers are slowed down by the collective phonon motions, called dynamic disorder, which localize charge carriers temporarily. Here, we present a streamlined simulation workflow that simplifies simulation of dynamic disorder and enables engineering of new molecular structures based on phonon dynamics. We combine this workflow with a novel visualization technique that enables per-atom insights into how μ is limited. We apply this workflow and analysis to a series of -acenes and a series of BTBT-based molecules. Then we identify design rules in each series that identify possible ways to improve the μ beyond current experimental limits using phonon engineering.

A Wave of Quantum Carbon Lapo Bogani; University of Oxford, United Kingdom

Graphene ribbons with nanometer-scale widths should exhibit half-metallicity, quantum confinement and edge effects. Magnetic edges in graphene nanoribbons have undergone intense theoretical scrutiny, because their coherent manipulation would be a milestone for spintronic and quantum computing devices. Experimental investigations are however hampered by the fact that most nanoribbons do not have the required atomic control of the edges, and that the proposed graphene terminations are chemically unstable. Several questions remain unsolved: how can spins be assembled into hybrid structures at the nanoscale? What is the influence of the graphene environment on the spin? How can we create and control coherent currents in such graphene devices? Here we try to provide an answer to these questions, exploring spin-graphene interactions by using atomically-shaped magnetic materials.
We first examine bottom-up shaping of molecular graphene quantum systems. We then show that, while the static spin response remains unaltered, the quantum spin dynamics and associated selection rules are profoundly modulated. [1] We then show how graphene nanoribbons made via molecular routes can be functionalized to create almost-ideal magnetic structures to test a decade of theoretical work. We observe the predicted delocalized magnetic edge states, and comparison with a non-graphitized reference material allows clear identification of fingerprint behaviours. We then examine how these systems can be considered excellent candidates for the observation of topological states, and unconventional types of magnetism such as Stoner interactions. We quantify the spin-orbit coupling parameters, define the interaction patterns, and unravel the spin decoherence channels. Even without any optimization, the spin coherence time is in the μs range at room temperature, and we perform quantum inversion operations between edge and radical spins.[2] The use of topological engineering and quantum decoupling sequences allows pushing coherence times up to almost ms at room temperature [3].
Eventually we discuss how these systems can push the limits of quantum electronic devices, showing spintronic[4] and electron-vibrational coupling effects[5], which can make them excellent emitting systems for carbon-based optical and optoelectronic devices.

3:30 PM *EL10.11.02
Molecular Electronics under Microscope Bingqian Xu, Kun Wang, Sneha Kandapal and Cunlan Guo; University of Georgia, United States

Electron transport through a single molecule is a central theme in molecular electronics. The ability to measure the conductance of a single molecule not only offers a new way to approach many interesting and fundamental problems in nanometer-scale science, but is also a necessary step towards the goal of building devices using single molecules. In order to measure single-molecule conductance, a molecular junction with a single molecule wired up to probe electrodes has to be fabricated. It is also essential to be able to efficiently and precisely control electron transport through such molecular junctions and understand the details of the factors that affect the transport before such devices can be made practical. SPM (STM & CAFM) based break junction (SPM-BJ) methods combing the imaging and measuring capabilities offer excellent capabilities to investigate single molecules transport properties through single molecule imaging and a complete control the junction by a series of modulation modes. This talk will focus on 1) introducing the SPM-BJ experimental platform for detailed junction modulation and control and 2) three exemplary research results obtained using the platform: molecule-electrode contacts issues, DNA structural effects on its conductance, and photo-electronic transport via exciton binding.

4:00 PM EL10.11.03
Demonstration of Terahertz Molecular Switches Imen Hnid[1], Ali Yassin[2], David Guérin[1], Lionel Sanguinet[2], Philippe Blanchard[2], Imane Arbouch[3], Colin Van Dyck[4], Jerome N. Cornil[3], Stephane Lenfant[1] and Dominique Vuillaume[1]; [1]IEMN-CNRS, France; [2]MOLTECH-Anjou, France; [3]Laboratory for Chemistry of Novel Materials, University of Mons, Belgium; [4]Laboratory for Theoretical Chemical Physics, University of Mons, Belgium

We study the electron transport properties under a terahertz (THz) irradiation of three molecules that consist of two conjugated systems, which are coupled through a non-conjugated linker. Due to this non-conjugation between them, each molecule can be seen as two weakly coupled sites in series and a resonant transport occurs only when the energy of the two sites are aligned leading to negative differential resistance (NDR) behaviors[1]. Moreover, it has been theoretically suggested that switching in such systems, between different current states in transport through molecules, is possible and may be triggered by a passing electromagnetic pulse in the THz range[2]. This mechanism relies on a THz-induced resonant electron transfer between the pair of neighboring subunits. As a consequence, the energy of the two sites are misaligned and therefore, the passage of current is turned off by the irradiation pulse and the NDR behaviors are eliminated.

Three molecules that differ by the spacer (phenyl vs. thiophene) and the anchor group (thiol vs. cyanide) were synthesized and corresponding SAMs were formed on very flat template-stripped gold electrodes (RMS<0.5nm). Solid-state molecular junctions (MJs), in which a C-AFM (Conducting-Atomic Force Microscopy) Pt/Ir tip is used as the top electrode, were formed. The electronic properties of the resulting MJs were investigated under an in-situ THz irradiation (30THz), and will be presented for the three molecules.

When the THZ irradiation is OFF, NDR behaviors at the nanoscale (for few tens of molecules) were observed with an unprecedented large peak-to-valley ratios (up to ca. 500 compared to ca. 15 in the MCBJ experiments[1]). To gain more insight into the origin of the NDR effect, we also investigated these molecules using density functional theory (DFT) and the non-equilibrium Green's function formalism (NEGF). The calculations reproduced well the observed experimental NDR behavior, which is explained by breaking the degeneracy of the HOMO and HOMO-1 levels under the effect of the applied voltage.

When the Thz irradiation is ON, the junction is immediately switched and the NDR behaviors are completely suppressed. These phenomena were reproducibly and reversibly observed for all three molecular junctions, whatever the nature of the spacer and anchoring group, and will be presented and discussed.

Generic Dynamic Molecular Devices by non-Steady State Proton Coupled Electron Transport Kinetics Xi Yu[1] and Lejia Wang[2]; [1]Tianjin University, China; [2]Ningbo University of Technology, China

Molecular devices operating at a non-steady state with time and history-dependent performance raised new challenges for the fundamental study of microscopic non-steady state charge transport dynamics, as well as functionalities that are not achievable by steady state devices. In this study, we reported a generic dynamic operation mode of molecular devices by addressing the transient redox state of ubiquitous quinone molecules by proton/water transfer. The diffusion limited slow proton transfer modulated fast electron transport, leading to a non-steady state transport process, as manifested by the negative differential conductance (NDR), dynamic hysteresis, and memory-like behavior. A theoretical model was further developed, which, combing transient state characterization, quantitatively revealed the non-steady state charge transport kinetics and the principle of the dynamic behavior of the device. At applying pulse stimulation, the dynamic device emulated the neuron synaptic response with frequency dependent depression and facilitation, implying a great potential for future non-linear and brain-inspired devices.

8:30 AM *EL10.12.03
Electrical Driven Hot Carriers Generation and Light Emission in Molecular-Scale Plasmonic Junctions Longji Cui; University of Colorado Boulder, United States

Molecular scale plasmonic nanojunctions have attrached much interests recent years as they have great potential to create the smallest on-chip light sources and sensitive photodetectors. It is crucial to understand the role of electrically generated hot carriers in these structures at the size limit of light matter interaction. This talk will present a series of our recent work and provide both experimental and theoretical insights into this topic. In particular, I will present our observation of above-threshold light emission from plasmonic tunnel junctions and our model that describes electrically driven hot carrier generation and enhanced light emission mechanisms. Further, I will present our recent experiments on tuning light emission crossovers, from below-threshold, coherent multielectron tunneling, to hot carrier enhanced light emission. These results demonstrate rich physics that can be obtained from plasmonic nanojunctions and electrically driven hot carrier geneation in these nanosystems, crucial to numerous future applications.

9:00 AM *EL10.12.04
Single-Molecule Reaction Dynamics Xuefeng Guo; Peking University, United States

This talk will exemplify our on-going interest and great effort in developing efficient lithographic methodologies capable of creating molecular electronic devices through the combination of top-down micro/nanofabrication with bottom-up molecular assembly. These devices use nanogapped carbon nanomaterials (such as single-walled carbon nanotubes (SWCNTs) and graphene) as point contacts formed by electron beam lithography and precise oxygen plasma etching. Through robust amide linkages, functional molecular bridges terminated with diamine moieties are covalently wired into the carboxylic acid-functionalized nanogaps to form stable carbon electrode-molecule junctions with desired functionalities. We have used these approaches to build functional devices that switch their molecular conductance upon exposure to external stimuli, such as ion, pH and light, and realize label-free, real-time electrical detection of chemical reactions at the single-event level for revealing their intrinsic mechanisms towards precise chemistry.

Enabling Long-Distance Singlet-Fission, Charge and Triplet-Exciton Transport via Molecular Bridges Spiros Skourtis; University of Cyprus, Cyprus

We discuss three examples of bridge-mediated transport processes where transport is analyzed in terms of dominant pathways and of important intermediate states. The first example relates to recent experiments of very-long-distance DNA charge transport where pathways that do not involve DNA-base states seem to play an important role [1]. The second example relates to recent experiments of bridge-mediated singlet-fission and triplet-exciton separation rates that observe a bridge-resonance enhancement of singlet fission [2]. The third is a proposal for building molecular wires that support very-long-distance coherent triplet-exciton transport that is robust to static and dynamic disorder [3].

11:00 AM EL10.13.02
Designing of a “Perfect” Porphyrin Molecule for the Mechanically Controllable Break Junction Experiments Diana Dulic; FCFM, Universidad de Chile, Chile

The biggest challenge of molecular electronics is to condense the functionality of an electronic device into a single molecule and to exploit the functional versatility offered by the chemical diversity of molecules for electronic device purposes.
Porphyrins and their related macrocycles are promising building blocks for the construction of bio-inspired molecular devices. Nature itself offers magnificent examples of porphyrin's usefulness, such as activating and transporting molecular oxygen in mammals and harnessing sunlight in plant photosynthetic systems.
In spite of their potential, obtaining well-defined single-molecule conductance features is a difficult task. Due to π-stacking porphyrins can form a variety of junction configurations, leading to a large spread in conductance values using the mechanically controllable break junctions (MCBJ) technique. This limits further progress in investigating the molecular functionalities on a single molecule level in porphyrin molecules.
In this presentation, I will show that by close interaction between synthetic chemists and physicists a “perfect” porphyrin molecular design for mechanically controllable break junctions can be achieved, leading to well-defined, highly conducting molecular junctions. This opens further prospects for “porphyronics” – porphyrin-based molecular electronics.

11:15 AM EL10.13.03
Spin-Dependent Charge Transport in Single Chiral-Molecule Junctions Anil K. Singh[1], Kévin Martin[2], Maurizio Mastropasqua Talamo[2], Narcis avarvari[2] and Oren Tal[1]; [1]Weizmann Institute of Science, Israel; [2]University of Angers, France

The experimental observation that electrons transferred through a chiral molecule favors a particular electronic spin orientation is known as the chiral-induced spin selectivity (CISS) effect. This effect has been extensively studied both experimentally and theoretically. However, the mechanism of this effect is still not fully understood. Here, we report on spin filtering by molecular junctions based on a single pi-conjugated chiral molecule suspended between a nickel electrode and a non-ferromagnetic electrode. The effect depends on the molecule chirality, applied voltage polarity, and the non-ferromagnetic metal type. We ascribe our observations to the CISS effect at the quantum coherent transport regime and discuss the influence of the electrode properties on the CISS effect.

11:30 AM *EL10.13.04
Quantum Interference Beyond Single-Molecule Transport Gemma C. Solomon; University of Copenhagen, Denmark

Over the last ten years, there has been a growing interest in quantum interference effects observed in molecules. Remarkably, given their fragility in mesoscopic physics, quantum interference effects can be readily observed in molecules at room temperature in solution. This robustness comes from the extremely small size of the molecular components (1-2nm) and thereby the small dimensions over which phase coherence is required. In this talk I outline our efforts to explore molecular quantum interference effects beyond single molecules and to use these effects for more than simply switching current on/off.
Firstly, I will outline our efforts to understand quantum interference beyond single molecules by studying clusters of molecules and monolayers of varying density. These studies indicate that current suppression at low bias due to destructive quantum interference may be either more or less pronounced for the same molecule, depending on whether the measurement is made on a single molecule or a monolayer.
Secondly, I will outline our efforts exploring the potential for molecules exhibiting destructive quantum interference effects to be employed as dielectric materials, for example as gate dielectrics in organic transistors. Our initial studies show that it is possible to increase the dielectric constant of the monolayer, while maintaining low levels of current, but challenges remain in developing chemical insight as to how best to tune these properties.

12:00 PM EL10.09.03
Self-Assembled Monolayers of Alkylselenolates on Gold with Lifetime Over Two Hundred Days Ningyue Chen and Yuan Li; Tsinghua University, China

Self-assembled monolayers (SAMs), based on thiol-metal chemistry, are widely investigated in multiple fields such as optics, biochemistry and organic electronics due to their simplicity, repeatability and controllability. The thiol-based SAMs, however, go no further than laboratory studies due to their weak property against oxidation. Therefore, it is necessary to pursuit an alternative anchoring group, which is expected to form similar supramolecular structure as thiol-SAMs and meanwhile, possesses air-stability with long lifetime. Here, we proposed diselenide as an advantageous candidate since selenium has similar properties as sulfur which enables it to be a promising precursor for well-ordered SAMs. By spectroscopy and tunnelling current, we demonstrated the chemisorbed and densely packed selenium-SAMs has, indeed, been fabricated. Notably, when we stored the selenium-SAMs in ambient condition, they own rigorously long-lifetime in ambient conditions over 200 days by the reason of the strong selenium-gold bond. We surveyed the stability of selenium-SAMs by the observations of a minor fluctuations of tunnelling current and the value of decay coefficient through SAMs as a function of days. Additionally, spectroscopy provides detailed structural characterization as the oxidation is much slow with selenium-gold bond and there was nearly no desorption of alkylselenolates during this process. Finally, we performed DFT calculations and the results illustrate the stronger binding energy and weaker affinity to oxygen of selenium-SAMs compared with thiol-SAMs, leading to the merely impossibility of peroxidation of selenium-gold bond.

12:15 PM EL10.09.04
A Conductive Ionogel Top-electrode for SAM-based Junctions Conducted in Liquid Environment Xiyue Bai and Yuan Li; Tsinghua University, China

Study of the charge transport through molecules in liquid environment is important for understanding the fundamental of complicated system such as electrochemistry, catalytic reaction, and biological activities in physiological environment. In this work, we designed a flexible and conductive top-electrode composed of ionic liquid and carbon powder wrapped with polymers (we call it ionogel-carbon black electrode, in short IG-CB) to form top-contact on a self-assembled monolayer (SAM) on Ag or Au bottom-electrode, at environmental conditions of solid states, pure water or other liquid. This IG-CB electrode is capable of measuring charge transport through SAMs of alkanethiolates with long stability and high reproducibility. We tested molecules with different hydrophilicity and lipophilicity in air, polar and non-polar solvent to discover the mechanism of electron tunneling in liquid environment. IG-CB electrode can reflect more molecular information and interfacial interaction compared to EGaIn due to the ability of IG-CB electrode to produce stable traces in different environments. The greatest advantage of IG-CB electrode is the tunability of chemical properties, which cannot be achieved by other top-electrodes. We demonstrated that the current density is highly dependent on both the hydrophobicity of the electrode and SAMs. One of the reasons for the correspondence is mainly from the mutual effect between the surface dipole of SAMs and polarity of the solvent.
Next we fabricated samples with the monolayer of proteins (three kinds of proteins with different numbers of heme groups inside) supported by SAM. The junction measurements show activationless behaviors of three proteins when they are in solid states, but, when the junctions immersed in pure water they become temperature dependent. We found that it requires about 100−120 meV for electrons passing through one heme group inside a hydrated protein molecule for the first time. We also show that the threshold voltage for heme group to be oxidized is −0.6 V in our system, and below that it is likely only involving reorganization of surrounding dipoles in water. Therefore, we provide a new approach to study the role of water in electron flowing through SAM in liquid environment, the mechanism of charge tunneling in proteins and could promote the study in electron transfer, enzymatic reaction and etc.

The Long Path to Long Lifetime Deep Blue Phosphorescent OLEDs Stephen R. Forrest and Haonan Zhao; University of Michigan, United States

Perhaps the single most important problem confronting the development of OLED displays and lighting today is how to achieve sufficiently long triplet-controlled emission device lifetime to prevent rapid color change during operation, while achieving 100% internal emission efficiency. It has been shown[1] that bimolecular (e.g. triplet-polaron, triplet-triplet) annihilation provides a source of energy sufficient to destroy the blue triplet chromophore (whether a phosphor or a TADF molecule) or its host. Since that time, many materials, structures and strategies to extend blue emission lifetime based on this understanding have been demonstrated. Furthermore, various molecular fragments have been identified whose presence leads to the observed luminance loss. Unfortunately, a fully satisfactory solution has not been shown where blue triplet emitter lifetime is sufficient to meet the standards of high performance displays, although white OLED illumination sources may now have adequate lifetime to meet industry standards. In this talk I will discuss progress in extending blue phosphorescent OLED (PHOLED) lifetime, and in understanding of the limitations to extending the lifetime of blue triplet emitters. In particular, I will focus on the relationship between radiative state lifetime, exciton density, and the longevity of the PHOLED. I will review efforts to shorten the radiative lifetime via emitter design and optical cavity engineering. Prospects for future advances will be discussed.

"Intrinsic luminance loss in phosphorescent small-molecule organic light emitting devices due to bimolecular annihilation reactions". N.C. Giebink, B.W. D'Andrade, M.S. Weaver, P.B. Mackenzie, J.J. Brown, M.E. Thompson, and S.R. Forrest, *J. Appl. Phys*., **103**, 044509 (2008).

11:00 AM *EL11.01.02
Addressing Fundamental Limits to Blue OLED Stability Marc Baldo; Massachusetts Institute of Technology, United States

Phosphorescence and triplet-triplet annihilation are two of the leading approaches to realizing more efficient and stable blue organic light emitting devices. To address the stability of blue phosphorescence, we modulate the exciton lifetime of the emitters without drastically decreasing the light extraction efficiency using plasmonic light extraction structures. The results are compared to all-optical studies suggesting very strong dependence of OLED stability on excitonic lifetime.

Increasing the fraction of singlet excitons generated from triplet-triplet annihilation (TTA) remains the major challenge confronting applications of solid-state excitonic upconversion in OLEDs. We will describe two recent efforts addressing this problem. First, we investigate rapid intersystem crossing (ISC) of high energy triplets (T_2) to the desired singlet state (S_1). Generating more singlet excitons is expected to improve efficiencies, but this approach comes with a tradeoff. Rapid ISC can exacerbate losses due to faster relaxation of the original triplet states (T_1) back to the ground state (S_0), as well as faster relaxation of $T_2 \rightarrow T_1$. We describe the computational design and experimental characterization of new TTA materials with predicted ISC rates more than three orders of magnitude faster than ISC in the classic material 9,10-diphenylanthracene (DPA). Experimentally, we find that the upconversion efficiency *doubles* in the limit of large enhancements in ISC, confirming that tuning the $T_2 \rightarrow S_1$ ISC rate can indeed provide a strategy for the systematic improvement of TTA materials, and demonstrating promising new materials for applications. Second, we show that the tailorability and highly porous, but ordered structure of metal-organic frameworks (MOFs) combine to minimize inter-triplet exchange coupling and engineer effective spin mixing between singlet and quintet triplet-triplet pair states. We demonstrate singlet-quintet coupling in a pyrene-based MOF, NU-1000. An anomalous magnetic field effect is observed from NU-1000 corresponding to an induced resonance between singlet and quintet states that yields an increased fusion rate at room temperature under a relatively low applied magnetic field of 0.14 T. Our results suggest that MOFs offer particular promise for engineering the spin dynamics of multi-excitonic processes and improving their upconversion performance.

11:30 AM EL11.01.03
The Role of Emissive Layer Spontaneous Orientation Polarization in Charge Accumulation and Exciton Quenching in Phosphorescent OLEDs
Evgeny Pakhomenko and Russell J. Holmes; University of Minnesota, United States

Many common organic semiconductor materials employed as active layers in organic light-emitting devices (OLEDs) possess an appreciable permanent dipole moment that can preferentially align forming a bound polarization charge, a phenomenon known as spontaneous orientation polarization (SOP). Intrinsic polarization of the film alters the device internal electric field, resulting in charge accumulation even at voltages below the turn-on. The presence of this additional charge impacts OLED efficiency and lifetime, with prior findings demonstrating a ~20% reduction in peak efficiency and a threefold reduction in lifetime when the SOP is present in the electron transport layer (ETL). While these findings highlight the impact of polar transport layer on OLED performance, the role of SOP in the emissive layer has not been considered in detail. Here, we demonstrate the significance of emissive layer SOP by systematically probing the polaron accumulation and exciton-polaron quenching in green phosphorescent OLEDs with various polar hosts. A comparative analysis of displacement current measurements (DCM) reveals that the presence of SOP in the host alters the accumulated charge distribution, with the majority of the charges still residing in the device emissive layer. By probing the emitter photoluminescence during device operation, the amount of exciton-polaron quenching is found to be compatible to the OLEDs with polar ETLs, and kinetic modeling of this phenomenon reveals additional details on the location of the accumulated charges. Finally, we implement a method to tune the location of accumulation and thus the amount of quenching by introducing an energy barrier at one of the active layer interfaces. This study improves the current understanding of how SOP impacts OLED performance by studying the exciton-polaron quenching induced by emissive layer SOP and developing means to manipulate the accumulated charge location to tune this quenching.

11:45 AM EL11.01.04
Engineering Polarization-Induced Quenching in Organic Light-Emitting Devices via Thin Film Processing Conditions Siliang He, Evgeny Pakhomenko and Russell J. Holmes; University of Minnesota Twin Cities, United States

Due to structural asymmetry, some molecules actively used as the electron transport layer (ETL) in organic light-emitting devices (OLEDs) have appreciable permanent dipole moments (PDMs). Preferential molecular orientation can lead to PDM alignment and net polarization, a phenomenon known as spontaneous orientation polarization (SOP). Prior work has shown that SOP leads to a macroscopic surface potential that can induce significant charge accumulation in an OLED. Accumulated charge densities can be large enough to quench excitons, significantly limiting peak device efficiency. Varying film processing conditions, like substrate temperature and deposition rate, have been previously shown to impact molecular orientation and SOP. In this work, OLED performance is enhanced by suppressing SOP-induced exciton-polaron quenching via an appropriate choice of processing conditions. More importantly, the impact of temperature and deposition rate are unified in a single framework that quantitatively considers the vapor-deposited film as a supercooled glass. The impact of varying relative temperature and deposition rate are understood as means to frustrate the ability of molecules in the film to relax to an equilibrium, isotropic configuration. This unification offers a useful and generalized approach to engineering the impact of SOP on OLEDs via variations in processing conditions.

SESSION EL11.02: OLED Materials I

Blue Phosphorescent OLED Stability Study Jason Brooks; Universal Display Corporation, United States

Today organic light-emitting devices (OLEDs) are used in billions of displays generating $38 billion in annual revenue in 2021. In 1986 the demonstration of an efficient planar heterojunction device (1) started OLEDs on a path to commercialization. Further efficiency improvements were realized by utilizing a fluorescent guest and host emissive layer (EML) system (2). The internal quantum efficiency (IQE) of these early fluorescent OLEDs was limited to approximately 25% as triplet excitons cannot emit radiatively in these materials. In contrast, in a phosphorescent OLED (PHOLED) system, first demonstrated in 1998, all the singlet excited state excitons are converted into the triplet excited state through inter-system crossing (S_1 to T_1) via the presence of a heavy metal atom (3).
Red and green PHOLEDS, pioneered by Universal Display Corporation (UDC), have been used in commercial OLED applications for several years now, however the device lifetime of high efficiency blue has until recently been a challenge. Here we will present a case study on a series of blue emitting imidazo-phenanthridine benzimidazole iridium (III) complexes, where an aromatic carbon is replaced with nitrogen on the ligand resulting in a dramatic blue shift in emission. The effect on device stability was probed by substituting aryl and alkyl groups on the ligand in close proximity to the nitrogen lone pair. Further modifications required to improve sublimation for the preparation of vacuum deposited devices through the use of ancillary ligands will also be described. Our results show that device stability is highly dependent on the type of substituent near the nitrogen, indicative of its reactivity in device operation.

Blue Emitting Square Planar Metal Complexes for Displays and Lighting Applications Jian Li; Arizona State University, United States

The successful development of efficient and stable molecular blue emissive materials will have a significant impact on the continued deployment of organic light emitting diodes (OLEDs) technology for display and lighting applications. Moreover, the successful development of alternate low cost technology for current solid state lighting devices will have a significant impact on the U. S. economy and national security. In this presentation, we will discuss our continuing efforts on the design, synthesis and characterization of novel platinum and palladium complexes for displays and lighting applications. The photo-physics, electrochemistry, electroluminescent properties and operational stability of these novel metal complexes, including deep blue narrowband emitters and amber emitting phosphorescent molecular aggregates, will be discussed.

OLEDs – Beyond Displays Franky So; North Carolina State University, United States

In contrast to inorganic light emitting diodes (LEDs) which require epitaxial growth on single crystal wafers, organic LEDs (OLEDs) can be fabricated virtually on any substrates without size limitation. When OLEDs are made on flexible substrates, they can be made very thin to replace conventional liquid crystal displays. Because of the form factor and flexibility, they can be used in applications which cannot be realized by conventional LCDs. Today, OLED technology has been developed to the point that it has become a mainstream display technology for mobile devices as well as televisions. In addition to displays, OLEDs are also being considered for lighting and sensing applications. In this presentation, we will describe the challenges and opportunities in OLED lighting. We will also present the opportunities in different imaging applications using OLEDs.

3:45 PM *EL11.03.02
Electrophosphorescence Generated from Ir(III) Carbene Phosphors and Respective Hyperluminescence Yun Chi; City University of Hong Kong, Hong Kong

Organic light-emitting diode (OLED) is considered as one most promising technology to facilitate visual communication in the form of monitors and wearable and head-mounted display devices. Therefore, much efforts have been devoted in improving their performances and, as the result, better and more reliable materials, particularly the emitters, have been developed in both academic and industrial sectors. Among the emissive materials, Ir(III) metal complexes have been recognized for their remarkable stability and efficient green and red luminescence and, nowadays, they have been employed as an integral component of commercially viable OLED devices. However, much less progresses have been made on the respective blue emitters. This shortfall prompted more research on both the blue emissive transition-metal based phosphors for future advancement of OLED technology.

In general, the Ir(III) metal atom is capable to promote the facile intersystem crossing facilitated by spin-orbit coupling, allowing full utilization of both the electro-generated singlet and triplet excitons. There are two possible class of Ir(III) complexes suitable for making the demanded blue phosphors. One involves functional cyclometalating chelates linked to N-donor fragment such as pyridine, pyrazole or imidazole, in the form of either the homoleptic or heteroleptic derivatives Ir(C^N)$_3$ and Ir(C^N)$_2$(L^X), C^N = N-containing aromatics and L^X = anionic ancillary. The alternative designs contain the Ir(III) complexes with N-aryl carbene cyclometalates which can be represented by the generalized formula *m*-Ir(C^C)$_3$ and *f*-Ir(C^C)$_3$, where *m*- and *f*-indicated the meridional and facial coordination arrangements, respectively.

Recently, we reported the successful preparation of several class of homoleptic Ir(III) carbene complexes and employed the same for fabrication of blue OLED devices. Their emission peak max. occurred in the region between 420 to 500 nm in solution state at RT. We believed that they are capable to display the genuine true-blue emission hue and to serve as the chosen blue emitter and sensitizer (or donor) in fabrication of phosphorescent and hyperluminescent OLED devices. Now, this task has been partially accomplished, to which the corresponding syntheses and applications will be discussed in this presentation.

4:15 PM EL11.03.03
Design and Synthesis of Asymmetric Au(III) Complexes Exhibiting Bright Anisotropic Emission for High-Performance Organic Light-Emitting Diodes Hsin-Hung Kuo[1,2], Sudhir Kumar[1], Rashen Lou Omongos[3], Marc E. Usteri[1], Michael Wörle[4], Daniel Escudero[3] and Chih-Jen Shih[1]; [1]ETH Zurich, Switzerland; [2]University of Cambridge, United Kingdom; [3]KU Leuven, Belgium; [4]ETH Zürich, Switzerland

Organic light-emitting diodes (OLEDs) are emerging as one of the most promising candidates for next-generation optoelectronics. However, most commercial OLEDs are based on rare-metal organometallic emitters, which bring challenges towards sustainable technology. Recent development of earth-abundant gold complexes has drawn a lot of attention, whereas the device efficiencies remain lower than the rare-metal counterparts. Here, we present rational molecular design of a series of Au(III) organometallic complexes consisting of asymmetric C^C^N ligands and carbazole moieties functionalized by phenyl or mesityl groups. The synthesized complexes exhibit shortened radiative lifetimes, and reach improved photoluminescence quantum yield, η_{PL}, of greater than 93% in thin films. Moreover, the asymmetric molecular design induces anisotropic emission with a high ratio of horizontally oriented transition dipole moment of up to 82% in host-guest films. Our computational results corrborated our experiemtnal data. It suggested that the asymmetric motifs of emitters give rise to pertubation in eletrostatic potential distribution. As a result, our chemically asymmetrical Au(III) complexes orient horizontally in bipolar host, 26DCzPPy, enchancing light out-coupling efficiency. Accordingly, we demonstrate high-performance OLED devices with record-high external quantum efficiencies, η_{ext}, and current efficiencies, η_{CE}, of up to 27% and 89 cd A^{-1}, respectively. We believe that the molecular design of anisotropic Au(III) emitters will be greatly facilitated by the fundamental principles and theoretical analysis presented here.

4:30 PM EL11.03.04
Planar Chirality Enables Narrow Bandgap Conjugated Polymers with Red Circularly Polarized Luminescence Teodora Moiseanu[1], Rituparno Chowdhury[1], Juan Manuel Moreno Naranjo[2], Larissa Hogenhout[1], Robert Phipps[1], Matthew J. Fuchter[2], Richard Friend[1] and Hugo Bronstein[1,1]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom

Materials with chiroptical properties have garnered interest in the field of optoelectronics due to their applications in circularly polarized (CP)-OLEDs, sensing, spintronics, optical quantum information, and many others. Chiral small molecules have been investigated, however they typically display very low dissymmetry factors on the order of 10^{-3}. The potential of supramolecular structures such as conjugated polymers to self-assemble presents an opportunity for much stronger chiroptical properties.

Previous work on chiral conjugated polymers has been restricted to wide bandgap materials due to a focus on chiral side chain polyfluorenes and weakly conjugated polymers. There is a lack of narrow band gap conjugated polymers with strong chiral emission within the field.

Here it is demonstrated that planar chirality holds the potential to obtain chiroptical behaviour alongside the strong main-chain conjugation essential to obtain narrow bandgap polymers. A series of polymers were investigated, endowed with planar chirality from paracyclophane moieties. Polymers with emission across the visible spectrum were assessed for their chiral response in solution and thin-film by circular dichroism (CD), and chiral photoluminescence (CPL). The novel materials display high dissymmetry factors, with g_{abs} reaching 0.1 in film for fluorene-based copolymers, and g_{lum} reaching 0.08 for thiophene-based copolymers. To the best of our knowledge, these are the highest values recorded for CD and CPL for planar chiral polymers with main-chain conjugation, to date, with strong potential to be applied in CP-OLEDs.

4:45 PM EL11.03.05
High-Performance Saturated-blue OLEDs Employing [3+2+1] Iridium Complexes as the Phosphorescent Sensitizer Chengcheng Wu[1,2] and Guodan Wei[1,2]; [1]Tsinghua-Berkeley Shenzhen Institute (TBSI), Tsinghua University, China; [2]Institute of Materials Research, Tsinghua Shenzhen International Graduate School, Tsinghua University,, China

By introducing the trimethylsiliyl (TMS) groups on the 2′,6′-difluoro-2,3′-bipyridine (dfpypy) main ligand, two promising [3+2+1] coordinated saturated-blue emitting iridium complexes are designed and synthesis to investigate their structural, photophysical and electrochemical properties. The existence of the inter/intramolecular interactions (C-F···H/C-N···H) are considering as an effective path to accelerate energy transfer and improve the photoluminescence quantum yield (PLQY) of the luminescent materials. Both the complex **B-4-TMS** and **B-5-TMS** functionalized the TMS on dfpypy ligand exhibited PLQY close to 90%, and the vibronic emission peak at 443/465 nm with rapid decay down to 0.36 μs in toluene solution, emerging high radiative decay (k_r) of up to 2.5×10^6 s^{-1}. The phosphorescent OLEDs based on the two phosphors exhibited the maximum external quantum efficiency (EQE$_{max}$) of 25.49% for device A, 27.77% for device B, respectively. To boost the color quality and efficiency, the hyper-OLEDs employing the two iridium complexes to sensitize the terminal emitter of *v*-DABNA are achieved in terms of the efficiency as high as 33.01% with the full width at half maximum (FWHM) of 17 nm and the CIEy values down to 0.123 as well as the LT_{50} close to 5000 h at an L_0 of 100 cd m^{-2}, demonstrating the mechanism of Förster resonance energy transfer (FRET) process. Such results which have been the among the highest efficiency reported for phosphor sensitized saturated-blue hyper-OLEDs.

SESSION EL11.04: OLED Optics I

8:30 AM *EL11.04.01
Efficient and High-Brightness Microcavity OLEDs—Overcoming Angular Color-Shifts Through Strong Light-Matter Coupling and Monolithic Integration of OLEDs for Minimally Invasive Brain Implants Malte C. Gather[1,2]; [1]University of St. Andrews, United Kingdom; [2]University of Cologne, Germany

With ever more stringent color requirements in the display industry (such as BT.2100) and the requirement for monochromatic emission in many emerging applications of OLEDs (such as fluorescence-based sensing), there is a growing need for OLEDs with narrow-band, saturated-color emission. While the peak emission wavelength of OLEDs can be adjusted via chemical modification of the emissive material, it has proven challenging to design emitters with extremely narrowband luminescence spectra. Micro-cavity OLEDs by contrast offer narrowband emission but show an intrinsic and often substantial and undesired change in spectrum and color with observation angle.

Here, we overcome these limitations by combining the concept of microcavity interference with the angle independent light absorption/emission of molecules in an efficient and synergistic manner. By introducing an assistant absorber layer into a microcavity OLED, we create a strongly coupled hybrid light-matter state (i.e., an exciton polariton) that inherits the angle insensitivity of molecular absorption and the narrow linewidth of the cavity mode. This new device architecture enables efficient OLEDs with angle-independent, narrowband emission (EQE >10%, FWHM <20nm, angle shift <10nm @60° tilt).

Besides the display industry, the unique properties of OLEDs – in particular their ability to monolithically integrate with a wide range of substrate materials – lend themselves favorably for next generation bioimplants that provide targeted and minimally invasive light delivery deep in living tissue. This is of particular interest for neuroscience, where the recently developed method of optogenetics has enabled new ways of studying neuronal networks. However, the delivery of light to the cells of interest in animal models remains an open challenge. We show how integration of high-brightness microcavity OLEDs on needle-shaped CMOS chips allows controlled light delivery through a minimally invasive implant with 1024 individually addressable pixels, each with a size comparable to a single neuron.

9:00 AM EL11.04.02
Highly Efficient Top-Emission Organic Light-Emitting Diodes Based on Ampicillin Micro-Structure Donghyun Kim, Changmin Lee, Amjad Islam, Geonwoo Jeong, Dong Hyun Choi, Tae Wook Kim, Sye Hamad Ullah Shah, Hyun Woo Jo, Yeong Beom Kim, MinJae Park, Keum-Jin Ko and Seung Yoon Ryu; Korea University, Korea (the Republic of)

The effort to enhance the efficiency of organic light-emitting devices (OLEDs) has led to the improvement of advanced materials with multiple advantages property. Herein, we present the robust contribution of a widely used antibiotic; ampicillin (Amp) in optoelectronics. The optimum fusion of Amp with poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT: PSS) considerably improved the device efficiency of a single-unit green phosphorescent OLED. The addition of 25% Amp in PEDOT:PSS provided a horizontal interfacial dipole. The dipole suppressed the hole injection by lowering the work function of the anode and improved the charge balance. Moreover, the parallel arrangement of molecules facilitated the generation of J-aggregations which contributed additional/extra excitons to the device. Additionally, to decrease the deviation in the efficiency and stability of Amp based OLEDs, we reinforced the microcavity effect through the top-emission OLED (TEOLED) structure and optimized the annealing conditions. Amp microstructures (Amp-MSs) of various sizes and shapes (α-/β-phase) are induced due to the increase of annealing temperature annealing temperature, time, and pH level, which led to different degenerated energy states and improved device stability. Amp-MSs induce photoluminescence (PL) and electroluminescence (EL). Additionally, Amp-MSs can adjust the charge-balance by Fermi-level (E_F) alignment, thereby decreasing the leakage current and Amp-PEDOT:PSS layer prevented In diffusion. Moreover, the Amp-MSs triggered light scattering through diffuse reflectance, as indicated by angle-resolved reflectance and optical simulations. Therefore, the wave-guided modes were significantly reduced. It can enhance the light-outcoupling through optical-scattering. As a result, it is suggested that high efficiency can be obtained by using carrier harvesting and photon harvesting through electroluminescence, photoluminescence and light scattering based on Amp-MSs. The TEOLED demonstrates an extraordinarily high current efficiency (CE) (maximum ~ 281.3 cdA^{-1} and average ~ 264.3 cdA^{-1}) and EQE (maximum ~ 68.7% and average ~ 63.4%) with a wide color gamut (~118%). The color coordinates were compensated owing to the extension of the spectrum by the Amp-MS (red-shifted by J-aggregated excitons). Moreover, the deconvoluted EL spectra systematically revealed each contribution of Amp-MS in the device EQE enhancement. These findings are expected to enable the development of high-performance optoelectronic/bioelectronic devices.

9:15 AM EL11.04.03
Using the Microcavity Effect to Understand the Light-Emitting Electrochemical Cell Joan Ràfols-Ribé, Xiaoying Zhang, Christian Larsen and Ludvig Edman; Umeå University, Sweden

The thin-film and planar architecture of electroluminescent devices such as the light-emitting electrochemical cell (LEC) and the organic light-emitting diodes (OLED) make them highly sensitive to microcavity effects. In OLEDs, the microcavity can be carefully designed to maximize the light outcoupling by fabricating a multilayered stack with the emission layer at its optical maximum position. In LECs, however, this microcavity control is more challenging due to its in situ formation of an emissive p-n junction by electrochemical doping upon an applied voltage. Here, we take advantage of microcavity effects to extract relevant parameters of a polymer-based LEC. First, we show that it is possible to shift the emissive p-n junction to a preferred position by the straightforward inclusion of an easily tuned additive in the active material. [1] Second, we show that the position of the emissive p-n junction shifts with time during LEC operation. Third, we discuss how the width and the dipole orientation of the emissive p-n junction can be determined and tracked over time with a “dark” device. Finally, we discuss how these results can be utilized to better understand the physics behind the LEC operation and to improve the device performance.

9:30 AM EL11.04.04
Singlet Oxygen Production by OLED Irradiation in Photodynamic Therapy Assay Using Metallic Nanoparticles Rafael d. Carvalho, Aline M. dos Santos, Arthur R. Barreto, João Paulo C. do Carmo, Tomás B. Duarte, Mariana G. dos Santos, Guilherme C. Concas, Tahir Jan, Tommaso Del Rosso and Marco Cremona; Pontifical Catholic University of Rio de Janeiro, Brazil

Nanotechnology is considered one of the key technologies for the future. One of the most strategic subjects of the century is the research on nanostructured materials for the development of new electronic devices towards to a more advanced society. Nanostructured materials can present both physics and chemical properties completely different from either solids or microscopic materials. Therefore, the capability of manipulation and control of such materials represents an actual challenge to the scientific and technological community. Furthermore, in the last few years, phototherapy have been calling attention due to recent development in scientific research that involves interactions of an incident photon over a chromophore present in a biological environment. Here stands out the photodynamic therapy (PDT) mechanism as a growing field of application of phototherapies with high relevance. Noble metal nanoparticles (NPs), such as AuNPs and AgNPs, plays an important role in the future of photomedicine experiments based on PDT, due to the concentration of light caused by the Localized Surface Plasmon Resonance (LSPR), and low citotoxicity. In particular, some metal oxide NPs synthesized by pulsed laser ablation (PLA) in water, can also produce via *water splitting* H_2 and O_2 gas phase that could enhance the free oxygen content. The PDT mechanism is non-invasive treatment for surface lesions, such as human skin, which uses visible light to excite a photosensitizer (PS), which is a photosensitive drug. The PS molecule in its ground state (S0) can absorb a photon and pass to its excited state (Sn) and, through vibrational and internal conversion processes, pass to the singlet excited state (S1). Furthermore, the PS molecule can go from the S1 state to the triplet excited state, via intersystem crossing. This triplet state has at least two reaction mechanisms known as type I and type II. Both mechanisms generate ROS and the production of singlet oxygen (type II mechanism) is the most relevant in treatments involving photodynamic therapy. In the absence of the irradiation light, the photosensitizer is non-toxic. The oxygen produced is reactive and can destroy nearby cells such as bacteria, fungi, and tumor cells. In a PDT treatment, the incident light must be within the therapeutic window, approximately between 600 nm and 1000 nm, which allows penetration of human tissue into deeper regions, between 5 mm and 20 mm, avoiding invasive treatments. In this work, we investigate the production of singlet oxygen using a PDT assay platform based on organic light-emitting diode (OLEDs), as light source with emission in the therapeutic windows, seeking applications in biological environments. The PDT assay consists of monitoring, as a function of time, the absorption spectra of a solution (phosphate buffer) with a photosensitizer, NPs, and a probe molecule. With the incidence of light in the range of the therapeutic window, PS can produce singlet oxygen modifying the probe while NPs can increase this effect. The influence of *water splitting* mechanism in the singlet oxygen consumed by the probe molecule is also investigated. Thus, it's possible to indirectly access information on the amount of singlet oxygen produced by OLED irradiation as well as on the efficiency of the PDT assay. Here we investigate the production of singlet oxygen dependence on: (i) the concentrations of different PS used; (ii) concentration and size of AuNPs and AgNPs and other metal-oxide NPs; (iii) the concentration of probe molecule; and (iv) the emitted light (wavelength and light power) of the OLEDs with different emissions.

9:45 AM EL11.04.05
High-Resolution Imaging and Statistical Analysis of Clustering in Phosphorescent OLED Materials Roland A. Bennett[1], Paul Niyonkuru[1], Michael Zachman[2] and Jeramy D. Zimmerman[1]; [1]Colorado School of Mines, United States; [2]Oak Ridge National Laboratory, United States

Since the early days of OLED research, emissive properties have indicated that guest clustering likely occurs in certain systems, but very few direct measurements of guest morphology have been published for vacuum-thermal-evaporation based OLED devices.

Here, we report on morphology measurement performed using atom probe tomography (APT)[1] and high-angle annular dark field scanning transmission electron microscope (HAADF-STEM) imaging of conventional phosphorescent guests (e.g., Ir(ppy)$_3$ and Ir(ppy)$_2$(acac)) in various host materials. The morphology measurements are analyzed using spatial statistical analyses, such as Ripley's K-function and G-function, and compared against statistical simulations of morphology to identify various aspects of morphology.[2-4]

We will present direct evidence for vertical stacking of guest molecules during growth, as well as variations in guest density over 5-10 nm scales in certain systems, and discuss principles governing these morphologies, bringing insight into long-standing questions surrounding morphology in nominally amorphous phosphorescent OLED systems.

Development of Deuteration Technology to Improve Lifetime of OLED EX and Identification of Stability of Deuterated Materials Ji-Ho Baek; LG Display Co., Ltd., Korea (the Republic of)

LG Display has recently completed the development of 'EX Technology' and is focusing on technological innovation. EX Technology, which consists of deuterium technology and presonalization algorithms, increases screen brightness (luminace) by 30% compared to existing OLEDs and reproduces natural colors more precisely.In this paper, we will explain the effect of improving the lifetime of OLED products through the developement of deuterium technology and the mechanism for the degradation phenomenon of deuterated materials. With substituting C-D bond for C-H bond, Isotope species show electrochemical stability, which leads to increasing device lifetime.

11:00 AM EL11.05.03
Strategies for High-Efficiency Simple Fluorescent Emitters in OLEDs Le Yang; Institute of Materials Research and Engineering, Singapore

For functionally viable single-colour organic light emitting diodes (OLEDs), we advocate that that they must satisfy three criteria: efficiency, lifetime, and colour (sharpness, gamut). The significant advances over the past decade has seen materials and device systems such as TADF take off, along with the earlier phosphorescent emitters – they have easily overcome the efficiency inadequacy of OLEDs. However, they often tend to have less decent stability and colour sharpness. First generation simple fluorescent emitters tend to have, in general, better lifetimes and emission sharpness, but they are severely limited by their internal quantum efficiencies of 25%, due to spin-statistics. In this talk, we would like to share and explore two main strategies in overcoming the efficiency bottleneck in these simple fluorescent OLEDs, to make them a competitive candidate in display tech. First we look at a dual-dopant system, lifting rubrene-derivative based OLEDs to unprecedented >20% external quantum efficiency.[1,2] Next, we look at single-dopant devices, in triplet fusion mechanism, by drawing parallels to (optically-excited and two-dopant) triplet-triplet annihilation upconversion, and how to enhance device efficiency ceiling.[3,4]

11:15 AM EL11.05.04
Predicting Photoluminescence Properties of OLEDs for High Throughput Screening Felix Therrien[1,1], Alexander Davis[1,1], Suhas Mahesh[1], Jeffrey Cheung[1], Brandon Sutherland[1], Eli Zysman-Colman[2], Edward H. Sargent[1] and Oleksandr Voznyy[1]; [1]University of Toronto, Canada; [2]University of St Andrews, United Kingdom

Widespread adoption of organic light emitting diodes (OLEDs) displays is hindered by the short operational lifetime of blue emitters in comparison to red and green ones despite their high energy efficiency, color contrast and the possibility for flexible and transparent displays. The discovery of new photoluminescent molecules that emit in the 450-465~nm range can be accelerated by high throughput screening (HTPS) and matter modeling. However, existing first principle prediction models have only been applied to a limited number of specific systems and are not suitable for HTPS. In this article, we develop a systematic methodology to predict wavelengths and photoluminescence quantum efficiency (PLQY) from first principle for any blue-green irridium complexes using density functional theory. We validate our predictions on a set of 450 molecules for which in-solution emission wavelengths and PLQY have been reported in literature. We show that our methodology is sufficiently versatile, efficient and accurate to be utilized on large amounts of data and suitable for large scale data generation for machine learning training.

SESSION EL11.06: QD-LED I

Blue Emissive Light Emitting Diodes Using ZnO-Graphene Oxide (GO) and ZnO-Polyaromatic Hydrocarbons Hybrid Quantum Dots Won Kook Choi[1,2] and Hong Hee Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]University of Science and Technology, Korea (the Republic of)

A self-emissive electroluminescent quantum dots (ELQDs) LED display is highly expected as a next generation flexible display. are highly demanded for achieving eco-friendly ELQDs. Ecofriendly ZnO semiconductors has a band gap of 3.37 eV and large exciton binding energy (~60 meV) at RT and thus expected to be good candidates for non-harmful Cd and inexpensive In-free blue QDs. ZnO QDs are hybridized with graphene oxide QDs (GO) [1] and functionalized poly-aromatic hydrocarbonds (f-PAHs) [2] to control the intrinsic defects located on ZnO surfaces causing green emission. From time-resolved PL (TRPL) for ZnO and ZnO-GO QDs reveals that conventional green emission of ZnO QDs has a longer lifetime by 10^3 times than ~ns of blue emission and disappear by hybridization with GO. Type I ZnO-GO QLEDs show deep-blue electroluminescence (EL) at 438 nm, brightness of 1980 cd m^{-2}, and an external quantum efficiency (EQE) of 2.78% with CIE (0.16, 0.11) without green emission. In a similar way, quasi type II ZnO/1-aminopyrene hybrid QDs-based QLEDs show EL of 3379 cd m^{-2} at $\lambda = 441$ nm with a full width at half maximum of 41.7 nm, a luminous efficacy (LE) of 3.32 cd/A, EQE of 2.35%, and remarkably long lifetime T_{50} of >17830 h at 100 cd/m^2.

Efficient Short-Wave Infrared Light-Emitting Diodes based on Heavy-Metal-Free Quantum Dots Li Jun Lim and Zhi Kuang Tan; National University of Singapore, Singapore

Short-wave infrared (SWIR) light emission is important for a diverse range of modern applications, such as eye-safe depth sensing, light detection and ranging (LiDAR), facial recognition, eye tracking, optical communication, and health-monitoring technologies. However, there are a very limited number of known semiconductors that can emit efficiently in the SWIR spectral range. Presently, SWIR light-emitting diodes (LEDs) based on colloidal quantum dots (CQD) are dominated by lead chalcogenide systems (PbS and PbSe CQDs), despite the presence of heavy metal and modest efficiencies (~8%). Here, we report highly efficient SWIR LEDs based on heavy-metal-free In(Zn)As-In(Zn)P-GaP-ZnS core-shell CQDs. The shell layers were judiciously chosen to possess decreasing lattice constant which allowed the lattice strain caused by mismatch to be gradually relaxed across the core–shell structure and was crucial in passivating surface traps in the In(Zn)As core which resulted in a constant increase in the PLQE from 2% to 10%, 30%, and 73% upon the growth of the In(Zn)P, GaP, and ZnS shells, respectively.

Using solution processing methods, an indium–tin oxide (ITO)/zinc oxide (ZnO)/ poly(9-vinylcarbazole) (PVK)/polyethylenimine ethoxylated (PEIE)/CQDs/poly(N,N′-bis-4-butylphenyl-N,N′-bisphenyl)benzidine (poly-TPD)/molybdenum trioxide (MoO_3)/silver (Ag) electroluminescent device was also fabricated using the synthesized CQDs. The implementation of an otherwise hole-transporting PVK layer on the electron-injecting side of the device stack led to a surprising enhancement in device performance, giving high external quantum efficiencies (EQE) of 13.3% at long emission wavelengths of 1006 nm. Single-carrier device and optical investigations reveal the origins of enhancement to be the electronic decoupling of the CQD layer with the electron-injecting ZnO layer, which mitigated luminescence quenching and improved charge balance. This work marks one of the highest efficiencies reported for heavy-metal-free solution-processed LEDs in the SWIR spectral region (>1000 nm), and could find significant applications in emerging consumer electronic technologies.

Quantum Dot Light Emitting Diodes for Next Generation Display Zhuo Chen, Yanzhao Li, Dong Li, Yuanming Zhang, Jingwen Feng, Yang Gao, Haowei Wang and Xiaoyuan Zhang; BOE Technology Group Co Ltd, China

Display is the central window for people to get information, while people's demanding for high quality display is never ending. As a type of semiconducting nanoparticles, quantum dots have unique advantages such as tunable emission with sizes, narrow emission, high stability, etc. Quantum dot light emitting diodes (QLED) is one of the most competitive technologies for next generation display. In this presentation, I will introduce the research and progress in the field of QLED in BOE Technology Group.
(1) Inkjet Printing
Inkjet printing is a drop-on-demand technique for pixelated patterning, which has maximal material utilization in theory. The ink stability, the quality of ink droplet, the accuracy of IJP equipment, as well as the morphology of printed film are the key factors in the IJP process. Via inkjet printing process, we have successfully fabricated 55-inch 4K and 8K AMQLED TV demos, whose color gamut reaches 119% NTSC and the contrast ratios are higher than 1,000,000:1.
(2) Sacrificial Layer Assisted Photolithography
To achieve higher pixel density, photolithography technique is considered to prepare the high resolution quantum dot patterns. Quantum dot damage, interfacial contamination, color mixing from residues of other colors and other factors should be considered in quantum dot photolithography. We developed a sacrificial layer assisted patterning (SLAP) technique. In this approach, in order to protect the quantum dot layer and QD/ET interface during the photolithography process, we introduced a sacrificial layer to isolate QD layer and photoresist. We achieved a 500 PPI R/G/B full-color device via the SLAP approach, in which the subpixels are without color impurity and color gamut reaches 114% NTSC.

3:45 PM EL11.07.02
Ecofriendly Solvent for Green QD-LED Fabrication Jang-Kun Song and Hyo-Bin Kim; Sungkyunkwan University, Korea (the Republic of)

Quantum-dot light emitting diode (QDLED) displays have been attracted great attention because of their high potential as a future display technology. The color performance and theoretical quantum efficiency of QDLEDs far exceed those of OLEDs, and solution processability is also regarded as an important advantage for low-cost manufacturing capabilities. However, the use of toxic and environmentally hazardous organic solvents is the dark side of solution processable QDLEDs. Chlorobenzene, chloroform, 1-4 dioxane, and 1,2-dichlorobenzene are representative toxic solvents for the manufacture of QDLEDs, and these are mainly used as solvents in the hole transport layer (HTL). For example, chlorobenzene is known as a solvent with long-term toxic effects on human causing dizziness and neurasthenia, central nervous system disease and renal degeneration, and also affects aquatic life if it enters rivers and seas. Therefore, it is important to find an environmentally friendly solvent for (HTL), but to date, this has not been studied. In this presentation, we report a new methodology for finding solvents that are environmentally friendly, have good processability, and have solvent orthogonality with adjacent layers. Using the proposed methodology, which is designed based on Hansen solubility parameters (HSPs) and solvent selection guidelines (SSGs), an alternative green solvent for HTL was found and an all-solution processed eco-friendly QDLED device was fabricated. The HTL layer fabricated using the green solvent exhibits lower roughness and does not have interlayer mixing; as a result, the device shows superior electro-optical performance compared to the reference device using chlorobenzene solvent. Thus, the new solvent selection method can provide a green solution for future QDLED displays.

4:00 PM EL11.07.03
Deterministic Quantum Light Arrays from Giant Silica-Shelled Quantum Dots Hao A. Nguyen and Brandi Cossairt; University of Washington, United States

Colloidal quantum dot (QD) single-photon sources are important for their applications in photonic quantum information technologies. To fully realize their potential applications, scalable deterministic placement of stable single QD emitters is required. In this work, we synthetically increase the QD size via silica encapsulation to facilitate deterministic positioning of single QDs into large arrays while maintaining their photostability and single-photon emission properties. By using different integration methods including template-assisted self-assembly and inkjet printing, giant silica-shelled QDs can be precisely positioned into order arrays with high yield. Finally, second order photon correlation measurements are used to confirm their single-photon emission. This work shows that giant silica-shelled QDs are a flexible class of materials that may be compatible with other device fabrication techniques to achieve deterministic single particle positioning in complex quantum photonic platforms.

Electrical Doping of Colloidal Semiconductor Nanocrystals—Electron-Only-Device & Hole-Only-Device Hakjune Lee[1], Jaemin Lim[2], Doyoon Shin[2], Seongbin Im[2], Wan Ki Bae[2] and Jong Ah Chae[2]; [1]Seoul National University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Auger recombination, whereby exciton recombination energy is transferred to a third carrier instead converted to a photon, in colloidal semiconductor

quantum dots (QDs) have complicated to accomplish high-performance optoelectrical applications. For analyzing dynamics of QDs inside applications, previous studies have primarily focused on bi-exciton states and negatively charged exciton states, whereas positively charged exciton states are hardly investigated due to difficulties in adding and stabilizing extra holes in QDs.
Herein, we demonstrate electronic systems, electron-only-device (EOD) and hole-only-device (HOD), injecting extra carriers to QDs and analyze auger lifetime spectroscopy in chorus with electrical characteristics. This method adds extra carriers to CdSe/CdS heterostructured QDs whose multi-carrier states are well studied for long time, so exhibits the key spectroscopic signatures including development of fast decay, 1S bleach, auger quenching of photoluminescence (PL), and PL spectra shift. We assign dynamics to three distinct states of different lifetimes attributed to single exciton, energy transfer to metal, and charged exciton respectively, and the expected PL intensities from the lifetime accord precisely with measured PL intensities. Additionally, these spectroscopic and electronic changes are recovered totally, just discharged without any bias. Out method offers a universal tool of creating multicarrier states of QDs in a non-destructive manner and opens a new prospect in analyzing positively charged trion in veil before.

4:30 PM EL11.07.05
Nondestructive Photopatterning of Quantum Dots via Ligand Crosslinking Moon Sung Kang; Sogang University, Korea (the Republic of)

Electroluminescence from quantum dots (QDs) is a suitable photon source for futuristic displays offering hyper-realistic images with free-form factors. Accordingly, a nondestructive and scalable process capable of rendering multicolored QD patterns on a scale of several micrometers needs to be established. In this talk, two different nondestructive direct photopatterning methods for QDs are introduced, both of which exploit crosslinking reaction between the ligands of neighboring QDs. The first method exploits an additive that can crosslink with native aliphatic QD ligands. This additive is referred to as light-driven ligand crosslinker (LiXers) [1]. Specifically, we employ LiXers in branched structure containing multiple azide units [2]. The branched LiXers effectively interlock heavy-metal-free QD films via photocrosslinking native aliphatic QD surface ligands without compromising the intrinsic optoelectronic properties of QDs. Using branched LiXers with six sterically engineered azide units, we achieved RGB QD patterns on the micrometer scale. The photocrosslinking process did not affect the photoluminescence and electroluminescence characteristics of QDs and extended the device lifetime. Alternatively, QD ligands by themselves containing a photocrosslinkable moiety (that can also directly crosslink with native aliphatic ligands of neighboring QDs) can be anchored onto QD surface [3]. Specifically, photocrosslinkable ligands (PXLs) based on benzophenone derivative are exploited. The use of PXL permits employing a secondary ligand system (which is referred to as dispersing ligand, DL) that is devised to control the solubility of QDs to solvent. Based on a dual-ligand passivation system comprising PXL and DLs, we demonstrate that QDs can be direct patterned on various substrates using commercialized photolithography (i-line) or inkjet printing systems without compromising the optical properties of the QDs or the optoelectronic performance of the device. Our approaches offer versatile ways of creating various structures of luminescent QDs in a cost-effective and non-destructive manner. This could be implemented in nearly all commercial photonics applications where QDs are used.

SESSION EL11.08: Perovskite-LED I

8:30 AM *EL11.08.01
Two Distinct Populations of QDs in QD-LEDs Vladimir Bulovic; Massachusetts Institute of Technology, United States

Electroluminescence of a colloidal quantum dot LED (QD-LED) originates from an electrically-excited thin QD film within it, which is just few QD layers in thickness. We show that within this QD film two distinct populations of QDs are formed, as manifested by their distinct responses to optical and electrical excitations. Our measurements are done on thin films of InP/ZnSe/ZnS (core/shell/shell) QDs on glass substrates and on forward and reverse biased QD-LEDs. We show that the nano-scale morphology of the QD layer can affect the QD-LED operation.

9:00 AM *EL11.08.02
Perovskite Nanocrystal Emitters for Efficient, Bright, and Stable Light-Emitting Diodes Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Metal halide perovskites (MHPs) are attracting great attention as promising next-generation light emitters because of their high color purity (FWHM ~ 20 nm) and low process cost. Although a lot of strategies have been reported, electroluminescence efficiency and stability of MHP still lag behind existing light-emitting diodes (LED). In this talk, advantages and strategies for the realization of efficient, bright, and stable PeLEDs will be delivered.
First, we report a comprehensive material strategy for the suppression of defect states in colloidal perovskite nanocrystal (PNC). Doping of guanidinium (GA^+) cation with additional hydrogen bonding compared with formamidinium (FA^+) into formamidinium lead bromide ($FAPbBr_3$) PNCs yields limited bulk solubility while creating an entropy-stabilized phase in the PNCs and leading to smaller PNCs with more carrier confinement. Furthermore, a PNCs surface-stabilizing bromine-based small molecule, 1,3,5-tris(bromomethyl)-2,4,6-triethylbenzene (TBTB), was applied as a halide vacancy healing agent. In addition, by applying the modified-bar coating method, we fabricated large-area devices which have similar efficiency with small-area devices made by the spin-coating method. Through these strategies, highly efficient large-area perovskite light-emitting diodes were achieved.
Next, we developed core/shell structured perovskite nanocrystals obtained using the simple in situ reaction of organic shell additive with 3D polycrystalline perovskite films. Large 3D crystals are split into nanocrystals and the shell molecule surrounds the nanocrystals, achieving strong carrier confinement while maintaining good charge-transport properties of 3D perovskites. With efficient charge confinement and transport at the same time, we demonstrated simultaneously efficient, bright, and stable PeLEDs. Our work sheds great light on the possibility that PeLEDs can be commercialized in the future display industry.

9:30 AM EL11.08.03
Efficient and Stable Blue Light Emitting Diodes Based on Surface Passivated $CsPbBr_3$ Nanoplatelets He Liu, Michael Worku, Animesh Mondal, Tunde Shonde, Maya Chaaban, Azza B. Akacha, Sujin Lee, Fabiola Gonzalez, Oluwadara J. Olasupo, Xinsong Lin, J.S. Raaj V. Winfred, Yan Xin, Eric Lochner and Biwu Ma; Florida state university, United States

Metal halide perovskite nanocrystals (NCs) have emerged as highly promising light-emitting materials for various applications, ranging from perovskite light-emitting diodes (PeLEDs) to lasers and radiation detectors. While remarkable progress has been achieved in highly efficient and stable green, red, and infrared perovskite NCs, obtaining efficient and stable blue emitting perovskite NCs remains a great challenge. In this talk, I will present our recent efforts in the development of efficient and stable blue PeLEDs based on perovskite NCs. First, a facile synthetic approach for the preparation of blue emitting

$CsPbBr_3$ nanoplatelets (NPLs) will be introduced, in which treatment by an organic sulfate, 2,2-(ethylenedioxy) bis(ethylammonium) sulfate ($EDBESO_4$), significantly enhances the photoluminescence quantum efficiency (PLQE) and stability. Detailed structural characterizations reveal that $EDBESO_4$ treatment affords surface passivation of $CsPbBr_3$ NPLs by both $EDBE^{2+}$ and SO_4^{2-} ions, which helps to prevent the coalescence of NPLs and suppress the degradation of NPLs. A simple PeLED with emission peaked at 462 nm has been fabricated to exhibit an external quantum efficiency (EQE) of 1.77% with a luminance of 691 cd m^{-2} and a half-lifetime of 20 min, which is the brightest pure blue PeLEDs based on NPLs reported to date. Secondly, to further improve the device performance of PeLEDs based on $CsPbBr_3$ NPLs, we have introduced semiconducting organic salts, the triphenyl(9-phenyl-9H-carbazol-3-yl) phosphonium sulfate ($TPPcarz_2SO_4$) and triphenyl(9-phenyl-9H-carbazol-3-yl) phosphonium bromide (TPPcarzBr) as surface passivation agent for blue emitting $CsPbBr_3$ NPLs. The charge transporting phenylcarbazole unit in $TPPcarz_2SO_4$ and TPPcarzBr is found to improve the conductivity and energy alignment of surface passivated $CsPbBr_3$ NPLs when they are used as a light emitting layer. PeLEDs based on dual semiconducting organic passivated $CsPbBr_3$ NPLs have been fabricated to exhibit EQEs of up to 2.44% and a half-lifetime of 100 min, providing a novel and effective strategy to make high efficiency and long operating lifetime PeLEDs. Our work shows clearly the potential of using properly surface passivated perovskite NPLs as emitters for highly efficient and stable PeLEDs.

9:45 AM EL11.08.04
Progress in Lead-free Hybrid Organic-Inorganic Metal Halides for Optoelectronic Applications Jonathan E. Halpert, Yanyan Li and Zhicong Zhou; Hong Kong University of Science & Technology, Hong Kong

Lead-based perovskites have advanced tremendously over the last decade, producing solar cells with PCE > 24% and LEDs with EQE over 20 % for both red and green. However, the toxicity and instability of lead halide perovskites will likely limit their use in many instances. Here we have synthesized a novel class of copper-based micro- and nanomaterials that have high QY, up to 100%, and are long lived when packaged under nitrogen. We show recent improvements in copper-based self-trapped excitonic (STE) emitters, to produce highly luminescent, long lived emitters with red to near-IR emission peaks. In particular, we report alkali copper(I) iodide (ACuI)-based (A = Na, K, Rb, and Cs) organic-inorganic hybrid materials with different structures and emission peaks by adjustment of the alkali atoms and organic molecules. We can also substitute bromide and chloride for pure and mixed halides, such as red emissive lead-free hybrid organic-inorganic copper halides $A_6(C_4H_8OS)_{12}[Cu_8X_{13}][Cu_4X_4(OH)(H_2O)]$ (ACX-THTO, A = K, Rb, and Cs; X = Cl, Br; THTO = C_4H_8OS). These compounds possess strong photoluminescence with emission peaks in the range of 530-660 nm with a highest PLQY of nearly 100%. In addition to copper based compounds we examined one-dimensional (1D) $Na_3SbBr_6(C_2H_6OS)_6$ and $Na_3SbBr_6(C_4H_8OS)_6$ single crystals, which exhibit bright yellow and orange emission with PL peaks at 610 nm and 664 nm, respectively, and a high photoluminescence quantum yield (PLQY) of 86% was obtained for $Na_3SbBr_6(C_2H_6OS)_6$. These two compounds can be reversibly converted into each other by the removal and addition of the organic components. In general, the technique for producing hybrid organic inorganic copper halides can be extended to several members of the family, with increasing stability, in order to synthesize a wide array of emissive species, covering the visible spectrum. Green, yellow, and red down-conversion light emitting devices (LEDs) can be fabricated by using these materials, and a white LED based on all-copper iodide phosphors is demonstrated with a high color rendering index (CRI) of 93 by utilizing a mixture of blue-emissive $Cs_3Cu_2I_5$ and yellow-emissive $Rb_2Cu_2I_4(C_4H_8OS)_3$ powders. With high brightness and large absorption cross sections in the UV, these materials are ideal for white light arrays, and could be used as well in displays where visible wavelength transparency is more critical than color purity of emission.

Metal Halide Perovskite LEDs as Bright Thin Film Emitters Barry P. Rand; Princeton University, United States

Hybrid inorganic-organic lead halide perovskites have captured significant interest in the thin film optoelectronics community due to their impressive optical and electrical properties. For light emitting diodes (LEDs), our group is exploring their operation under very high current densities, for high-brightness applications, exploring whether they can operate at brightness akin to inorganic LEDs. We demonstrate high brightness, and show that Joule heating and voltage-induced electrochemical interface reactions present substantial challenges to these operating conditions for sustained periods of time.

11:00 AM *EL11.09.02
Suppressing Ion Interdiffusions in Halide Perovskite Devices Hanwei Gao and Brendon Jones; Florida State University, United States

Halide perovskites showed great potential for cost-effective optoelectronics. Low activation energy of ion migration, however, posed a challenge to implement viable devices with desirable lifetime. Not only were the ions mobile within the perovskite layer, they would also diffuse across heterogeneous interfaces in devices and degrade the charge transport layers and electrodes. In this work, we demonstrated that ultrathin, inorganic interlayers could suppress such interdiffusions without compromising the optoelectronic performance of the devices.

SESSION EL11.10: OLED Device II
Session Chairs: Jun Yeob Lee, Jian Li, Lin Song Li and Biwu Ma
Thursday Afternoon, April 13, 2023
Moscone West, Level 3, Room 3024

1:30 PM *EL11.10.01
(carbene)M(amide) Complexes as TADF Emitters in OLEDs Mark E. Thompson[1], Jonas Schaab[1], Collin Muniz[1], Peter Djurovich[1], Haonan Zhou[2] and Stephen R. Forrest[2]; [1]University of Southern California, United States; [2]University of Michigan, United States

I will focus on the photophysical and electroluminescent properties of two-coordinate copper, silver and gold carbene complexes, *i.e.* (carbene)M^I(donor), where the carbene acts as an acceptor and the donor is an amide group. These complexes show high phosphorescence quantum yield (F_{PL} = 0.7 – 1.0), with radiative lifetimes in 0.2-3 ms regime, with emission lines spanning from the violet to red. The "tuning" of emission between violet and red involves careful manipulation of the carbene-acceptor and donor ligands to control the donor-acceptor energy difference. Binuclear analogs show a further increase in radiative rate. Cryogenic photophysical measurements show these complexes emit via thermally assisted delayed fluorescence (TADF) with properties rivaling the state-of-the-art iridium based phosphors. The high radiative rates are due predominantly to the small singlet-triplet energy gaps in these materials. Interestingly, these materials maintain a high radiative rage out of their singlet state, even with the small exchange energy that leads to the small singlet-triplet gap. This is not typically observed in organic TADF materials, which give very low singlet radiative rates. We have prepared organic LEDs with these dopants and achieved ~ 100% EL quantum efficiency for blue and green emissive OLEDs at comparatively low drive voltages. By careful ligand design we have achieved radiative lifetimes (carbene)M^I(donor) complexes as low as 250 ns, while maintaining a high F_{PL}. I will talk about our recent results of these fast phosphors in high efficiency OLEDs.

2:00 PM EL11.10.02
Achievement of Highly Efficient and Strong Emission of Eu(III) Complex in a Host-Guest Film by Triplet Sensitization Shiori Miyazaki[1], Kiyoshi Miyata[1], Kenichi Goushi[1], Yuichi Kitagawa[2,2], Yasuchika Hasegawa[2,2], Chihaya Adachi[1] and Ken Onda[1]; [1]Kyushu University, Japan; [2]Hokkaido University, Japan

Trivalent lanthanide (Ln(III)) materials are ideal for luminescence applications owing to their narrow-band emission and superior color purity. However, they suffer from the inherent drawback of the tiny absorption coefficient. To overcome their tiny absorption coefficient due to the forbidden f-f transitions, tremendous effort has been devoted to developing photoluminescent Ln(III) complexes using molecular technology focused on realizing efficient energy transfer from antenna ligands to Ln(III) as well as strong light absorption of the antenna ligands. However, the development of antenna ligands that can be used for sensitization is limited due to difficulties in controlling the coordination structures of lanthanides.
In this study, we overcame the challenge by a simple strategy using solution-processed host-guest films: host-molecule-based sensitization of trivalent europium (Eu(III)) via triplet exciton. When compared to conventional luminescent Eu(III) complexes, a system composed of mT2T (2,4,6-tris(biphenyl-3-yl)-1,3,5-triazine) host molecules and $Eu(hfa)_3(TPPO)_2$ (hfa: hexafluoroacetylacetonato, TPPO: triphenylphosphine oxide) significantly increased overall photoluminescence intensity (I_{PL}). We achieved a 500-fold enhancement of the I_{PL} of an Eu(III) complex with a common ligand. Moreover, the combination realized sensitization from more than 40 host molecules per Eu(III).
To investigate the source of the relatively high I_{PL}, we used time-resolved photoluminescence spectroscopy (TR-PL) and femtosecond transient absorption spectroscopy (fs-TAS) in a multiscale temporal range from sub-picoseconds to hundreds of microseconds and investigated the emission mechanisms of the host-guest film. Beginning with the initial excitation of the host molecules and ending with the emission of the Eu(III) complex, we elucidated the mechanisms of all processes in the film: (1) the intersystem crossing (ISC) in the host molecule, (2) the inter-molecular energy transfer process from the host molecules to the ligands of the guest Eu(III) complex, (3) the intra-molecular energy transfer process from the ligands to Eu(III), and (4) the emission processes of f-f transitions in Eu(III). Furthermore, we discovered that the yields of all energy transfer processes, (1)-(3), are nearly unity and that the yield of the Eu(III) emission process (4) determines the overall quantum yield of the film. This highly efficient photoluminescence is attributed to the ideal triplet sensitization processes: rapid and efficient ISC in mT2T results in efficient triplet-triplet inter-molecular energy transfers with no loss. Finally, we propose clear design strategies for efficient light harvesting of Eu(III): the host-guest system with host molecules (1) which shows efficient ISC, and (2) whose triplet state energy matches that of the ligand of the Eu(III) complex.
Our discovery paves the way for efficient light harvesting of Eu(III) complexes with simple fabrication using a solution process.

2:15 PM EL11.10.03
Highly Crystalline Rubrene Light-Emitting Diodes with Epitaxial Growth Shu-Jen Wang, Anton Kirch, Hans Kleemann, Sebastian Reineke and Karl Leo; TU Dresden, Germany

Conventional organic optoelectronic devices suffer from low carrier mobility limited by static and dynamic disorder. Organic crystals with long-range order can circumvent the effects of disorder and significantly improve the charge transport. While highly ordered organic crystals offer the desirable electronic coupling strength and charge transport, their integration into large-area optoelectronic devices remains a challenge. Here, we introduce monolithic integrated triclinic crystal rubrene light-emitting diodes (LEDs) using epitaxial growth with functional additives being engineered into the films. We demonstrate superior charge transport, excellent operational and long-term stability in our light-emitting devices. By comparing two rubrene-based LEDs, one made from amorphous and one from crystalline rubrene layers, their exciton dynamics is analyzed by using comprehensive transient electroluminescence simulation. Finally, we provide an outlook on the potential applications of rubrene and/or its derivatives crystalline films for enhancing the performance of organic and hybrid optoelectronic devices as well as the prospect on extension of this fabrication process to other organic semiconductor materials.

5:00 PM EL11.11.04
Enhanced Performance of Quantum Dot Light-Emitting Diodes Using Self-Assembled Monolayer Treated ZnO Taewoong Yoo and Jeonghun Kwak; Seoul National University, Korea (the Republic of)

Among various types of quantum dots (QDs), InP-based QDs are spotlighted as the emitting materials for commercial quantum dot light-emitting diodes (QLEDs) due to their environmentally benign features. However, the efficiency of InP-based QLEDs is restricted because the excess injection of electrons compared to that of holes can induce charge imbalance. In this study, self-assembled monolayers (SAMs) were treated on the ZnO electron transport layer (ETL) in order to form molecular dipoles and improve the charge balance. To investigate the effects of molecular dipoles on the device properties depending on the materials consisting of SAM, 4-methoxybenzoic acid (4-MBA) and 4-cyanobenzoic acid (4-CBA) having the opposite dipole moments are adopted. Compared to pristine ZnO, the valence band maximum (VBM) and the conduction band minimum (CBM) of 4-MBA coated ZnO were reduced by 0.1 eV. This resulted in the suppression of excess electrons and improvement in the charge balance. Furthermore, surface defects of ZnO which induce non-radiative recombination were passivated by the carboxyl group in the benzoic acid. As a result, our InP-based QLED with 4-MBA exhibits a maximum external quantum efficiency of 5.3%, which is 15% improvement compared with that of pristine device. The result implies that appropriate SAM treatment between the ETL and the EML is an effective method to optimize the charge balance of the QLED device.

5:00 PM EL11.11.05
The Magnetic Filed Effect of the Singlet Fission and Triplet-Triplet Annihilation Reactions in Polycrystalline Tetracene-Based Diodes Tzung-Fang Guo and Shi-Hong Lou; National Cheng Kung University, Taiwan

We characterize the magneto photocurrent (MPC) response in polycrystalline tetracene-based diodes and magneto photoluminescence of the tetracene film and attribute the initially decreasing and then increasing MPC responses to the feature of the singlet fission (SF) reaction. The SF reaction in polycrystalline tetracene active layer is more evident when the device was irradiated with the short wavelength of irradiation. This observation indicates a possible route to utilize the excess exciting energy for the generation of extra excited states (triplet) to contribute the higher photocurrent. Additionally, through the measurement of magneto electroluminescence of tetracene-based diodes operated under the forward bias regime, we are able to characterize the reaction of triplet-triplet annihilation (TTA) to singlet. The TTA process may harvest the energy from triplet to singlet excitons in tetracene active layer and in part contribute the emission to fluorescence especially in the high current density and low temperature regime.

5:00 PM EL11.11.06
Efficient, Color-stable and Long-lived White Organic Light-emitting Diode Utilizing Phosphorescent Molecular-Aggregates Aden S. Seeglitz, Jian Li, Lydia Ameri, Linyu Cao and Xinqiang Zhu; Arizona State University, United States

White organic light-emitting diodes have the potential to become the new form of solid-state lighting used in housing and commericial buildings. Highly efficient and stable single-stack hybrid white organic light-emitting diode (WOLED) devices are developed using two emissive layers, one with amber colored phosphorescent molecular aggregate emission from the Pd (II) complex, Pd(II) 7-(3-(pyridine-2-yl-κN)phenoxy-κC)(benzo-κC)([c]benzo[4,5]imidazo-κN)[1,2-a][1,5]naphthyridine, Pd3O8-Py5, and the other with blue fluorescence emission. An optimized device structure achieved high color stability under various current densities, an external quantum efficiency (EQE) of 45.5%, a power efficiency of 97.4 Lm W^{-1}, and an estimated LT$_{95}$ (operational time to 95% of the initial luminance) of 50,744 hours at an initial luminance of 1000 cd m^{-2}.

5:00 PM EL11.11.07
Ligand-Engineered Emissive Quantum Dots for Direct Patterning Jaemin Lim, Doyoon Shin, Dongju Jung, Hakjune Lee, Seongbin Im, Kahyung Kim and Wan Ki Bae; Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

Nanocrystal quantum dots (QDs) are a new class of luminophores that stand at the forefront of nearly all light-emitting applications. Specifically, QDs have become mainstream of display technologies, in which the combinations of primary colors realize images in response to electrical or optical excitation. The success of next-generation QD displays demands multicolor QD patterns on desired substrates over a large area with high-precision and high-definition, and most importantly, without compromising on optical or optoelectronic characteristics of QDs.

Previously, transfer printing, inkjet printing and photolithographic patterning have been suggested to realize such QD patterns, but only marginal success has been awarded. Transfer printing can only cover small area patterns, and standard instruments for its use have yet to be developed. Inkjet printing is effective only for low resolution patterns due to the limitation in the feature size of ejected drops, which in return constrains its use for high-definition QD patterns for near eye display applications (*i.e*, resolution > 3,000 ppi). Photolithography, for which the standard fabrication equipment and procedures are established, promises high-throughput, high-definition QD patterning over a large area. The only problem with conventional photolithography is the use of photoresists and photoinitiators, which deface the optical and electrical properties of QDs.

Here, we devise QD materials that can be processed *via* photolithographic processes without the presence of photoresists and photoinitiators. Specifically, we endow the essential functions for photocrosslink to the ligands that exist at the perimeter of QDs - the surface of QDs is functionalized with the photocrosslinkable ligands and the dispersing ligands. Photocrosslinkable ligands are photoreactive organic scaffolds that recruit structurally engineered benzophenone moieties whose sensitivity to UV-A improved by two orders of magnitude compared to unsubstituted benzophenone molecules. Consequently, even a short exposure time to UV-A irradiation confer the structural robustness to the QD films. Only a small fraction of photocrosslinkable ligand displacement (less than 10 mol%) is necessary for fully crosslinking, which in return leaves room for extending process compatibility with a range of solution-processing techniques by engineering the rest of the majority dispersing ligands. The success in controlling the structure of both ligands allows direct patterning of QDs *via* commercialized photolithography (*i*-line) without altering optical or optoelectronic characteristics of QDs. The advantages of the present approach are well represented by the high-definition QD patterns over a large area achieved by means of standard photolithography equipment (*i.e.*, pixel resolution for primary colors over 15,000 ppi on a 6-inch wafer).

5:00 PM EL11.11.08
Impact of Morphological Inhomogeneity on Excitonic States in ZnSeTe Quantum Dots Dongju Jung[1], Hakjune Lee[2], Doyoon Shin[1], Jaemin Lim[1], Seongbin Im[1], Jeongwoo Park[1] and Wan Ki Bae[1]; [1]Sungkyunkwan university, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Colloidal quantum dots (QDs) made of heavy metal free elements can have high quantum efficiency, tunable color, and narrow spectral linewidth, making them suitable for use as light sources. In a recent study, QDs with high luminous efficiency with a color range from purple to blue and cyan were synthesized using ZnSe$_{1-X}$Te$_X$ alloys. However, as the ratio of Te was increased to adjust the color toward the blue region, a sudden increase in linewidth occurred in all previous reports. The lack of understanding of its origin makes it difficult to fabricate blue ZnSe$_{1-X}$Te$_X$ QDs with narrow linewidth. In this study, temporally and spectrally resolved ensemble measurements and single dot measurements were performed on ZnSe$_{1-X}$Te$_X$ QDs with various Te ratios. Through this, it was possible to analyze inhomogeneous and homogeneous broadening which makes it possible to predict the existence of a new state caused by the influence of Te. And through density functional theory, it was found that a hole trap state can occur when two Te exist adjacent to each other in the crystal structure, and this is the reason of the sudden increase in linewidth. These results may suggest future research directions for making blue light-emitting sources through ZnSe$_{1-X}$Te$_X$ QDs.

5:00 PM EL11.11.09
Perovskite Quantum Dot Stabilization Using Molecular Sieves with Water-Selective Trapping Properties of Mesoporous Trap Dong Hwan Wang, Jin Young Kim, Woongsik Jang and Byung Gi Kim; Chung-Ang Univ, Korea (the Republic of)

Recently, lighting and display technologies require the search for materials that emit high-purity colors at high resolutions and realize vivid, natural colors. Quantum dots (QDs) are attracting attention as next-generation functional materials due to their superior color turnability and narrow band emission. Among them, perovskite QDs have been widely used due to their good optical and electronic properties, but still need to be discussed due to their structural issue [1]. In this research, a mesoporous material was introduced into a solvent to maximize the stability associated with surface defects in QDs using perovskite materials [2]. So far, the use of molecular sieves, which are mesoporous structural materials, has not been discussed to improve the efficiency and stability of QDs. For perovskite material, moisture and humidity control in the ambient environment and within the material is important [3].

Therefore, molecular sieves were introduced in the process of dissolving precursors to trap H_2O molecules before the synthesis of perovskite QDs. We used the split-ligand re-precipitation (S-LMRP) method for synthesis in the ambient environment, and tried to trap H_2O of dimethylformamide (DMF), which is the main solvent for dissolving the perovskite precursor and has a high hydration rate [4]. As a result, it was confirmed by FT-IR spectra analysis that H_2O molecules were declined in DMF, and it was also confirmed that H_2O was declined in the synthesized QDs using the dehydrated DMF. As a result of comparing the particle sizes of each, the dehydrated QDs were synthesized with slightly smaller sizes. This means that the ligand is better attached because the perovskite surface defects caused by HO are passivated. And, by removing H_2O through the molecular sieve, the quantum yield (QY) increased by about 14%. Additionally, the photoluminescence (PL) intensity stability of the perovskite QD solution and the stability of the surface on which the solution was coated to the film were confirmed. As a result, the PL intensity of the dehydrated QD solution was maintained at 83.7% after 50 days, but the pristine QD solution decreased by about 50%. In addition, cracks were observed only on the surface of the glass/pristine QD thin film after 30 days, which is caused by ligand separation of the QDs coated on the surface. Also, as a result of observing each surface through FE-SEM, it was confirmed that aggregation was significantly suppressed in the thin film coated with dehydrated QD. Thus, we provide that the efficiency and stability of QDs were able to greatly improved by a facile method.

5:00 PM EL11.11.10
Silicone-Integrated Organic Light-Emitting Semiconductor for Ultrahigh-Density OLEDs Hyukmin Kweon[1], Keun-Yeong Choi[2], Ryungyu Lee[2], Ukjin Jeong[1], Min Jung Kim[3], Hyunmin Hong[3], Borina Ha[1], Jiyeon Ha[1], Hayoung Oh[1], Bokyung Kim[1], Sein Lee[4], Jang-Yeon Kwon[4], Kwun-bum Chung[3], Moon Sung Kang[5], Hojin Lee[2] and Do Hwan Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Soongsil University, Korea (the Republic of); [3]Dongguk University, Korea (the Republic of); [4]Yonsei University, Korea (the Republic of); [5]Sogang University, Korea (the Republic of)

Due to unprecedented color purity, thin form-factor, near-instant response time, and expanded color-gamut, organic light-emitting diodes (OLEDs) have a wide spectrum of application from commercialized displays to frontier displays like microdisplays. To successfully realize the broad range of the OLEDs technologies, a precise pixelation technique that can implement fine red/green/blue (RGB) pixels with high production and reliability regardless of the dimensional form factor of the display is strongly required. To this end, various patterning methodologies for OLEDs have been developed, such as fine metal masks, inkjet printing, orthogonal photolithography, template-directed growth, and photoresist-type organic semiconductors. However, these approaches suffer from restricted resolution (limited to below 1,000 pixel per inch, ppi), pattern reliability, and productivity issue. Alternatively, photolithography with reactive ion etching (RIE) can be the promising solution for well-defined high-resolution of OLEDs. This is because the RIE-coupled photolithography (RCP) process induce anisotropic etching profiles, so that well-defined patterns down to sub-micron scales are effortlessly obtained. However, organic light-emitting semiconductor (OLES) has low compatibility to the RCP process because it is intrinsically vulnerable to chemical and physical damages which are inevitably encountered during the photolithography and RIE processes, so that distortion of patterns and degradation of its luminance property are obtained. This indicates that it is a big challenging task in the OLEs to develop fine RGB pixels with photolithographic patterning process.
Here, to facilitate high-resolution OLEDs with the RCP process, inspired by etching nature of silicon, we demonstrate silicone-integrated OLES (SI-OLES) in which OLES is molecularly entangled with a ladder-like organosilica network. The SI-OLES showed high chemical and physical endurance, as well as, anisotropic etching behavior toward RCP process. The developed precise anisotropic etching profile of the SI-OLES is originated from in-situ formation of non-volatile etch-blocking layer during the RIE, which is analogous to RIE etching chemistry of silicon materials. On the basis of unique features of the SI-OLES, we demonstrated ultrahigh-density RGB OLES anisotropic patterns corresponding to 4,216 ppi (4,938,271 patterns/cm^2). Furthermore, the electroluminescence characteristics of SI-OLES-based OLEDs (SI-OLEDs) exhibited non-destructive even after pixilation by the RCP process. Consequently, full-color SI-OLEDs (949 ppi) was realized by the application of three cycles of consecutive RCP processes, indicating that our material design of the SI-OLES can contribute toward practical realization of well-defined micro-OLEDs.

5:00 PM EL11.11.12
Opto-Electronic Device Signatures and Sensing with Organic Molecule Exciton States Emily G. Bittle[1], Chad Cruz[1], Sebastian Engmann[2,1], Katelyn P. Goetz[1], David Gundlach[1], John Stephenson[1] and Jared Wahlstrand[1]; [1]National Institute of Standards and Technology, United States; [2]Theiss Research, United States

Many new molecular materials being developed to increase efficiency in organic light emitting diodes and photovoltaics (OLEDs and OPV) rely on exciton interconversion between singlet and triplet states. These high binding energy excitons, with tunable spin character, are also under investigation for applications in quantum information science and spin- based computation. While detailed information about interconversion processes is accessible to ultra-fast optical measurements, within opto-electronic (OE) devices a multitude of processes can overwhelm reliable signal related to exciton dynamics. Certain signature measurements, such has half bandgap turn on in OLEDs as an indicator of triplet fusion, have proved to be unreliable indicators of interconversion processes. In our projects, we work to connect the photophysics to OE device physics to uncover the relationship between exciton dynamics and device output. We demonstrate measurements and modelling of the spin dependent singlet fission process in magnetic field-dependent OE device measurements and corresponding ultra-fast photophysical measurements that show simple EO devices can be used to estimate the zero field splitting spin parameters and sense magnetic fields using exciton states in molecules. Recent results that connect the impact of varying the molecular packing on singlet fission dynamics and related changes to OE device output will be shown.

5:00 PM EL11.11.13
Integrated Substrate for Enhanced Outcoupling Efficiency in Organic Light-Emitting Diodes Mohammad Mehdi Zarei and Paul Leu; University of Pittsburgh, United States

Organic light-emitting diodes (OLEDs) exhibit advantages of wide viewing angle, high contrast ratio, low weight, and power consumption as well as flexibility for applications such as displays and solid state lighting. However, their low light extraction efficiency hampers their overall external quantum efficiency (EQE). OLEDs are also utilize ITO for a transparent electrode where ITO is costly and brittle. In this work, we demonstrate high transparency, high haze glass that may be fabricated via a simple, one-step reactive etching process to improve quantum efficiency. The glass provides for graded refractive index at the substrate/air interface and reduces substrate mode losses. Furthermore, we demonstrate a metal microgrid that may be utilized to replace indium tin oxide (ITO), which is a costly transparent electrode material. The metal microgrid has low index of refraction and may reduce waveguide mode losses. The transmission, haze, and sheet resistance properties of integrated substrates are correlated with OLED performance as characterized by EQE, current density-voltage, radiance-voltage, and EQE-current density. The results demonstrate a pathway to improving the performance of OLEDs as well as lowering their manufacturing costs.

5:00 PM EL11.11.14
Growth Control of II-VI Epilayer on III-V Nanocrystals Doyoon Shin, Hakjune Lee, Jaemin Lim, Dongju Jung, Seongbin Im and Wan Ki Bae; Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

III-V/II-VI core/shell heterostructured nanocrystals (*h*-NCs) are promising photonic materials for various light-emitting applications. The photophysical properties and stability of III-V/II-VI *h*-NCs and the performance of photonic applications are governed by the morphology that determine their optoelectronic properties and photochemical stability. However, unlike conventional *h*-NC synthesis system, III-V/II-V core/shell *h*-NCs has been relatively difficult because of hetrerovalent surface polarity.
Herein, we unveil the growth rate of each facet to make anisotropic growth. Specifically, we design III-V/II-V core/shell *h*-NCs that control the surface dependent growth. We conduct a comprehensive study across synthesis, spectroscopic analysis, and calculation to identify the growth mechanism and photophysical properties according to the shape. Following the guidelines for structure engineering, we discuss the impact of engineered structure and reveal optical and optoelectronic properties across III-V/II-V core/shell *h*-NCs.

5:00 PM EL11.11.16
Solution Processed ZnO-based Electron Injection Layer for Stable OLEDs Tianxin Li[1], Jian Li[1] and Lin Song Li[2]; [1]Arizona State University, United States; [2]Henan University, China

With the introduction of zinc oxide nanoparticles as the most preferred electron transport layer (ETL), solution-based light-emitting diodes (LEDs) technology was significantly improved because of high transparency, high electron mobility, and low production cost in ZnO and a favorable alignment of its energy bands. Using ZnO as the ETL, we have developed highly efficient and stable Pd(II) 7-(3-(pyridine-2-yl-κN)phenoxy-κC)(benzo-κC)([c]benzo[4,5]imidazo-κN)[1,2-a][1,5]naphthyridine (named Pd3O8-Py5) inverted inorganic-organic hybrid OLEDs. By applying ZnO in various device architectures, we carefully examined the electrical properties and explored how to optimize device performance. According to our studies, a Pd3O8-Py5-based OLED achieved a peak EQE of 23.9%, retained high EQEs of 23.5%, and 18.7% at 1,000 and 10, 000 cd m^{-2}. As a result of optical outcoupling enhancement, its peak EQE reached 48.6%. Furthermore, the device demonstrated outstanding operational stability with a measured LT_{90} of 207 h at 10,435 cd m^{-2}, which corresponds to an estimated LT_{90} of 11,180 h at 1,000 cd m^{-2}. It is expected that such hybrid inorganic-organic OLEDs will emerge as a potential competitor to conventional OLEDs, since they have intrinsically stable electrodes and can be partially solution-processed, resulting in low-cost, large-area, and shadow mark-free OLEDs for future display and lighting applications.

5:00 PM EL11.11.17
Photo-Crosslinking Hole Transport Layer for Solution Processed Quantum Dot Light-Emitting Diodes Seongjae Lee[1] and Moon Sung Kang[2]; [1]Seoul National University, Korea (the Republic of); [2]Sogang University, Korea (the Republic of)

Quantum dots (QDs) have recently attracted many researchers' interest as promising materials for lighting. Despite much progress in QD light-emitting diodes (QD-LEDs), the performance of environmental-friendly QD-LEDs still lags behind that of heavy metal-based devices. In addition, since QD-LEDs are multilayer devices, an effective method of minimizing the underlying layer erosion by subsequent solution process is required for solution-processed QD-LEDs, which is significant for the cost-effective manufacture of large-area QD displays. Here, we demonstrate high-performance solution-processed Indium phosphide (InP) QD-LEDs via photo-crosslinking of the hole transport layer (HTL) with an efficient photo-crosslinker. Photo-crosslinking of hole transport materials (TFB and PVK) using an azide-based crosslinker allows a robust HTL minimizing the damage that may occur when the QD emissive layer is deposited onto the HTL in the solution process. The solvent resistance of photo-crosslinked HTL enables fabricating high-performance green InP QD-LED through the solution process. Optimizing the photo-crosslinked TFB layer, the maximum current efficiency of crosslinked TFB-based QD-LEDs is improved by about five times compared to pristine TFB-based ones. Also to investigate the effect of photo-crosslinking on the electrical properties of HTL, we analyze pristine and crosslinked TFB based hole-only devices by using an orthogonal solvent. Furthermore, double HTLs in the conventional QD-LEDs are implemented through photo-crosslinking to reduce the hole injection barrier, resulting in efficient hole injection.

5:00 PM EL11.11.19
Performance Improvement of Quantum-Dot Light-Emitting Diodes Using Double-Layered Electron Transport Layer Yisu Kim and Jeonghun Kwak; Seoul National University, Korea (the Republic of)

Quantum-dot light-emitting diodes (QLEDs) are emerging as a next-generation display due to the excellent light-emitting properties of quantum dots (QDs). In QLEDs, ZnO or ZnMgO nanoparticles (NPs) are widely used as the materials for an electron transport layer (ETL) due to their high electron mobility and similar conduction band minimum (CBM) level with that of QD emissive layer (EML). However, these characteristics of ZnO ETL induce the spontaneous injection of excess electrons to the EML, causing a charge imbalance with holes. To solve this issue, in this study, ZnS/ZnMgO double-layered ETL is introduced into the inverted InP-based red QLEDs. Compared to previously reported organic interlayers to block excess electrons, ZnS ETL has chemical robustness and good processability. The synthesized ZnS NPs have a wider bandgap, with their CBM upshifted by 0.7 eV compared with that of ZnMgO NPs. This high CBM becomes an effective energy barrier, which can suppress the injection of excess electrons and improve the charge balance. Consequently, our red-emitting InP QLEDs with ZnS/ZnMgO double-layered ETL exhibit 1. 30-fold higher external quantum efficiency (EQE) and 1. 37-fold higher current efficiency (CE) compared to those of pristine devices. We believe that ZnS/ZnMgO double-layered ETL structure is a promising alternative to improve device efficiencies by controlling the charge balance.

5:00 PM EL11.11.20
Direct Photolithography of Perovskite Nanocrytstals via *i*-Line Ligand Crosslinking Yong Hyun Jo and Moon Sung Kang; Sogang University, Korea (the Republic of)

Perovskite nanocrystals (PeNCs) are promising materials for electroluminescence (EL) applications in display due to their high quantum yield, narrow emission line as well as low-cost, simple synthesis method. In fabricating EL devices, patterning of PeNCs is a crucial step that determines the resolution and color purity. While conventional photolithography using photoresist is the seemingly adequate patterning process to meet the industrial requirement, the polar solvents commonly used for processing the photoresist is detrimental to PeNCs with strong ionic characteristics. Herein, we demonstrate photoresist-free, direct photolithography of $CsPbX_3$ PeNCs using an *i*-line (365 nm) UV source. This is specifically achieved with aids of light-induced ligand crosslinker (LiXer) that forms chemical bonding with the ligands of neighboring PeNCs to interlock them. Because *i*-line UV was exploited, the photoluminescence (PL) characteristics of PeNCs could be fully preserved upon irradiation, which was not the case when using 254 nm-DUV source. The use of benign *i*-line UV source is critical not only that it permits patterning PeNCs non-destructively but also because the apparatus is most widely available in display industry.

5:00 PM EL11.11.21

Universal Low-Temperature Thermal Crosslinker for Photolithographic Lift-Off Ptterning of Solution-Processed Electronic Materials Chang Hyeok Lim[1], Myeongjae Lee[2], BongSoo Kim[3] and Moon Sung Kang[1]; [1]Sogang University, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Electronic materials containing moieties with good solubility to organic solvents (such as alkyl pendent groups in organic semiconductors or organic ligands on nanoparticles/nanocrystals) can exploited through cost-effective solution process in device manufacturing. However, the capability to solution-process these materials yields technical challenges in making patterns through photolithographic process available in industry, as the materials are likely to degrade during the process exposed to solvent (the solvent in photoresist or in developer). In this work, we propose photolithographic lift-off patterning applicable to various solution-processible materials (including light-emitting quantum dots, light-emitting polymer semiconductors, metallic nanoparticles) using a low-temperature crosslinker universally applicable to the materials without degrading the intrinsic electronic/optoelectronic properties. The crosslinker is designed to undergo direct crosslinking reaction with neighboring alkyl chains (included in the ligands on inorganic nanoparticles or the pendent chains in polymers) at an annealing temperature low enough not to degrade the chemical/structural properties of photoresist. Exploiting the chemical robustness of the resulting crosslinked film, we demonstrate that films of colloidal InP quantum dots, light-emitting Super Yellow polymers, or Au nanoparticles can be patterned at a few micro-meter scale through conventional photolithographic lift-off process. We believe that this approach paves a novel route to form micro-meter scale patterns of solution-processible materials without compromising electronic/optoelectronic properties.

8:15 AM EL11.12.02
Theoretical Characterization of Excited States in Organic Light-Emitting Diodes Based on Thermally Activated Delayed Fluorescence Copper(I) Complexes Ajith Ashokan[1], Veaceslav Coropceanu[2] and Seyhan Salman[1]; [1]Clark Atlanta University, United States; [2]The University of Arizona, United States

Thermally activated delayed fluorescence (TADF) represents currently one of the most promising ways to realize highly efficient organic light-emitting diodes (OLEDs) without the use of heavy transition metals and offers flexibility to fine-tune the electronic and optical properties of purely organic molecules or complexes of affordable metals. Within the TADF materials, Cu(I) complexes received a great attention due to their cost-effectiveness and fine color tunability in addition to their large spin-orbit coupling which leads to at least 2-3 orders of magnitude larger rates of intersystem crossing between singlet and triplet states. As of now, however, a thorough description of the excited state and microscopic parameters of these systems is missing. A fundamental understanding of electron-vibrational couplings, spin-orbit couplings and other factors that define the radiative and non-radiative rates in metal-TADF complexes is also necessary for improving the device performance. The main goal of this project is to elucidate the excited-state dynamics of the electronic processes that take place in TADF OLEDs incorporating Cu(I) complexes. Here, we will present the results of Screened Density Functional Theory methods to describe the electroluminescence properties two-coordinate Cu(I) complexes featuring N-heterocyclic carbene ligands. We will also include spin-orbit coupling effects in the modelling scheme to describe the intersystem crossing, radiative and non-radiative transitions in these materials.

10:30 AM *EL12.01.01
The Complexity of Charge Transport in Molecular Break Junctions Herre S. van der Zant; TU Delft, Netherlands

Break junctions are a popular method to characterize the electrical properties of single moleucles [1]. However, the behaviour of a molecule in a junction is complicated and therefore difficult to assess experimentally. For example, the end to end single-molecule (fully stretched) configuration may not be the most probable one, while this is the benchmark in the comparison with theoretical calculations. So, the questions "What are the pathways for charge transport through a molecule and what is the conductance of the fully stretched molecule" can still not be answered in all cases. In this talk, I will discuss possible causes for the observed dispersion in the conductance histograms and show that by using unsupervised clustering methods, [2] preferably in combination with clever chemical engineering of molecule families, conduction pathways can be identified and the end-to-end single-molecule conduction can be established [3-6].

11:00 AM EL12.01.02
Increased Molecular Conductance in Oligophenylene Wires by Thermally Enhanced Dihedral Planarization Woojung Lee, Shayan Louie, Austin Evans, Nicholas M. Orchanian, Ilana B. Stone, Boyuan Zhang, Yujing Wei, Xavier Roy, Colin Nuckolls and Latha Venkataraman; Columbia University, United States

Understanding and manipulating the electron transport within single-molecule wires are key for the development of molecular-scale devices. Significant efforts have been made to control electron transport properties with a variety of parameters including chemical designs of molecular three-dimensional conformations. As electron transport occurs much faster than intramolecular rotations, the average conductance of single-molecule wire is assumed to relate to its energy-minimum molecular conformation. Moreover, in a coherent tunneling regime, electron transport through a single-molecule wire has been theoretically established as a temperature-independent process. As such, the influence of temperature-driven dynamic molecular conformation on electron transport has not been widely investigated. Here, we demonstrate how the dynamic molecular conformation influences the electron transport through oligophenylene wires within a coherent tunneling regime. Using a custom-built variable-temperature scanning tunneling microscopy break-junction (STM-BJ) instrument, we find that the conductance of oligophenylene wires can be manipulated via subtle temperature control (296-328 K). Our DFT-based calculations disclose that thermally accelerated intramolecular rotations allow the oligophenylene wires to have a higher probability of being in a planar conformation compared to lower temperatures. The thermally enhanced planarization substantially increases the time-averaged electron tunneling probability, as the tunneling occurs primarily through π-orbitals. These calculations are consistent with the observation that more rotational pivot points in longer oligophenylene molecular wires lead to larger temperature dependence on conductance. These findings show that molecular conductance within coherent and off-resonant electron transport regimes can be controlled by manipulating dynamic molecular structures.

11:15 AM EL12.01.03
Radical-Enhanced Charge Transport in Non-Conjugated TEMPO Molecules Jialing Li[1], Ying Tan[2], Songsong Li[1], Hao Yang[1], Teng Chi[2], Brett M. Savoie[2], Bryan W. Boudouris[2] and Charles M. Schroeder[1]; [1]University of Illinois at Urbana Champaign, United States; [2]Purdue University, United States

Air and thermally stable organic radical molecules are ideal candidates for molecular spintronic devices. Although prior work has considered a wide variety of chemical structures for spintronics applications, key challenges remain in understanding the structure-property relationships in organic radical molecules at the molecular level. In this work, we study the charge transport properties of (2,2,6,6-tetramethylpiperidin-1-yl)oxyl (TEMPO) radical containing non-conjugated molecules using single molecule conductance experiments and semi-empirical quantum chemical simulations. Our results show that the TEMPO pendant groups promote the molecular charge transport compared to the quenched TEMPOH and neutral benzyl pendant groups. Furthermore, the molecular conductance of TEMPO-containing molecules decays with increasing length of molecular backbones similar to non-conjugated alkane chains, but the molecular conductance remains at larger values compared to alkane chains. Temperature-dependent single molecule experiments show that tunneling is the dominant charge transport mechanism in TEMPO-containing molecules. Experimental results are complemented by molecular simulations, which reveal the importance of molecular conformation on charge transport. Results from molecular simulations further show that TEMPO radicals interact with gold metal electrodes near the interface to facilitate a stabilized high-conductance configuration. Overall, our work directly reveals enhanced charge transport in non-conjugated molecules by incorporating open-shell radicals, which will help to inform the design of new materials for molecular electronic devices.

11:30 AM *EL12.01.04
Assembly and Transport Characteristics of Paramagnetic and Charged Single Molecule Circuits Masha Kamenetska; Boston University, United States

Incorporation of paramagnetic and charged molecules into single molecule circuits can increase the scope of observable phenomena due to new degrees of freedom in such molecules. Here I discuss my group's recent advances in establishing chemical design rules for forming stable junctions with coordination complexes containing transition metal atoms, charged linkers and organic paramagnetic compounds. We use Scanning Tunneling Microscope Break Junction (STMBJ), density functional theory (DFT) and non-equilibrium Green's Function methods to determine conductance, geometry and evolution of molecular junctions. We successfully form and measure the conductance of organic diradicaloid compounds with installed thioanisole linkers. In contrast, the formation of junctions with *ex situ* synthesized paramagnetic coordination complexes containing transition metal atoms is complicated due to disassembly of these complexes on gold. Instead, we find that transition metal centers can be reliably wired into single molecule junctions by coordinating *in situ* to anionic linkers during junction elongation. Through environmental control, we can tune the charge on anionic molecules to affect formation and transport properties, including quantum interference effects. *In situ* control and assembly of molecular junctions using charged moieties presents a new approach for creating molecular circuits with non-trivial electronic and spin functionality.

SESSION EL12.02: Molecular Junctions, Properties and Functionalities II

Single-Molecule Measurements Probe Nanoscale Physics and Chemistry Latha Venkataraman; Columbia University, United States

Over the past decade, there has been tremendous progress in the measurement, modeling and understanding of structure-function relationships in single molecule circuits. Experimental techniques for reliable and reproducible single molecule junction measurements have led, in part, to this progress. In particular, the scanning tunneling microscope-based break-junction technique has enabled rapid, sequential measurement of large numbers of nanoscale junctions allowing a statistical analysis to readily distinguish reproducible characteristics. Although the break-junction technique is mostly used to measure electronic properties of single-molecule circuits, in this talk, I will demonstrate its versatile uses to understand both physical and chemical phenomena with single-molecule precision. In this talk, I will present results from a recent work where we demonstrate that molecular wires can behave as one-dimensional topological insulators. We focus on a family of oligophenylene-bridged bis(triarylamines) with tunable and stable (mono-/di-)radicaloid character. These wires can undergo one- and two-electron chemical oxidations to the corresponding monocation and dication, respectively. The oxidized wires exhibit high reversed conductance decay with increasing length, consistent with the expectation for the Su-Schrieffer-Heeger-type one-dimensional (1D) topological insulators. Importantly, we show that for one length, the dication displays a significantly high conductance greater reaching beyond 0.1 G_0 ($2e^2/h$, the conductance quantum).

2:15 PM EL12.02.03
Formation and Evolution of Molecular Junctions Containing Metal Ions and Organic Radicals Brent Lawson[1], Efrain Vidal[2], Michael Haley[2] and Masha Kamenetska[1]; [1]Boston University, United States; [2]University of Oregon, United States

Creating single molecule-metal junctions containing metal ions or organic radicals is a promising route to achieving functional molecular devices. Here I discuss our recent advances in understanding formation and evolution of molecular junctions formed with organometallic molecules and organic radicals. Our work indicates that the atomic structure of the electrodes can influence charge transfer at the metal-molecule interface and affect junction evolution characteristics. With organic radicals, controlling charge transfer is critical to preserving radical properties. We measure the conductance of indenoindenodibenzothiophene (IIDBT) diradicaloid, an organic molecule with a stable singlet diradical-like character in its ground state, using Scanning Tunneling Microscope Break Junction technique. We incorporate thioanisole linkers into the molecule to decouple the electronic state from the electrode and to anchor it in place. We find reproducible conductance signatures using these molecules in ambient conditions in organic solvents. A combination of experimental and theoretical work using DFT suggests this family of stable diradicaloid organic molecules is a promising choice for studying and understanding electron transport through diradicaloid molecule-metal junctions.

2:30 PM EL12.02.04
Probing the Out-of-Plane Charge Transport in Organic Semiconductors Using Atomic Force Microscopy Mindaugas Gicevičius[1], Haoxin Gong[1], Nicholas Turetta[2], Martina Volpi[3], Yves Geerts[3], Paolo Samori[2] and Henning Sirringhaus[1]; [1]University of Cambridge, United Kingdom; [2]Université de Strasbourg, France; [3]Université libre de Bruxelles, Belgium

Recent years have seen a remarkable progress in the field of organic electronics with the in-plane charge carrier mobility routinely surpassing 10 cm^2/Vs in the best-performing materials. However, the miniaturization of organic semiconductor devices to achieve sub-micrometer active channel lengths and high switching frequencies is still limited by the contact resistance between metal electrodes and the organic semiconductor material. Efficiently controlling the contact and access resistance is, therefore, of crucial importance in pursuit of developing efficient electronic devices based on organic materials. Conventional approaches for achieving low contact resistance usually focus on interface engineering to achieve better alignment of energy levels. However, another significant contributor to high contact resistance is the out-of-plane mobility. Despite its importance, the out-of-plane mobility remains an often-overlooked parameter mainly due to the lack of available measurement techniques.

Herein, we report a novel method for evaluating the out-of-plane mobility and contact resistance based on conductive-probe atomic force microscopy (C-AFM). In this study, we prepared multi-layered single crystal films of the molecular semiconductor C8-DNTT-C8 by a solution shearing technique on electrically conducting substrates and investigated them using C-AFM. By using scanning probe microscopy to map the local changes in the out-of-plane electrical current we gain a close-up view of the out-of-plane conductivity and access resistance at an unprecedented molecular length scale. This study opens a new pathway for gaining a better understanding of structure-property relationships and enabling a more accurate engineering of materials and interfaces in organic semiconductor devices.

A Ladder-Type Conjugated Molecule as Highly Robust Multi-State Single-Molecule Switch Lei Fang[1], Jialing Li[2], Bo-Ji Peng[1], Charles M. Schroeder[2] and Daniel Tabor[1]; [1]Texas A&M University, United States; [2]University of Illinois at Urbana-Champaign, United States

Ladder-type constitution strongly enhances the chemical stability and yields well-defined physical properties that enables the fundamental studies of charge transport in multi-state, reversibly switchable aniline derivatives. Herein, we report the change in charge transport properties of a conjugated ladder-type cyclohexadiene-1,4-diimine directive at various protonation, lithiation and oxidation states. Our results demonstrate a 10-fold conductance increase from the reduced benzenoid structure to the oxidized quinonoid structure. Furthermore, acid/lithium salt addition renders two-step protonation/lithiation of the quinonoid molecule to a dicationic form in resonance with an air-stable open-shell diradical state. The fully protonated/lithiated state displays a conductance level 15 times higher than the neutral quinonoid state. Surprisingly, the charged quinonoid state also exhibits the possibility of interchain charge transport, which is not observed in the neutral state. A core-anchor group type and anchor group-anchor group type of dimerization are found to contribute to the intermolecular charge transport via DFT simulations(consider to remove such detail in abstract). Beside the chemically induced conductance changes, a stable and reversible conductance switch of over two orders of magnitude is achieved *in-situ* by electrochemical gating. Overall, this work highlights a highly robust, multi-state, single molecule switch, in which fully fused ladder-type constitution is incorporated to advance the stability, programmability, and efficiency of the single-molecule devices.

3:45 PM EL12.02.07
Self-Assembly in Supercritical Fluids—Connecting Top-Down and Bottom-Up Approaches to Nanoengineering Loren G. Kaake; Simon Fraser University, Canada

The development of devices based on single-molecule junctions requires not only robust control over molecular self-assembly but integration into structures that can interface with the macroscopic world. Accomplishing this task requires a manufacturing technique that simultaneously offers the reproducibility and accuracy of photolithography as well as the nanoscale control offered by solution phase self-assembly. In order to unify top-down and bottom-up approaches to nanoengineering, we are developing physical supercritical fluid deposition. This technique leverages the unique solubility properties of supercritical fluids to deposit molecules without the need for in-situ chemical reactions. The process relies on a peak in the isobaric saturation solubility with respect to temperature allowing thin films to be formed via precipitation onto heated substrates. The location of material deposition can be accomplished by controlling the local temperature on the substrate via simple joule heating. The resistive traces used for joule heating can be created via photolithography, allowing us to direct the solution phase self assembly with the accuracy of photolithography. Progress towards improving the resolution limit of the technique will be discussed as will the mechanisms of self-assembly and their effect on the nanoscale morphology of polymeric materials.

4:00 PM EL12.02.06
Combining Automated Synthesis with Single Molecule Electronics—Understanding the Role of Side Chains on Molecular Charge Transport
Jialing Li, Songsong Li, Edward Jira, Nicholas Angello, Martin Burke and Charles M. Schroeder; University of Illinois at Urbana-Champaign, United States

The development of next-generation organic electronic materials critically relies on understanding structure-function relationships in conjugated polymers. However, a major challenge lies in accessing the vast chemical space encompassed by synthetic organics while efficiently managing the large synthetic workload to survey new materials. Here, we use automated synthesis to overcome synthetic bottlenecks hindering access to the large chemical space for organic electronics. A library of terphenyl derivatives with different side chain compositions and anchors was prepared using a custom synthesis instrument for automated iterative Suzuki coupling. The role of side chain chemistry on the charge transport properties of conjugated oligomers was then systematically studied using single-molecule charge transport experiments. Our results show an unexpected concentration-dependent bimodal conductance in terphenyl molecular junctions with long alkyl side chains. We found that high conductance states arise due to surface adsorption and backbone planarization induced by the long side chains, which is confirmed by density functional theory simulations and a series of control experiments with asymmetric, planarized, and sterically hindered oligomers. Molecular junctions with oxygen-containing side chains are also investigated, showing high levels of conductance and reduced molecular adsorption behavior compared to alkyl side chains. Overall, our work highlights the role of side chain chemistry on charge transport and opens new avenues in combining automated synthesis with single molecule characterization to develop new materials for organic electronics.

4:15 PM *EL12.02.08
On the Origin of the Chirality-Induced Spin Selectivity in Molecular Junctions and Beyond Yonatan Dubi; Ben-Gurion University, Israel

When electrons are injected through a chiral molecule, the resulting current may become spin polarized. This effect, known as the chirality-induced spin-selectivity (CISS) effect, has been suggested to emerge due to the interplay between spin–orbit interactions and the chirality within the molecule. However, such explanations require unrealistically large values for the molecular spin–orbit interaction without any physical justification. Put simply, to date, the physical origin of the CISS effect is unknown.Here, we present the “spinterface mechanism” for the CISS effect, based on the interplay between spin–orbit interactions in the electrode, the chirality of the molecule (which induces a solenoid field), and spin-transfer torque at the molecule–electrode interface. The spinterface mechanism has already been shown to allow remarkable fit between theory and data for numerous experiment. We will provide new examples for such fits, further corroborating the mechanism. We will describe a set of experiments which can be used as a “smoking gun” for differentiating this mechanisms from other theoretical explanations. Finally, we will describe a spinterface mechanism for the CISS effect in photo-excited electrons scattered off a layer of chiral molecules.

SESSION EL12.03: Poster Session: From Molecules to Emerging Molecular Devices
Session Chairs: Masha Kamenetska and Farnaz Niroui
Tuesday Afternoon, April 11, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM EL12.03.01
Charge Transport across Biomolecular Electronic Junctions. Ultraviolet and X-ray Photoemission Spectroscopy Studies Tatyana Bendikov[1], Jerry A. Fereiro[1,2], Cunlan Guo[1,3], Israel Pecht[1], Mordechai Sheves[1] and David Cahen[1,4]; [1]Weizmann Institute of Science, Israel; [2]Indian Institute of Science Education & Research, India; [3]Wuhan University, China; [4]Bar-Ilan University, Israel

Biomolecules such as proteins and peptides are potential candidates for building diverse functional electronic devices. Measuring and controlling electron transport (*ETp*) through these molecules, especially, as assemblies on solid substrates, i.e., part of an electronic device structure with solid electrodes, is a major goal of bio-molecular electronics. The electronic structure of the peptide/protein monolayer and/or its orientation in contact with an electrode can be directly related to the energy barrier and electrode/molecule coupling in the resulting junction.
Ultraviolet and X-ray Photoelectron Spectroscopies (UPS, XPS) with their high surface sensitivity have been used extensively to study the electronic and chemical structure of *molecular* thin films or monolayers on solid surfaces. Here we show how UPS and XPS measurements can provide a crucial information for understanding the mechanism(s) of *ETp* through biomolecule/Au electrode-containing junctions.
In the first example we show how the spatial position of a singe tryptophan “dopant” in a linear oligo-alanine chain may significantly influence *ETp* across

a self-assembled monolayer of these peptides between gold contacts.[1] In the second example we explore the effect of the side-chain of the peptide (*2Ala* vs *2Trp*) on its electronic properties.[2]
In the two next examples, the bacterial electron transfer protein Azurin (*Az*) [3] and a mutant (*N42C Az*)[4] are studied on Au substrates. We find that the *ETp* mechanism can be changed by changing just a linker (binding)[3] or the orientation[4] of the protein with respect to the Au substrate.
Finally, we demonstrate that the direction of current rectification and the conductance-voltage characteristics of the Photosystem 1 complex (*PS1*) can be controlled by its orientation on Au substrates.[5]

5:00 PM EL12.03.03
Defining Qubit Properties in High-Valent Actinide Complexes Megan E. Hoover, Stephanie Gamble and Lindsay Roy; Savannah River National Laboratory, United States

Quantum computing is a rapidly emerging technology that has the potential to revolutionize computations unattainable with classical computers, and *f*-element systems have shown exceptional promise in quantum information processing. While progressing through the actinide series, the relativistic effects change the energetics of the 5*f* and 6*d* orbitals wherein control of a quantum bit (qubit) could be possible. For example, protactinium contains interesting characteristics and adopts the behavior of transition metals because of its near degeneracy of the 6*d* and 5*f* orbitals. This presentation outlines the potential for high-valent $5f^1$ early actinide complexes to act as qubits by evaluating the atomic properties, including spin-orbit coupling, crystal electric field, and nuclear spin. This research is set to establish basic understanding of the interplay between the *d* and *f* orbitals thereby generating a set of features to enhance quantum coherence in actinide complexes.

5:00 PM EL12.03.04
Single Molecule Detection of Metal-Biomolecule Binding Conformations Using Conductance Signatures Xiaoyun Pan[1], Cheng Qian[2,2], Lu Wang[2,2] and Masha Kamenetska[1,1,1]; [1]Boston University, United States; [2]Rutgers University, United States

Developing a fundamental understanding of the interactions between biogenic molecules and noble metal surfaces is important for guiding and advancing the development of biotic-abiotic interfaces, conductance measurements of biomolecule conductivity, and biosensing. Here, we use the Scanning Tunneling Microscope-based Break Junction (STMBJ) technique to measure the conductance and binding orientation of a single nucleobase, Adenine (Ade), and its derivatives on gold. We systematically study the conductance features of Ade and other structurally similar molecules that lack one or more of the candidate binding sites of Ade to assign individual molecular conductance features to specific metal-Ade binding configurations. Our results allow us to determine the binding orientations of Ade on gold unambiguously. To demonstrate the biosensing potential of these measurements, we show that we can sense and distinguish Ade from its biologically relevant variants, 6-methyladenine and 2'-deoxyadenosine. Finally, we apply these methods to determine the molecular conductance and binding configurations of other biologically functional molecules on gold, such as histidine and histamine. Our work establishes STMBJ as a powerful tool for characterizing the atomic structure of metal-organic interfaces and lays the foundation for biosensing on gold using single molecule conductance readout.

5:00 PM EL12.03.05
Vertical Organic Permeable Base Transistors with the Passivated Pinholes in Permeable Base Electrode In-Hye Lee and Kyung-Geun Lim; Korea Research Institute of Standards and Science, Korea (the Republic of)

Vertical organic transistors (VOTs) are emerging electronic devices that can overcome the limitations of conventional organic thin film transistors (OTFTs) based on lateral architecture. Here, organic permeable base transistors (OPBTs) were formed with an oxide layer on the base electrode as a dielectric layer by using an electrochemical oxidation called anodization, and passivated by self-assembled monolayer (SAM) treatment after forming AlO_x on the aluminum base electrode. The VOTs with the electrochemical oxidation and molecular passivation are simply manufactured and the charge carrier transport is significantly improved. SAM treatment is a regularly ordered organic monolayer that is spontaneously formed on a solid surface. Since the properties of the surface can be controlled, it is used on the surface of a base insulator to improve the carrier transmission performance of organic transistors. In this study, the oxidation and passivation of permeable base electrode were systematically controlled. The SAM treatment can reduce the leakage current of the base electrode and improve the current transmittance between the emitter and the collector. In addition, we observed the specific behaviors of vertical OPBT depending on the applied potential correlations between the middle base electrode and the bottom collector electrode.

5:00 PM EL12.03.06
Manipulating Quantum Interference in Single Molecule Junctions via Chemical Substitution and Environmental Control Hannah Skipper, Brent Lawson and Masha Kamenetska; Boston University, United States

Understanding and manipulating quantum interference (QI) effects through chemical design and external control is important for the development of molecular-scale devices. QI results from electrons tunneling through multiple molecular orbitals (MOs) each with a distinct phase with respect to the electrode attachment points on the molecule. In this work, we use Scanning Tunneling Microscope Break Junction (STMBJ) single molecule conductance measurements and electronic transport calculations to explore the effects of chemical composition and substitution in pyrazine-based molecular junctions. We find that QI effects dominate observed transport characteristics of these molecules, resulting in distinct conductance peaks through the meta but not the para pathway. Critically, destructive interference through the para position of the pyrazine ring can be manipulated via substitution at the meta position. By varying the environment surrounding the junction, we can control the charge of the chemical substituents and manipulate the alignment of individual MOs with the Fermi energy to tune QI through the para channel in pyrazine-based junctions from destructive to constructive. This work demonstrates environmental control of molecular QI, opening the door to *in situ* tuning of QI effects in single molecule junctions.

5:00 PM EL12.03.07
Ladder-Type Polyaniline Derivatives as a Highly Robust Multi-State Switch in Single-Molecule Junction Bo-Ji Peng[1], Jialing Li[2], Daniel Tabor[1], Lei Fang[1] and Charles M. Schroeder[2]; [1]Texas A&M University, United States; [2]University of Illinois at Urbana-Champaign, United States

Polyaniline (PANI) is of considerable interest due to its versatile chemical and electrochemical doping states. However, they suffer from chemical instabilities at acidic and oxidative conditions, which limits their applications in higher oxidative and protonated states. Herein, we reported a series of ladder-type PANI derivatives flanked with methylthiol groups on both ends as the model molecule for single-molecule conductance studies. The implementation of the ladder-type constitution prevents undesired hydrolysis and isomerization, rendering high stability of these molecules at different protonation and oxidation states. We studied the single-molecule charge transport properties of ladder-type PANI derivatives using the scanning tunneling microscope-break junction (STM-BJ) method. Our results demonstrate a 10-fold conductance increase from the reduced benzenoid structure to the oxidized quinonoid structure. Furthermore, leveraging the chemical stability that ladder-type constitution provides, acid/lithium salt addition renders two-stage protonation/lithiation of the quinonoid molecule to a dicationic form which shows open-shell diradical character in ambient conditions. The fully protonated/lithiated state displays a conductance level 15 times higher than the neutral quinonoid state. Surprisingly, intermolecular charge transport is also observed via the formation of stacked dimers assisted by pi-pi interaction. The experimental results are complemented by DFT calculations, which reveal smaller energy gaps and extended molecular conformations for higher protonated and lithiated states. Overall, this work highlights a highly robust, multi-state, single-molecule switch where a ladder-type constitution is incorporated into the PANI system to advance the stability, programmability, and efficiency of the single-molecule devices.

5:00 PM EL12.03.08
Performance of High-Mobility in BDT Trimers—Visualization of Electron-Phonon Coupling by ElPh Workflow Farahnaz Maleki[1], Makena Dettmann[1], Daniel Vong[1], Luke L. Daemen[2], John Anthony[3] and Adam J. Moule[1]; [1]University of California, Davis, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Kentucky, United States

Phonons limit charge mobility in organic semiconductors by dynamically localizing charge carriers to a few molecules. The main synthetic strategy to overcome dynamic localization has been to use side chains to “damp out” phonon modes that limit charge mobility. Here we examine a different strategy, to introduce “large” small molecules that form extended crystals and reduce molecular motion. Tri(n-hexyl)silylethynyl benzodithiophene (BDT) trimer, has demonstrated one of the highest mobilities recorded (1.6 cm^2/Vs). To understand why the BDT trimer performs so well, the phonons spectra, are computed using our DFT based open source Davis computational spectroscopy (DCS) workflow and verified using inelastic neutron scattering (INS) measurements. We separately developed a workflow called ElPh to compute the atom specific contribution to electron-phonon coupling, which enables us to quantitatively map which parts of the molecule are actively engaged in charge mobility reduction. This process offers understanding for why this material performs so well. The simulation process is transferrable to design of other high-mobility organic electronic materials.

5:00 PM EL12.03.10
Probing the Rate of Singlet Fission in Tetracene Using Temperature and Magnetic Field-Dependent Transistor Measurements Katelyn P. Goetz, Chad Cruz, Sebastian Engmann, Curt A. Richter and Emily G. Bittle; National Institute of Standards and Technology, United States

Singlet fission results in the creation of a correlated pair of triplet excitons, making it an attractive phenomenon for devices that perform quantum computing tasks. While ultrafast optical techniques have proven insightful in understanding singlet fission and related processes, there is a need to experimentally probe them within a device context. Here, processes occurring on longer timescales, such as intersystem crossing, can become relevant and overlap with signals of singlet fission.

We access the spin dynamics of triplet excitons in organic field-effect transistors (OFETs) using magnetic field-modulated photoconductivity (MPC) measurements. We chose to use tetracene as the active layer because singlet fission in it has an energetically uphill component, as well as to enable comparison with a vast body of spectroscopic literature. Tetracene was grown as single crystals by the physical vapor transport technique to limit the effects of defects and microstructure. Measuring MPC as a function of temperature allows us to modulate the singlet fission rate, and applying a simple model gives insight into changes observed. Over the range of 350-170 K, the MPC signal, measured from -200 mT-200 mT, takes an M-shape with peaks at 8-10 mT and shoulders at 41-50 mT. These features are thermally activated, showing an MPC of 0% or slightly above at room temperature and decreasing until about 220 K. Our model suggests that this change is attributed to the thermal activation of singlet fission in tetracene. At the end points (+/- 200 mT), the much stronger decrease in MPC (as much as 11% at 220 K, with the exact value depending on the orientation of the triplet dipole with respect to the magnetic field) may be an indication that intersystem crossing is becoming a dominant spin-dependent process. Below 220 K, the MPC starts increasing again, which we attribute to a subtle phase transition. This work indicates that intersystem crossing should be considered when understanding photophysical processes in singlet fission devices.

Strain-Enabled Exciton Delocalization in Crystalline Phthalocyanine—A Pathway Towards Room-Temperature Macroscopic Coherence in Organic Semiconductors Libin Liang[1], Tabassum Joyee[2], Varun Mapara[2] and Madalina I. Furis[2]; [1]Intel Corporation, United States; [2]University of Oklahoma, United States

Rapid exciton (energy) transport is critical for the realization of efficient organic semiconductor devices that surpass current efficiency limitations. Solution -based fabrication techniques for crystalline molecular thin films with macroscopic ordering show potential for overcoming the limitations of the molecular Frenkel exciton hopping transport. Once static/ structural disorder is removed from these films, spectroscopy experiments reveal the superluminescent signature of exciton delocalization in an entire class of small molecules where the packing motifs favor stronger intermolecular coupling.[1]
In small molecule crystals the formation of delocalized and coherent excitons is the result of a complex balance between the long-range Coulomb interactions, short range π- stacking coupling and electron phonon coupling. The delocalization takes place when the latter is of the same order of magnitude as the nearest neighbor intermolecular coupling. Small energy phonon modes assist in the formation of coherent states while high energy molecular vibrations (dynamic disorder) introduce decoherence and localize the exciton.[2] The delocalization will favor ballistic energy transport through the system.
Here we report on how uniaxial strain induces a more robust coherent delocalized exciton state. The molecular thin films under study are deposited from solutions of metal-free octabutoxy Phthalocyanine (H_2OBPc) using a capillary pen - writing technique that results in macroscopic crystalline grains sizes, with molecules stacked in a J-like configuration along the [110] crystal axis.[3] It was shown theoretically and experimentally that exciton delocalization only occurs along this molecular stack making the films a 1D excitonic system.[4]
Temperature, strain-dependent luminescence, absorption and linear dichroism microscopy indicate applying uniaxial strain along the stacking axis has a similar effect lowering the temperature by 100K, in terms of the prevalence of the coherent exciton state. The coherence length is estimate from the ratio between the delocalized exciton photoluminescence intensity and its first phonon replica. Increasing strain to 4.2 % initially shortens the coherence length at low temperatures, however, further increase in the strain results in a surprising recovering of the initial value of 22 molecular units (approx. 10 nm). This can be explained by the trend observed in the ratio between the intermolecular coupling and the electron-phonon interaction, also estimated from the temperature dependence of photoluminescence and the associated radiative lifetime. The applied strain results in stronger intermolecular interactions that maintain the delocalization up to a temperature of 200K.[5]
Finally, the mechanism of delocalized exciton formation is confirmed through strain -dependent transient absorption measurements and confocal photoluminescence microscopy that reveal the excited Frenkel excitons delocalize in less than 500fs. The dynamic disorder induces the formation of a more localized exciton-polaron state 5ps later. This process suffers significant changes in the presence of strain.

Molecular Design of Color Centers Danna E. Freedman; Massachusetts Institute of Technology, United States

Physical structure creates electronic structure. By precise positioning of atoms through molecular chemistry we can design electronic structures for applications in quantum information science. We use ability to design both coarse and fine electronic structure through synthetic chemistry to create materials for quantum information science. Results on creating molecular color centers will be described.

9:00 AM EL12.04.02
High-Multiplicity States in Luminescent Organic Radicals Sebastian Gorgon[1,2], Jeannine Gruene[3], William Myers[2], Feng Li[4], Emrys Evans[5] and Richard Friend[1]; [1]University of Cambridge, United Kingdom; [2]University of Oxford, United Kingdom; [3]University of Wurzburg, Germany; [4]Jilin University, China; [5]Swansea University, United Kingdom

Organic luminescent radicals present a new and exciting platform for exploring molecular functionalities at the interface of their unique optical and spin properties.[1] Near-unity internal quantum efficiency for red emission was demonstrated for donor-acceptor structures based on the tris(2,4,6-trichlorophenyl)methyl (TTM) radical.[2] This opens these materials towards applications in technologies ranging from organic light-emitting diodes and photovoltaics with eliminated triplet losses, to photomagnetic devices and molecular-scale information transfer.

Here we present a new family of molecules based on the TTM radical motif which contain high-multiplicity states in their emission mechanism. By combining light-induced EPR with ultrafast transient absorption and temperature-dependent transient luminescence spectroscopy we find a mechanism that uniquely supports both a high emission yield and a high yield of generation of the high-spin species. This is enabled by very low activation barriers between excited states, which arises from energy level matching in our molecular design. Pulsed EPR spectroscopy allows us to characterize the potential of our system for future quantum information science applications.

Investigating the Emergent Properties of Organized Spin Ensembles and Their Behavior at Interfaces Daphne Lubert-Perquel and Justin Johnson; NREL, United States

Quantum information science (QIS) remains an important field of research due to its far-reaching implications in computing, communication and advanced sensing applications. Molecular systems are the most recent candidates for QIS, with several recent perspectives and reviews discussing the valuable properties unique to such systems. Coordination compounds provide precise tailoring of specific magnetic properties through structural tuning, and phthalocyanines have been established as a versatile system. Vanadyl phthalocyanine (VOPc) is considered here, a spin ½ system with long (μs) coherence times. It is easily and predictably deposited on a range of substrates and so has been directly implemented in resonant cavities to promote spin-photon coupling, placed on functionalized surfaces, or incorporated into hybrid architectures for sensing applications.

Read-out of the stored quantum information is a key requirement of all spin qubits and much work is being done on molecular compounds to achieve optical readout. Here, we investigate the possibility of a digital state readout by combining a molecular spin system to a valleytronic material. Films consisting of a few layers of transition metal dichalcogenides (TMDC) have demonstrated circular polarized photoluminescence (PL) from the transition to a direct band gap semiconductor. Chiral emission is relevant to spin-selective optoelectronics and combining the molecular spin qubit with a TMDC substrate could lead to interesting opportunities in QIS. However, at this stage little is known of the electronic and spin interactions at such an interface and the extent of spin-valley cooperativity. We therefore present a comparative magneto-optical study of the VOPc thermally evaporated on MoS_2, $MoSe_2$ and WSe_2 as a function of polarization. This provides critical information to design new architectures for quantum devices.

9:30 AM *EL12.04.04
Quantum Control and Coherence of Spins from Semiconductor Devices to Synthetic Qubits Pratiti Deb[1], Sam Bayliss[1,2], Leah Weiss[1], Nikita Onizhuk[1], Daniel Laorenza[3], Giulia Galli[1], Danna Freedman[3] and David Awschalom[1]; [1]University of Chicago, United States; [2]University of Glasgow, United Kingdom; [3]Massachusetts Institute of Technology, United States

Quantum technologies benefit from atom-scale control of both the quantum bit and its local environment. In semiconductor materials, defects and dopants house localized electrons where the spin degree of freedom can be initialized and coherently controlled with a combination of optical and microwave signals. These semiconductor spin-qubits can be embedded in devices where their optical and spin properties can be enhanced by controlling both their electronic and nuclear-spin environment. Organometallic molecules provide an analogous platform for localized, coherent quantum states where both the qubit and its environment can be further modified via chemical synthesis. We have demonstrated optical addressability and coherent microwave control of the electron-spin ground-state of organometallic molecules containing a central chromium ion [1]. We have shown that the spin-optical interface of these molecular qubits can be tuned by modifying the structure and symmetry of the ligand field [1,2]. Atomistic modification of not only the qubit itself, but also its host environment can further be used to protect the qubit from magnetic field noise, for example due to the fluctuating electron or nuclear spin bath, yielding a five-fold improvement in spin coherence times by inducing noise-insensitive clock transitions [3]. This scalable approach to engineering quantum systems from the bottom up opens new avenues for tailoring synthetic qubits toward device-scale integration.

10:30 AM *EL12.04.05
Quantum Optics with Organic Molecules Vahid Sadoghdar; Max Planck Institute for the Science of Light, Germany

Laboratory manipulation of single quantum emitters and single photons has matured to a routine procedure over the past two decades. Nevertheless, each solid-state emitter system (quantum dots, color centers, ions, etc) is still confronted with a range of material constraints that pose challenges for scaling and reliable use in devices. Our group has explored organic molecules in the class of polycyclic aromatic hydrocarbons (PAH) for about 25 years. In this presentation, I discuss our efforts of the last decade in coupling molecules to high-finesse Fabry-Perot open cavities, plasmonic nano-antennas and chip-based photonic circuits. We demonstrate dipole-induced transparency, strong coupling, single-photon nonlinearities as well as the cooperativity of two molecules via a common mode of a micro-resonator. Moreover, I present data on high-resolution spectroscopy of the vibronic transitions in single molecules as well as a theoretical proposal for a hybrid optomechanical platform that can lead to long coherence and storage times.

11:00 AM EL12.04.06
Electrical Initialization and Readout of Triplet Exciton Spins Taylor Wagner[1,2] and Obadiah Reid[2,3]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States; [3]University of Colorado Boulder, United States

Molecular electronics offer several important advantages for spintronic, quantum sensing, and quantum computing fields. The ease of synthesis and fabrication combined with tunable spin physics makes some of these organic systems promising initial candidates for use in quantum information, however a key challenge is the ability to address individual molecular spins. Promising gate operations and coherence times have already been demonstrated with triplet exciton spin transfer using optical techniques, but electrical readout of these states would move these systems closer towards functional microelectronic circuits. Here we present a pathway towards electrical initialization and readout of triplet spins using the phenomenon of organic magnetoresistance (OMAR) with polycrystalline pentacene.

Pentacene and many of its derivatives and dimers, including 6,13-Bis(triisopropylsilylethynyl)pentacene (TIPS-pentacene), are studied for their ability to undergo a process known as singlet fission. Under illumination, these molecules readily excite to the first excited singlet state and efficiently and rapidly fission into two first excited triplet states onto neighboring molecules. This phenomenon has been fairly well explored for use in photovoltaics, and because of this, the process is well known to generate triplets of relative polarized spin due to their initial entanglement upon formation. Interactions of these polarized triplet spins with charge carriers creates a mixed state that holds information of both triplet spins. This triplet-charge spin-spin interaction is electrically detectable and forms the basis for singlet fission molecules to be explored for quantum information science. Polycrystalline pentacene is therefore a great model system for manipulation of these spin-spin interactions due to its large carrier mobility and ability to generate a high density of long-lived triplet excitations.

As the detection mechanism of these spin states, we look to theory of OMAR, where it has been shown that the interaction between triplets and mobile charges fundamentally changes the resistance through a thin film organic layer based on the applied magnetic field. We have fabricated polycrystalline pentacene devices that minimize the other commonly observed OMAR effects to isolate the response seen from these triplet-polaron encounters. Development of a quantum kinetic model through the application of the Stochastic Liouville equation of the triplet-charge mixed states reveals predictions that agree well with experiment. The model also provides predictions of the magnetoresistance when spin selective contacts are introduced, which would allow only anti-aligned triplet spins to quench, eventually purifying the triplet spins aligned with the applied field.

This triplet spin purification acts as an initialization process and can be achieved through a secondary thin film using a phenomenon known as chirality induced spin selectivity (CISS). This relatively newly discovered effect uses spiral-like chiral constituents to polarize either light or polaron spin of a specific orientation under an applied magnetic field. We show the effect of using the (S) and (R) chiral versions of $(PEA)_2PbI_4$ perovskite as a polarizing hole injection layer into polycrystalline pentacene. These results combined with detection via magnetoresistance provide promising first steps in the room temperature initialization and readout of molecular triplet spins.

Creating Mass-Scale Precision Plasmonic Nanocavities and Their Functionalities Jeremy J. Baumberg; University of Cambridge, United Kingdom

Light can be confined through plasmonics to the nanoscale using coinage metals, particularly tightly within nm-wide dielectric gaps between metal facets. I will present recent advances in the nanoparticle-on-mirror concept [1] which creates robust and atomic-scale precision nanocavities that finally open up systematic exploration of many light-matter coupled phenomena. I will demonstrate how the size and shape of the nanoparticle facets play a key role, and can be controlled to modify in-/out-coupling of light. Enhanced structures can show hundred-fold increases in SERS emission (exceeding a million counts/mW/s) which enables high speed real-time interrogation of the dynamics of individual atoms and molecules in the nanocavities.
I will show a variety of phenomena from single de/protonation events [2], single molecule catalytic chemistry, and electrochromic functionalities [3], to the ability to create low-cost uncooled detectors of mid-IR light through upconversion in such plasmonic nanocavities [4]. I will also show that these structures can be simply wired up for a variety of molecular electronics and photoconductive devices [5,6]. I will introduce how optical forces are hundred-fold enhanced in such nanocavities [7-9]. I will finally discuss the prospects for such nanoscale building blocks across a variety of fields.

Mechanically-Reconfigurable Molecular Junctions with Sub-Nanometer Tunability Weikun Zhu, Peter Satterthwaite and Farnaz Niroui; Massachusetts Institute of Technology, United States

Diverse and unique functionalities of molecules have extended their applications beyond electronics to fields including optics, plasmonics, mechanics, spintronics, and quantum technologies. Molecular devices with structurally-tunable, nanometer-thin critical dimensions are highly desirable for their extended sensitivity, energy efficiency and speed. Building such molecular platforms reliably, however, has been a challenge due to the fabrication limitations posed by top-down techniques.

Here, we present nanoparticle contact printing as a technique for scalable fabrication of molecular junctions in the form of mechanically active plasmonic resonators where the molecules serve as nanoscale reconfigurable springs with sub-nm control. The plasmonic resonator is configured as a nanoparticle-on-mirror structure, where a compressible dielectric molecular spacer is sandwiched between a metallic nanoparticle and a metallic film. To achieve scalable patterning of these active resonators, we developed nanoparticle contact printing, where >2000 colloidal plasmonic gold nanoparticles are deterministically patterned onto template-stripped gold with sub-50 nm control over positional accuracy. The resulting nanoparticle-on-mirror constructs are highly sensitive to sub-nm structural changes in the molecular junction. We demonstrate the dynamic mechanical tunability of the molecular junction and its limits by testing the resonators under thermal cycling, where the molecular layer undergoes thermal expansion and recovery. The ~1.2 nm spectral tunability observed upon heating reflects a mere ~30 pm change in the molecular gap, highlighting the sensitivity and precision of this platform. Such tunable structures, whose response can be modified through choice of the molecular layer, can form building blocks for mechanically active molecular devices, enabling high-throughput statistical and correlative characterization of the molecular mechanics, and integration into emerging nanoscale sensors, actuators, reconfigurable optical devices, and tunable metasurfaces.

SESSION EL12.05: Molecules in Electronic and Spintronic Devices

1:30 PM *EL12.05.01
Integrating Single-Molecule Electronic Devices Josh Hihath; Arizona State University, United States

In recent years incredible strides have been made in the development of molecular electronic systems that possess unique functionality. By combining chemical design with physical modeling and electrical characterization techniques it has become clear that molecules are capable of a wide range of impressive electronic functions that extend far beyond the development of standard devices such as transistors and diodes. An array of electromechanical, electrochemical, thermoelectric, and quantum devices now provide promise for memory devices, sensors, and multi-state logic units which could yield new paradigms for in-memory computing, various post von Neumann architectures, or for chemical and biological sensing systems. But, despite these possibilities, one of the major issues that arose in the nascent days of molecular electronics still lingers and limits its ultimate utility. That issue is integration. Despite a wide range of unique devices, and novel chemical and physical properties, it has remained difficult to integrate these materials into a larger-scale system in a way that is reliable, reproducible, and eventually manufacturable. In this talk we will discuss emerging approaches aimed at moving molecular-scale electronic systems from the lab and into applications. To integrate top-down lithographic approaches with bottom-up self-assembly methods we utilize novel micro-electromechanical systems (MEMS) that allow robust single-molecule electrical measurements at the chip-level; the programmability imparted by DNA nanotechnology to create novel nanoscale electrical and lithographic systems; and finally the utility of carbon nanotubes for making secure and robust contact to a single-molecule to allow facile integration with traditional photolithographic processes.

2:00 PM EL12.05.02
Template Stripping of Diverse and Heterogeneous Surfaces for Scalable Molecular Electronics Peter Satterthwaite, Sarah Spector and Farnaz Niroui; Massachusetts Institute of Technology, United States

Reliable molecular junctions require high-quality self-assembled molecular monolayers. To form such monolayers, clean, ultra-smooth (< 1 nm root-mean-square roughness) growth surfaces are required. One approach to such surfaces is template stripping, where the material of interest is deposited on a template, such as a silicon wafer, then delaminated from the underlying substrate, revealing a clean, ultra-smooth surface suitable for molecular assembly. Conventionally, this template stripping approach has been limited to large-area surfaces of metals such as Au, Ag, Pd and Pt, which naturally have low adhesion to the underlying silicon surface, allowing for delamination. Though suitable for fundamental studies, these large-area surfaces of low-adhesion noble metals have limited prospects for integration into molecular devices and systems.

Here, we demonstrate template stripping of diverse materials (Au, Pt, Al, SiO_2, Al_2O_3) including and beyond those achievable through conventional template stripping approaches. We overcome the requirement for a low-adhesion material by functionalizing the underlying silicon substrate with molecular release layers that enable reliable stripping regardless of material adhesion, while maintaining the surfaces ultrasmooth (< 1 nm). This expands the use of template stripped surfaces to the assembly of diverse molecular monolayers beyond those readily compatible with assembly on conventional, noble metal surfaces. This approach further opens the possibility of integrating molecules with materials, beyond noble metals, that display functionalities, such as spintronic or semiconducting, critical for the emerging molecular devices. We further demonstrate lithographic patterning of template stripped surfaces to realize ultra-flat, ultra-smooth surfaces composed of multiple materials. These planarized heterogenous surfaces allow for orthogonal assembly chemistries to be run on the same substrate, opening possibilities for fabrication of more complicated molecular device architectures. Because our template stripping approach mirrors conventional wafer bonding, we discuss its prospects for scalable fabrication of substrates suitable for molecular electronic devices on an industry-compatible toolset.

2:15 PM EL12.05.03
Manipulation of Spin-States in All-Organic Di-Radicals Molecular Junctions Thomas Baum[1], Saleta Fernández[2], Diego Peña[2] and Herre S. van der Zant[1]; [1]TU Delft, Netherlands; [2]Centro Singular de Investigación en Química Biolóxica e Materiais Moleculares (CiQUS) , Universidade de Santiago de Compostela, Santiago de Compostela, Spain

Graphene is believed to be an optimal material for a promising new generation of nanoscale devices using spin as information carrier, storage and

processing [**1**]. During the last years, atomically precise synthesis of poly-aromatic hydrocarbons (PAH) has been developed [**2**-**3**] allowing new possibilities to engineer their transport properties and controll the separations between the spins. The intrinsic pi-paramagnetism emerging spontaneously as radical states in open-shell graphene structures give rise to a more delocalized, mobile and isotropic magnetism than electrons in *d*-orbitals. Nonetheless, graphene-based nanomaterials also emerge as an ideal solution to combine excellent spin transport properties with large diffusion length and long coherence time needed for quantum spintronic applications with energy scales compatible with room-temperature operations.
We report on manipulation of spin-spin interactions for PAH di-radical molecules [**4**] in a mechanically controlled break junction (MCBJ) and in 3-terminal device (electro-migration break junction EMBJ) at low temperature. Magnetic fingerprints of the molecules manifest themselves by zero-bias peaks in the differential conductance spectra attributed to a Kondo resonance arising from hybridization of one of the radical electrons with the metallic electrodes and spin-flip inelastic electron tunnelling spectroscopy (IETS) steps originating from the singlet-triplet gap of the free electrons [**5**]. Varying the distance between the electrodes in the MCBJ affects the coupling strength and varying the gate voltage in the EMBJ affects the energy level alignment with the Fermi level of the electrodes. Thus, by mechanical manipulation and electrostatic gating the spin signature of the molecule can be adjusted and controlled. This study provides new insight on the interplay between magnetic fingerprints of all-organic molecules embedded in solid-state devices.

Detection and Identification of SARS-CoV-2 Variants Using Single-Molecule Conductance Measurements Zahra Aminiranjbar[1], Mashari Alangari[2], Caglanaz Akin[3], Yiren Wang[4], M.P. Anantram[4], Ersin Emre Oren[3] and Josh Hihath[5]; [1]University of California, Davis, United States; [2]Hail University, Saudi Arabia; [3]TOBB University of Economics and Technology, Turkey; [4]University of Washington, United States; [5]Arizona State University, United States

Since the start of the 2019 pandemic (COVID-19), the development of rapid and cost-effective testing has been an ongoing effort to help combat this highly transmittable and infectious disease. Over the past two years, the virus has continued to mutate and evolve, and several variants of SARS-CoV-2 have emerged which have reduced the vaccines' effectiveness. Therefore, there is a significant need for surveillance of the SARS-CoV-2 variants of concern to track the spread of the disease and help to confine the virus. Currently, the standard identification method for the subvariants utilizes reverse-transcription polymerase chain reaction (RT-PCR). However, this method is not suitable for rapid, high throughput testing of large populations, it is costly, time-consuming, and requires expert staff. Here we present an alternative to RT-PCR based on single-molecule conductance measurements which open new avenues for sensitive and cost-effective detection of the SARS-CoV-2 variants of concern.
Previous studies using the single-molecule break junction (SMBJ) approach have demonstrated that this technique is capable of detecting and identifying RNA: DNA hybrids via their conductance values. This work focuses on identifying SARS-CoV-2 variants of concern based on the codon sequences that represent mutations in the spike protein. Our hypothesis is that using a specific DNA probe that is complementary to the RNA for every mutation would result in a specific conductance value that represents the presence of the variant in the sample. Therefore, we can detect and identify each variant in a mixed sample based on their unique electronic fingerprints.
We focus on the alpha, beta, and delta variants which according to the World Health Organization (WHO) are classified as SARS-CoV-2 variants of concern. We design a series of 12 base-pair DNA probes that contain the mutation and would bind to the corresponding RNA section of the alpha and beta variant genome block. Our experimental results indicate that in the presence of the mutation, the conductance value of the hybrid RNA: DNA sequence is significantly different from when there is no mutation present. We further utilize the XGBoost machine learning classifier to aid in the rapid detection of the SARS-CoV-2 variants. This work demonstrates the utility of the SMBJ technique for the accurate detection and identification of SARS-CoV-2 variants with the potential for real-time application.

4:30 PM *EL12.05.08
Materializing Cognition - Information Processing with Cognitive Matter Wilfred G. van der Wiel[1,2]; [1]University of Twente, Netherlands; [2]University of Münster, Germany

Throughout history, man has exploited matter to carry out tasks well beyond his biological constraints. Starting from primitive tools with functionality solely derived from shape and structure, we have moved on to responsive matter that can change its properties upon external stimulus and even further to adaptive matter that can change its response depending on the environment. One of the grand scientific and intellectual challenges is to make matter that can actually *learn*. Such matter's behavior would not only depend on the here and now, but also on its past. It would have memory, autonomously interact with its environment and self-regulate its action. We may call such matter 'intelligent'.
Here we introduce the concept of "intelligent matter"[1] and discuss a number of experiments on disordered nanomaterial systems, where we make sure of "material learning" to realize functionality. We have shown that a 'designless' network of gold nanoparticles can be configured into Boolean logic gates

using artificial evolution[2]. We further demonstrated that this principle is generic and can be transferred to other material systems. By exploiting the nonlinearity of a nanoscale network of boron dopants in silicon, referred to as a dopant network processing unit (DNPU), we can significantly facilitate classification. Using a convolutional neural network approach, it becomes possible to use our device for handwritten digit recognition[3]. An alternative material-learning approach is followed by first mapping our DNPU on a deep-neural-network model, which allows for applying standard machine-learning techniques in finding functionality[4]. We also show that the widely applied machine-learning technique of gradient descent can be directly applied *in materia*, opening up the pathway for autonomously learning hardware systems[5]. Finally, we show that kinetic Monte Carlo simulations of electron transport in DNPUs can be used to reproduce the main characteristics and to depict the charge trajectories[6].

8:00 AM *EL12.06.01
Opportunities and Challenges in Single-Molecule Sciences Xuefeng Guo; Peking University, United States

This talk will exemplify our on-going interest and great effort in developing efficient lithographic methodologies capable of creating molecular electronic devices through the combination of top-down micro/nanofabrication with bottom-up molecular assembly. These devices use nanogapped nanomaterials (such as silicon nanowire (SiNW) and graphene) as leads or probes formed by electron beam lithography and precise oxygen plasma etching. Through robust chemical linkages, functional molecular bridges terminated with active moieties are covalently wired into the functionalized graphene/SiNW nanogaps to form stable single-molecule junctions with desired functionalities. We have used these approaches to reveal the dependence of the charge transport of individual metallo-DNA duplexes on p-stacking integrity, and fabricate molecular devices capable of realizing label-free, real-time electrical detection of biological interactions at the single-event level, or switching their molecular conductance upon exposure to external stimuli, such as ion, pH and light.

Tetrathiafulvalenes as Anchors for Building Highly Conductive and Mechanically Tunable Molecular Junctions Qi Zhou, Kai Song, Guanxin Zhang, Xuwei Song, Junfeng Lin, Yaping Zang, Deqing Zhang and Daoben Zhu; Institute of Chemistry, Chinese Academy of Sciences, China

In our work, we demonstrate that tetrathiafulvalene (TTF), which is an important building unit for functional materials, can act as a new anchor for molecular devices. We show that, in TTF-fused naphthalene diimide molecular wires, the sulfur atoms in TTF directly bind to gold electrodes and form single Au-molecule-Au junctions. The unique TTF-Au contacts created via Au-S bonding enable highly efficient hybridization of Au orbitals and molecular conducting π-channels, yielding strong electrode-molecule coupling and remarkably high conductance. Moreover, we introduce additional thiohexyl (SHe) anchors to the TTF unit and show that the multiple Au-S binding sites in these molecular wires offer mechanically switchable binding modes through either TTF-Au or SHe-Au interaction. This leads to mechanically tunable metal-molecule electronic coupling and conductivity in single molecule devices. These findings provide a new strategy for building highly tunable molecule-metal interfaces for molecular devices.

8:45 AM *EL12.06.03
Carbon Nanorings and Nanobelts for Molecular Devices Yaping Zang; Institute of Chemistry, Chinese Academy of Sciences, China

Carbon nanorings cycloparaphenylenes (CPPs) and carbon nanobelts (CNBs) are typical hoop-shaped nanocarbons that have unique radially oriented π-systems. This talk will summarize our recent work on incorporating these unique nanocarbons into molecular electronic devices using the scanning tunneling microscope-break junction technique. We show that, compared with traditional linear molecular devices, the hoop-shaped CPP and CNB based devices have significantly higher conductance. DFT-based calculations elucidate that the high performance of these devices arises from the distorted, radially π-conjugated molecular structures. These findings demonstrate the potential of using hoop-shaped conjugated nanocarbons to achieve unprecedented electronic performance, and may stimulate future design of nanoscale devices based on unconventional molecular geometries.

9:15 AM EL12.06.04
Electric Field Catalysis of Electrophilic Aromatic Substitution of Cycloparaphenylenes Junfeng Lin and Yaping Zang; Institute of Chemistry, Chinese Academy of Sciences, China

Electrophilic aromatic substitution (EAS), which involves the formation of charge-transfer complex between electrophiles and the electron-rich aromatic rings, is one of the most fundamental reactions in organic chemistry. Due to the relatively large energy barrier for the charge transfer activation, EAS reactions are often limited to systems containing highly activated (nucleophilic) nuclei or very strong Lewis acid catalysts. Here, instead of traditional chemical reagents, we demonstrate the utilization of an oriented external electric field (OEEF) to catalyze the EAS reactions based on the scanning tunneling microscope break junction technique. Using cycloparaphenylenes with unique radially π-conjugated structures as the aromatic substrates, we can apply the OEEF perpendicular to the aromatic ring, which is crucial for harnessing the field effect. Under a very mild condition (a voltage of <1 V), the applied OEEF can significantly accelerate the EAS by the otherwise unreactive Au electrophile, cleaving the inherently inert $C(sp^2)$-$C(sp^2)$ bond and leading to high-yield (~97%) formation of linear oligophenylenes terminated with covalent Au-C bonds. These results not only demonstrate the feasibility of OEEF catalysis of EAS, but also offer a way of exploring new mechanistic principles of classic organic reactions aided by OEEF.

Chemical Control Of Heat Transport And Vibrational Energy Redistribution In Molecules Gemma C. Solomon; University of Copenhagen, Denmark

Controlling heat flow is an important goal for materials, for example, to thermally insulate components or, conversely, to allow heat to rapidly dissipate. One area where this is technologically relevant is the microelectronics industry where computer chips are limited both by the challenges of miniaturization but also thermal management. At the same time, chemical control of heat transport is not part of traditional chemistry, where there has been much more focus on the electronic processes involved in making and breaking chemical bonds, so we cannot rely on established chemical knowledge to design new thermal management materials. Today, we need new methods and understanding to broaden our chemical intuition for thermal transport properties of molecules.
In this talk I will outline our efforts to develop chemical intuition for how we can control heat transport in molecules. While our understanding is far from complete, we can outline some general principles. Structural disorder in flexible systems, perhaps unsurprisingly, results in vibrational mode localization and reduced heat transport. While one might expect that breaking chemical bonds to yield non-bonded, self-assembled systems, would reduce heat transport it can also increase heat transport in certain cases. Finally, mass-disorder, for example from by changing to an inorganic complex instead of an organic molecule can be very effective at suppressing heat transport. Less clear are the effects of changing the structure of an organic molecule, for example between conjugated and saturated systems, leaving open a broad area of uncertainty as to ideal systems.

11:00 AM EL12.07.02
Thermocurrent Spectroscopy of Yu-Shiba-Rusinov States in Single-Molecule Junctions Serhii Volosheniuk[1], David Vogel[2], Christina Wegeberg[2], Marcel Mayor[2,3,4], Herre S. van der Zant[1] and Pascal Gehring[5]; [1]Delft University of Technology, Netherlands; [2]University of Basel, Switzerland; [3]Karlsruhe Institute of Technology (KIT), Germany; [4]Sun Yat-Sen University (SYSU), China; [5]Université Catholique de Louvain, Belgium

The interaction between magnetic impurities and superconductors leads to fascinating physical phenomena resulting from the competition between Kondo screening and Cooper pair formation [1]. To this end, individual magnetic impurities can form states within the superconducting gap, called Yu-Shiba-Rusinov (YSR) states [1,2]. YSR states are of great interest because they have the potential to realise topological superconductivity. Here we show that such YSR states form in a neutral and stable all-organic radical molecule coupled to proximity induced superconducting break-junction electrodes. We experimentally study the thermoelectric response [3] of the system at mK temperatures, both in the YSR regime and – by applying magnetic fields – in the Kondo regime [4]. Ultimately, we observe a two-fold increase of the thermoelectric efficiency which is induced by the YSR states. This study highlights the power of thermocurrent measurements as a new spectroscopic tool to study nanoscale devices, and reveals new strategies for engineering highly efficient thermoelectric energy conversion at cryogenic temperatures.

11:15 AM EL12.07.03
Controlling Quantum Interference for Molecular Electronics Hatef Sadeghi and Sara Sangtarash; University of Warwick, United Kingdom

Thanks to their sub-10 nanometre size, molecules offer a fantastic platform for exploiting quantum effects at room temperature. Recently, it was shown that molecular wires can mediate long-range, phase-coherent tunnelling with remarkably low attenuation beyond a few nanometres, even at room temperature [1]. This opens up the possibility of using quantum interference (QI) to control the transport of electrons, spins and phonons through molecular junctions consisting of a single or a few molecules between electrodes.

In this talk I will present evidence for room-temperature QI in molecular junctions and discuss the agreement and disagreement between experiments and predictions based on phase-coherent quantum transport theory [2]. Then, I will discuss strategies to control QI in molecular junctions [3] including chemical and structural modifications of molecules, and the application of electric field or light. I will then discuss how these strategies can be used to improve the efficiency of thermoelectric materials for energy harvesting and cooling, to improve spin filtering through molecules for quantum information applications, and to selectively sense biological species.

Robust Resistive and Mem-Devices for Neuromorphic Circuits T. Venky Venkatesan[1,2]; [1]University of Oklahoma, United States; [2]National Institute of Standards and Technology, United States

Artificial intelligence (AI) has been heralded as the flagbearer of the fourth industrial revolution but comes with a cost and that is computing power. It is projected that by 2040, we will need more computing energy than the total energy we can produce now. So, we need devices that can offer higher computing/ storage density with low energy consumption like neurons. We are addressing these challenges using oxide and molecular-electronic based memristors, which enable us to overcome the von Neuman bottleneck by co-locating the memory and computing functions on the same device, as in neuromorphic computing.
I will discuss a variety of strategies for forming oxide based memristors using different phenomena- band filling and creating a quasi-conduction band, using oxygen vacancies to create conductive percolation, using metal-insulator transitions, or using asymmetric tunneling at a ferroelectric barrier. The relative merits of the various approaches will be detailed.
In addition, I will touch upon memristive devices and circuits made from an azo-aromatic complex with extra-ordinary reproducibility, robustness, and scalability. These devices have been shown to switch with energies approaching atto-joules with measured switching times shorter than 5 ns. By using a simple cross bar array, we have shown that these devices perform with an energy-speed product 5000 times that of a state-of-the-art CMOS circuit.

Thousands of Conductance Levels in Memristors Monolithically Integrated on CMOS J. Joshua Yang[1,2,3]; [1]University of Southern California, United States; [2]University of Massachusetts Amherst, United States; [3]TetraMem Inc., United States

Neural networks based on memristive devices have shown potential in substantially improving throughput and energy efficiency for machine learning and artificial intelligence, especially in edge applications. Because training a neural network model from scratch is very costly, it is impractical to do it individually on billions of memristive neural networks distributed at the edge. A practical approach would be to download the synaptic weights obtained from the cloud training and program them directly into memristors for the commercialization of edge applications. Some post-tuning in memristor conductance may follow afterward or during applications. Therefore, a critical requirement on memristors for neural network applications is a high-precision programming ability to guarantee uniform and accurate performance across a massive number of memristive networks. This translates into the requirement of many distinguishable conductance levels on each memristive device, not just lab-made devices but more importantly, devices fabricated in foundries. High precision memristors also benefit other neural network applications, such as training and scientific computing. Here we report over 2048 conductance levels, the largest number among all types of memories ever reported, achieved with memristors in fully integrated chips with 256x256 memristor arrays monolithically integrated on CMOS circuits in a standard foundry. We have unearthed the underlying physics that previously limited the number of achievable conductance levels in memristors and developed electrical operation protocols to circumvent such limitations. These results reveal insights into the fundamental understanding of the microscopic picture of memristive switching and provide approaches to enabling high-precision memristors for various applications.

11:00 AM *EL13.01.02
Materials and Device Concepts Based on Organic Electrochemical Transistors for Sensing and Signal Processing Jonathan Rivnay; Northwestern University, United States

Organic mixed ionic/electronic conductors (OMIECs) have gained considerable interest in bioelectronics, power electronics, circuits and neuromorphic computing. These organic, often polymer-based, semiconductors rely on a combination of ionic transport, electronic transport, and high volumetric charge storage capacity. Despite recent progress and a rapidly expanding library of new materials, the understanding of stability and transport/coupling of ionic and electronic carriers remain largely unexplored. We highlight recent synthetic and processing approaches used to tailor electrochemical device properties revealing new classes of OMIEC active materials, as well as new opportunities enabled by such advances. Control of ionic transport and trapping for example presents a promising avenue towards the development of non-volatile electrochemical transistors. We show that additives in prototypical conducting polymers can lead to neuromorphic function which can mimic basic neural function. In addition, the bulk transport properties of OMIECs enable device concepts that achieve co-localization of sensing with signal processing including amplification of electrophysiological and biochemical sensors, and devices with highly non-linear responses for spiking neurons.

11:30 AM EL13.01.03
Hysteresis and Temperature-Dependence of Organic Electrochemical Transistors Lukas M. Bongartz[1], Matteo Cucchi[2,1], Anton Weissbach[1], Tommy Meier[1], Hans Kleemann[1] and Karl Leo[1]; [1]Technische Universität Dresden, Germany; [2]Neuro-X Institute, EPFL, Switzerland

Due to their synaptic functionality of interacting electronic and ionic charge carriers, organic electrochemical transistors (OECTs) are highly attractive candidates for a new generation of organic neuromorphic devices. While such systems are regularly realized by a liquid electrolyte on an organic mixed ionic–electronic conductor, this very feature of a liquid operation represents a severe challenge for employing OECTs in dense integrated circuits. By using a solid-state electrolyte composed of an ionic liquid in a photopatternable polymer matrix, we realize devices of outstanding performance in terms of high on-off-ratio ($\sim 10^5$), low threshold voltage (<200 mV) and a subthreshold swing close to the thermodynamic limit of 61 $\mathrm{mVdec^{-1}}$. The devices are further characterized by a pronounced hysteresis in their transfer curves, for which we define an empirical parameter that allows for straightforward and well-fitting description of its strength. Investigating it as a function of various parameters, we find a significant dependence on the scan rate, in which two regimes can be identified: for descending scan rates, we first see the hysteresis to increase until a certain limit, after which it gradually decreases again to a minimal, non-zero degree. We show that the paths of the hysteretic transfer curve remain separate even after hours, and thus present themselves as two separate states that give the OECT an inherent memory functionality.

Given the remanent nature of this share of hysteresis, we use the solid OECT system for the first systematic, temperature-dependent characterizations of this device class. These reveal several special insights into the thermodynamics of the system, two results of which are particularly impressive. First, we find a non-linear decreasing hysteresis with temperature. Second, we observe that the subthreshold swing decreases in a certain range with increasing temperature. This behavior is contrary to what is expected from MOSFET theory and thus represents a reverse Boltzmann dependence. To study this finding, we delve into the thermodynamics of the system and describe the underlying Gibbs free energy via the interaction of neutral and polaronic species. We identify the relative strengths of these interactions as the cause of a bistable Gibbs function and show that the model can well explain the dependencies of both the hysteresis and the subthreshold swing.

Considering the importance of stable hysteresis as a memory functionality in neuromorphic devices, the explanation of such via suitable models is of considerable significance. Using the presented framework, we can derive statements about device optimizations from the Gibbs free energy function and thus point out directions to realize *e.g.*, transistors of certain hysteresis and switching behavior in a targeted way. As such, we also show ways to specifically realize hysteresis-free solid OECTs by introducing external components to the system.

We consider the results of these investigations to greatly enhance the understanding of OECTs and finally accelerate their usage in advanced applications.

11:45 AM EL13.01.04
Stabilizing Neural Networks on Forgetful Organic Neuromorphic Devices Daniel Felder[1,2], Katerina Muche[2], John Linkhorst[2] and Matthias Wessling[2,1]; [1]DWI–Leibniz Institute for Interactive Materials, Germany; [2]RWTH Aachen University, Germany

Organic neuromorphic device networks can accelerate neural network algorithms and directly integrate with microfluidic systems or living tissues. Proposed devices based on the bio-compatible conductive polymer PEDOT:PSS have shown high switching speeds and low energy demand. However, as electrochemical systems, they are prone to self-discharge through parasitic electrochemical reactions. Therefore, a neural network's synapses forget their trained conductance states over time. In this work, we integrate single-device high-resolution charge transport models to simulate entire neuromorphic device networks and analyze the impact of self-discharge on network performance. Furthermore, we search for robust algorithms for artificial and spiking neural networks through model-based hardware-algorithm co-design. The simulations reveal that artificial neural networks are affected differently by self-discharge-induced weight drift depending on their structure. For example, a single-layer nine-pixel image classification network commonly used in experimental demonstrations shows no significant impact of self-discharge during the first 10 hours. On the other hand, a multi-layer network for the approximation of the circle function is shown to degrade significantly over twenty minutes with a final mean-squared-error loss of 0.4. For artificial neural networks, we propose to counter the effect by periodically reminding the network based on a map between a synapse's current state, the time since the last reminder, and the weight drift. With a map obtained through validated simulations, this method can reduce the effective mean-squared-error loss to below 0.1, even with worst-case assumptions. On the other hand, spiking neural networks are shown to stabilize their weights within a narrow range through spike-timing-dependent plasticity and have the potential to compensate for the effects of self-discharge with optimized algorithms fully. Electrochemical organic neuromorphic devices have yet to be integrated into larger device networks. This work predicts their behavior under nonideal conditions, proposes two strategies to mitigate the worst-case effects of parasitic self-discharge, and opens pathways toward implementing fast and efficient neural networks on organic neuromorphic hardware.

SESSION EL13.02: Materials for Neuromorphic Devices I

1:30 PM *EL13.02.01
Thermodynamic Engineering of Oxygen Transport in Materials for Nonvolatile Resistive and Electrochemical Memory Yiyang Li; University of Michigan, United States

In-memory computing using analog resistive memory promise substantial improvements in the energy efficiency of deep neural networks. Valence-change memory (VCM) and electrochemical random-access memory (ECRAM) are two promising analog resistive memories that stores information through the migration of oxygen vacancies. In this work, we show how materials thermodynamic engineering and especially phase separation can be used to control oxygen transport and create nonvolatile memory devices. We first investigate two-terminal filamentary VCM, and show that the widely used transport model based on Fickian diffusion does not accurately describe oxygen migration during retention. Instead, oxygen transport is governed by phase separation and spinodal decomposition, which enables certain resistance states to be indefinitely nonvolatile. Next, we apply these thermodynamic principles to design three-terminal ECRAM cells and achieve the first nonvolatile ECRAM cell that operate under short circuit configurations without a switch.

2:00 PM EL13.02.02
Tunable Intervalence Charge Transfer in Ruthenium Prussian Blue Analogue Enables Stable and Efficient Biocompatible Artificial Synapses
Donald A. Robinson, Michael Foster, Raga Krishnakumar, Mark D. Allendorf and A. A. Talin; Sandia National Laboratories, United States

Reversible electrochemical doping of ruthenium hexacyanoruthenate, a type of Prussian blue analogue (PBA), enables the on-demand tuning of electronic conductivity by more than four orders of magnitude. Inkjet-printed electrochemical random access memory (ECRAM) devices based on Ru-PBA and lithium- or proton-conducting ionogel electrolytes exhibit excellent switching efficiency and long-term memory retention, important characteristics for analog artificial synapses in neuromorphic circuits. We also demonstrate excellent biocompatibility with live neurons and the use of Ru-PBA ECRAM devices to detect dopamine, promising first steps toward connecting artificial and biological neural networks. In-situ probing of metal-metal charge transfer by UV/Vis/NIR absorption spectroscopy reveals a switching mechanism whereby electrochemically tunable valence mixing between N-coordinated Ru sites controls the carrier concentration and mobility, as independently supported by both Marcus-Hush electron transfer theory and more conventional band structure predictions from DFT. The experimental agreement achieved by both theoretical approaches supports a general mechanistic picture that intramolecular charge transfer reactions, more commonly studied in polynuclear mixed valence small molecules, are central to electronic conductivity in extended coordination frameworks.

2:15 PM EL13.02.03
Brain-Inspired Biomolecular Networks for Reservoir Computing Joshua Maraj and Stephen A. Sarles; The University of Tennessee, Knoxville, United States

Biomolecular structures assembled using the droplet interface bilayer (DIB) technique of lipid coated aqueous droplets in a hydrophobic medium allow construction of modular aqueous compartments separated by artificial lipid membranes. These membranes can be functionalized with active biomolecules to enable sensing and information processing, including but not limited to transmembrane proteins. When doped with alamethicin (Alm) or monazomycin (Mz), DIBs become volatile memristors that exhibit voltage-dependent short-term synaptic plasticity (STP). This property has led to their use as artificial synapses for neuromorphic hardware implementations of artificial intelligence algorithms, such as reservoir computing (RC).
RC is an algorithm that uses specific device properties such as nonlinearity and fading STP to simplify classification of dynamic signals. We have previously demonstrated that individual Mz-doped DIB biomolecular synapses (BS) are suitable for use in RC classification and dynamic function learning, but little research has been done into forming BS networks for use in RC. An advantage of this approach is the ability to combine sensing and information processing into elements of the same network. Due to the customizability of individual compartment contents, sensing functions can be assigned to specific network locations by including thermoreceptors, mechanoreceptors, etc. into those droplets, but not others. In this work we present methods for rapid assembly and characterization of BS networks and schema for use in an RC framework, as well as hypothetical architectures for multimodal sensing.
For assembly of BS networks, we develop a multi-welled “egg crate” style structure to hold droplets stationary to both maintain contact with neighboring droplets and electrodes in the bottom of each well. These electrodes are controlled and measured by multichannel NI-DAQs. Tested network structures will include linear networks, multilayer perceptrons of linear layers, and hexagonally packed clusters. To test the RC capability of each network, we use the UCI Epileptic Seizure Recognition Data Set to stimulate the reservoir. Additionally, using real world sensor data from a morphing airfoil in a wind tunnel, we input these signals as voltages into the droplet network and measure the conductance states of each node to classify and predict gusting behavior. For a visual task, we classify a custom set of 5x5 digits. We hypothesize that using a combination of Alm and Mz will yield higher accuracy than either alone in most cases.
The above cases represent an electrical task, a mechanosensitive task, and a light sensitive task. In the future, these signals can be directly processed and classified by including the relevant transmembrane sensing channels used in organisms. Ongoing work seeks to stabilize these networks into devices that may be used in-device.

2:30 PM *EL13.03.01
Organic Nervetronics for Next-Generation Computing and Nerveprosthetics Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Real-time information processing is an important feature of biological nerves. To implement such properties (event-driven, parallel operation, etc.) artificially, organic nervetronics have been upsurged. Furthermore, artificial synapses can be combined with sensors and actuators to emulate the functions of biological sensory and motor neurons with a simple circuit structure. In addition, it consumes 10^{-6} times less energy in operation than a CMOS-based von Neumann computing system. This organic neural electron can become a new strategy for soft robotics, next-generation computing, and neuroprosthetics by imitating biological neuroplastic events which can replace the damaged nerves.
First, we controlled the microstructure of various organic semiconductors, and blended two diketopyrrolopyrrole (DPP) based semiconductor with different side chain to achieve long-term plasticity. Also, by producing trapping site for ions, ion-gel gated artificial synapses showed extremely long-term retention time.
Furthermore, we developed an artificial nerve that emulates biological afferent and efferent nerve. The connection of biological organs and artificial afferent nerves shows a hybrid reflex arc that shows future applicability for neural prostheses. The movement of the detached cockroach leg can be controlled by external sensory information. Also, an artificial auditory system was developed by integrating a triboelectric nanogenerator an artificial

synapse. The optoelectronic artificial sensorimotor nerve emulates optogenetically engineered neurons and synapses. The contraction of artificial muscles well imitates biological muscle contraction. The stretchable nervetronics reproduced coordinated bipedal movement and practical motions such as 'kicking a ball' and 'walking/running' in living animals. Neuroplasticity-based artificial nerves can be not only used for next-generation computing systems but also restore the biological afferent and efferent nerve response which can pave a new way to future neuromorphic computing.

An Artificial Sensory Neuron System Based on Pieozo-Ionic Synaptic Transistors with Suspended Porous Ion Gel Yun Goo Ro, Dahun Lim, Cheolhong Park, Youngoh Lee, Youngsu Lee and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Electronic skin (e-skin) composed of sensors mimicking human mechanoreceptors became an indispensable technology in wearable electronic systems, robots, and human-machine interfaces (HMIs). To embody humanoid robots that have human-level perception and cognition, recent endeavors are devoted to the development of intelligent e-skin. Humans are capable of remembering and learning from external information by brain neurons that communicate with each other through synapses. In response to external stimuli, synapses are strengthened or weakened and the connections between neurons are controlled. Through this synaptic process, humans have persistently evolved cognition and intelligence by adapting to different environments. Artificial synaptic device that mimics a biological synapse is an emerging electronic platform that can realize human-like robots when integrated with e-skin.
We report an artificial sensory neuron system composed of an artificial synapse and a mechanoreceptor that allows tactile perception and learning based on a pressure sensitive organic electrochemical transistor (OECT). The OECT is composed of an organic semiconductor poly(3-hexylthiophene-2,5-diyl) (P3HT) as a channel and a piezo-ionic gel of ferroelectric polymer poly(vinylidene fluoride-trifluoroethylene (P(VDF-TrFE)) and ionic liquid (1-ethyl-3-methylimidazolium bis(trifluoromethanesulfonyl)imide) as both a gate dielectric layer and a pressure sensing layer. To increase the pressure sensitivity, the piezo-ionic gel with the porous structure is utilized for the effective structural deformation and localized stress concentration in response to pressure. In addition, a suspended gate dielectric structure, where the piezo-ionic gel is floating above the channel with the help of spacers having an air gap in between, is adopted. When the piezo-ionic gel contacts the semiconductor channel under external pressure, spontaneous piezopotential is created inside the polymer matrix, which induces movements of ions and formation of electric double layers (EDLs) at each gate electrode/ion gel and ion gel/channel interfaces, and consequent modulation of the drain current of the channel. The suspended gate dielectric structure induces the abrupt generation of EDLs under application of pressure, enhancing the pressure sensitivity. In contrast to the conventional synaptic transistors that require external gate bias for the transistor operation, in our device, piezopotential created by pieozo-ionic gel from external stimuli replaces the external gate bias, enabling low energy consumption of the device. Moreover, monolithic integration of the tactile sensing component and the synaptic transistor, where they are stacked vertically, enables high density integration of pressure sensitive synaptic transistor per unit area. In particular, the precise control of ion migration and trapping in the channel enables an artificial sensory neuron system exhibiting not only highly-sensitive detection of external pressure with different pulse frequencies, but also excellent synaptic learning behaviors such as excitatory postsynaptic current (EPSC), paired-pulse facilitation (PPF) and transition of short-term plasticity (STP) to long-term plasticity (LTP). For the potential application in humanoid robots, we integrate our OECT device on a robotic hand and demonstrate that the robotic hand can respond and adapt to different types of external pressure.

2D+ and 3D Electrodes Provide Tight Connections with Neurons Andreas Offenhaeusser, Pegah Shokoohimehr, Bogdana Cepkenovic and Jamal Shihada; Forschungszentrum Julich, Germany

Our understanding of the brain and general neural systems is based on models of increasing complexity, from 2D cell culture to organoids and organotypic slices to animal models. These models provide significant insight into neuronal information processing in the brain, but require advanced electrophysiological measurement technologies to achieve long-term stable recordings with single-cell and millisecond space-time resolution. Thus, challenges remain to study information processing between neurons with high spatiotemporal resolution and high signal-to-noise ratio (SNR). These challenges are overcome by well-established planar multichannel devices, but at the expense of signal-to-noise ratio. Without sufficient electrode-cell coupling, planar microelectrode arrays (MEAs) provide low-amplitude signals that are difficult to correctly assign by spike sorting algorithms. Furthermore, the unresolved subthreshold signals lose valuable information that is essential for direct estimation of synaptic weights and correct generation of connectivity matrices in neural networks.

To yield better cell-electrode coupling, numerous vertical nanostructures and nanoelectrodes have been developed by several groups. Here we present the concept of nanocavity (NC) MEAs with vertical nanostraws. High aspect ratio nanostraws (NS) were engineered to initiate tight cell-structure coupling, while the nanocavity reduces the electrode impedance. This combination yields a spontaneous tight mechanical coupling and results in long-term recordings with increased signal amplitude, with no poration-inducing external forces or surface functionalization. Moreover, simultaneous patch-clamp and MEA recordings of the coupled neuron directly demonstrated the capability of our device to record post-synaptic potentials. Here we show that PSP resolution persisted throughout the measurements, indicating a stable and long-term subthreshold amplitude sensitivity.

Simultaneous electrical recordings with good spatial and temporal resolution from 3D neuronal structures (organoids or organotypical slices) is also technological limited. Here we present our recent developments to overcome this limitations by 3D MEA which allow the recording from inside the neuronal tissue.

Optical Detection of Neuroelectric Signals Using Electrochromic PEDOT Bianxiao Cui; Stanford University, United States

Neurons encode input and output information through electrical signals. Optical detection and imaging of electric activities provide unprecedented spatial flexibility and parallelization. In the last decade, the advancement of voltage-sensitive fluorescent proteins, and small potentiometric dyes, has drastically enhanced the capability of optical recording of electrical activity in cells. However, the use of fluorophores requires membrane insertion and suffers from photobleaching, phototoxicity, and limited time resolution. We exploit the unique physical properties of electrochromic PEDOT material, whose optical properties can be modulated by the applied electric potential. Combined with sensitive optical detection, we developed an electrochromic optical recording (ECORE) technique that achieves label-free and non-perturbative detection of action potentials in neurons, cardiomyocytes, and brain slices.

Optically Stimulated Synaptic Transistor using Polyimide and Indium-Gallium-Zinc Oxide Co-Sputtered Layer for Flexible Neuromorphic Device Jong Hyuk Ahn, Min Seong Kim, Jong Bin An, Kunho Moon, Sujin Jung and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

Recently, light stimulation-based synaptic devices are attracting attention as artificial neuromorphic systems due to their capability to mimic the functions of visual neurons, such as light recognition and image processing. These devices have advantages, such as wide bandwidth, low crosstalk, and high processing speed, compared to electrical stimulation-based synaptic devices. So far, various kinds of materials including carbon nanotubes, quantum dots, organics, oxide semiconductors, and halide perovskites have been researched for the realization of optoelectronic synaptic devices. Among them, oxide semiconductors are considered as one of the promising materials, due to their superior characteristics of simple, large area manufacturing capability coupled with excellent electrical properties. However, most oxide semiconductors cannot absorb long wavelength visible light because of their large optical bandgap (> 3.0 eV), so additional light absorbing layer is essential for detecting full range of visible light. In this paper, we proposed a facile method for fabricating optoelectronic synaptic transistor in which polyimide (PI) and indium-gallium-zinc oxide (IGZO) co-sputtered layer (PICL) was introduced for visible light absorption. PI is an organic material that can reduce the brittle nature of oxides, which can open up the potential of applicability to flexible devices, and also has the advantage of being applicable to vacuum sputtering process.

We compared the persistent photoconductivity (PPC) of the IGZO thin-film transistor (TFT) and the PICL optoelectronic synaptic transistor after illumination of red-light pulses of 1 mW/mm^2 intensity, 0.2 Hz frequency. In the case of the IGZO TFT, the drain current (I_{DS}) was maintained at 4.48×10^{-13} A for 400 s. In the case of the PICL optoelectronic synaptic transistor, the I_{DS} continued to increase during the cycle of 400 s, from 5.86×10^{-10} A to 2.71×10^{-7} A. Unlike the IGZO TFT, the PICL optoelectronic synaptic transistor showed PPC characteristics. PPC is due to the slow recombination speed of carriers, generated by light, when the light is turned off. PI and IGZO co-sputtering process formed sub-gap states, such as uncoordinated oxygen species, metal hydroxides, hydrogen anions, and organic components inside the IGZO bandgap, and these sub-gap states attributed to the PPC in the PICL optoelectronic synaptic transistor.

Synaptic functions including excitatory postsynaptic current (EPSC), paired pulse facilitation (PPF), and short/long term memory (STM/LTM) behaviors of the PICL optoelectronic synaptic transistor were demonstrated. EPSC of the PICL optoelectronic synaptic transistor was measured under illumination of a single red-light pulse of 5 mW/mm^2 intensity, 0.2 Hz frequency. After applying the light pulse, the I_{DS} sharply increased from 0.50×10^{-10} A to 0.57×10^{-8} A. After turning off the light, the I_{DS} gradually decreased and converged to 4.41×10^{-9} A. When the light is turned off, electrons excited by light into the conduction band of the IGZO channel layer start recombination with holes in the valence band. PPF index of the PICL optoelectronic synaptic transistor was 192.6% under illumination of red-light pulses of 5 mW/mm^2 intensity, 0.8 Hz frequency. The I_{DS} of the 1st EPSC and 2nd EPSC was 2.69×10^{-9} A and 5.18×10^{-9} A, respectively. The I_{DS} decayed right after the light was turned off and converged to 2.78×10^{-9} A. Both STM/LTM behaviors were measured under illumination of red-light pulses of 10 mW/mm^2, 0.05 Hz frequency, and 5/20 (STM/LTM) pulse numbers. The I_{DS} of the 1st EPSC, 5th EPSC, and 20th EPSC were 1.10×10^{-11} A, 8.88×10^{-9} A, and 1.21×10^{-7} A, respectively. From the STM result, the I_{DS} decayed sharply right after turning off the light, whereas the LTM result showed much slower decay of the I_{DS}. These results showed the strong potential of the PICL optoelectronic synaptic transistor in the field of photonic neuromorphic systems.

5:00 PM EL13.04.02
Quantum Dot Embedded Photonic Synapse-Based Biomimetic Autonomous Light Modulation System Seongchan Kim[1,2], Hong Chul Moon[3], Sohee Jeong[4] and Jeong Ho Cho[5]; [1]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); [2]The Pennsylvania State University, United States; [3]University of Seoul, Korea (the Republic of); [4]Sungkyunkwan University, Korea (the Republic of); [5]Yonsei University, Korea (the Republic of)

In order to perceive objects clearly, humans receive an appropriate amount of light through the light modulation response. In this study, we fabricated a biomimetic autonomous light modulation system that mimics the pupil and corneal reflections. For the fabrication, the photonic synapse was designed by embedding quantum dots in a metal oxide semiconductor layer. Here unlike other quantum dot based photonic synapses, the introduction of quantum dots can improve the inhibitory properties of photonics synapse. Subsequently, we emulate the pupillary light reflex through the incorporation of the quantum dot embedded photonic synapse, electrochromic device, and CMOS components. Moreover, corneal reflex was stimulated through the connection between a solenoid-based eyelid and the pupillary light reflex system. The system capable of perceiving an appropriate amount of light through autonomous light modulation presents a platform for biomimetic prosthesis.

5:00 PM EL13.04.03
Electrochemically Driven One-Body Torsional Artificial Muscles from Polymer-Coated Carbon Nanotube Yarn Seongjun Kim, Jae Sang Hyeon and Seon Jeong Kim; Hanyang University, Korea (the Republic of)

Torsional artificial muscles are being developed to replace electric motors in the field which needs miniaturization. Among the various types of torsional muscles, electrochemical torsional muscles have many advantages including fast reaction, easy control, high energy efficiency, and a natural latching state. For the electrochemical artificial muscle, carbon nanotubes (CNTs) are one of the best materials due to their remarkable mechanical strength and high capacitance. Previously reported electrochemical torsional CNT muscle used a CNT yarn made by twist insertion into the sheets. These CNT muscles showed great rotating performance. However, these muscles could only use a half of the available voltage range for actuation, which means that only one of the positive and negative voltage ranges could be used, so their rotation performance is limited. In addition, counter and reference electrodes made it difficult to make a compact muscle system. To solve these problems, we demonstrate a torsional muscles which rotate in one direction throughout the whole available voltage range. By coating the CNT yarn with an ion-exchange polymer, poly(sodium 4-styrenesulfonate) (PSS), the potential of zero charge of CNT yarn shifts to the outside to the electrochemical stability window of aqueous electrolytes. It means that only cations participate to a muscle rotation for the whole voltage range, resulting the rotation in the one direction from -1 to +1 V. The rotation degree and speed of the PSS-coated CNT muscles are higher than the neat CNT muscles, since the voltage range is doubled. Moreover, the PSS-coated CNT muscles are easy to make a compact one-body structure which consists of upper and lower muscles. The upper muscle and the lower muscle of the pedal rotates in the opposite direction when a voltage is applied to the one-body muscle system. One muscle works as electrochemical and mechanical counter for the other muscle, so the rotation of the pedal is maximized and its rotation also has high reversibility. This high-performance and one-body torsional muscle is useful for various applications, such as microbotics and microfluidics.

5:00 PM EL13.04.04
Gel Mechanoreceptor Sensor Inspired by Merkel Disk Kyoung-Yong Chun, Seunghwan Seo and Chang-Soo Han; Korea University, Korea (the Republic of)

The tactile sensor existing in human skin is a complex and efficient biosensor. Many researchers have been inspired by skin sensors and have manufactured advanced tactile sensors through the development of various materials and structures. In this study, the signal types of slow adapting (SA) and rapid adapting (RA), which are one of the characteristics of the skin sensor, were analyzed according to the material and structure of sensors. Also, the optimization process was described. For the experiments poly(vinylidene fluoride-trifluoroethylene) (PVDF-TrFe) gel was used to manufacture the self-powered sensor, and copper and Ag wire were used as electrodes. For pressure sensing, PVC gel electrolyte adding ionic liquid was prepared and used. Basically, PVDF-TrFe gel and PVC gel were applied to obtain RA and SA signals, respectively. We tried to optimize the sensor sensitivity through the optimization of PVC ion gel electrolyte.

Temporal Information Decoding with Organic Electrochemical Memory Transistors Yuyang Yin, Shaocong Wang, Zhongrui Wang and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

In the big-data era, information processing heavily relies on advances in computing methods and hardware. Being a promising contender for new-generation computing hardware, neuromorphic devices manifest better energy efficiency compared to traditional CMOS-based digital systems by collocating the memory and processing units in a bio-inspired manner. Organic electrochemical transistors (OECTs) possess rich nonlinear dynamics, such as short-term plasticity, which enables integrating of temporal inputs with a fading memory. This property favors time-domain signal processing using reservoir computing, which allows classification or prediction at a substantially low training cost. In this talk, we will demonstrate how to use the OECT memory to classify human electrophysiological signals. PEDOT:Tos/PTHF based OECT devices are employed as reservoir computing hardware to encode images or biological signals by tailoring the dynamics of the devices. Devices with different channel dimensions can discriminate different temporal inputs encoded in the form of voltage pulse trains and can further recognize binary digit patterns and decode electromyography (EMG) signals at decent successful rate. Such reservoirs, featuring multiple memristive devices with different dynamics, would provide better adaptability and generality in handling complex temporal data.

5:00 PM EL13.04.06
Neuromorphic Device Based on Glycoprotein Extracted from Epithelial Mucus for Skin-Attachable Electronics Kunho Moon, Sung Min Rho, Sujin Jung, Jong Hyuk Ahn, Youjin Seo and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

As technological advances are heading toward hyper-connectivity between entities, an unprecedented amount of data is being processed. Thus, conventional von Neumann architecture is gradually reaching its intrinsic limit called the 'von Neumann bottleneck' where the system's throughput is degraded due to the physical separation between processing and memory units. Inspired by human brains consisting of neurons and parallelly connected synapses, neuromorphic devices capable of multilevel storage and data processing at a single device level with low power consumption are expected to resolve the bottleneck issue. While several attempts are being made to integrate neuromorphic devices in various applications, it is also the case for skin-attachable healthcare monitoring devices for remote diagnostics. For such devices to be realized, several requirements including biocompatibility and flexibility should be met, which can hardly be achieved using inorganic materials like silicon.
In this work, organic material called mucin, a type of glycoprotein prevalent in the epithelial mucus of most animals was introduced as an active layer of a two-terminal neuromorphic device or a neuromorphic memristor. The fabricated device has an Mg/mucin/p^+-Si structure of metal-insulator-metal configuration while the mucin layer was deposited by a simple spin-coating technique. The utilization of two-terminal devices as neuromorphic memristors has been extensively studied due to their structural resemblance with biological synapses. The top and bottom electrodes each correspond to pre- and post-synapses, and the modulation of neural connectivity is emulated by conductivity adjustment of an active layer with an input voltage pulse. Several synaptic functions including excitatory post-synaptic current (EPSC), paired-pulse facilitation (PPF), long-term potentiation (LTP), and long-term depression (LTD) were successfully emulated with the mucin-based neuromorphic memristor.
Applying a 1.5 V, 10 ms voltage pulse to the top electrode has generated a 55.0 µA EPSC, characterized as a sudden increase in current level and immediate return close to the initial level but with a slight increment. While EPSC corresponds to the short-term memory (STM) behavior of the human brain, PPF property was further tested to demonstrate STM to long-term memory (LTM) transition. 1.5 V, 10 ms voltage pulses were consecutively applied with 10 ms intervals between them, resulting in increased EPSC from 55.0 to 67.1 µA and thereby achieving the PPF index of 122% (PPF index = $A_2/A_1 \times 100(\%)$, A_n: Peak current of the n^{th} EPSC). LTP and LTD properties were finally examined using 10 consecutive 1.5 V positive voltage pulses and -1.0 V negative voltage pulses. The current level gradually increased and decreased with repetitive positive and negative voltage pulses, and this tunability of the current level well resembles the memory behavior of biological synapses.
An X-ray photoelectron spectroscopy (XPS) depth analysis was conducted to figure out the mechanism of the synaptic behavior of the device. The Mg *2p* spectrum was deconvoluted to the Mg-Mg peak centered at 49.6 ± 0.2 eV and the Mg-O peak centered at 50.7 ± 0.2 eV. The area percentage of the Mg-O peak was larger as 57.5% for the Mg/mucin interfacial site, indicating the formation of the Mg oxide layer. As the diffusion coefficient of Mg (24.9×10^{-6} m^2/s) is known to be larger than that of O (4.3×10^{-9} m^2/s) in an Mg oxide system, migration of Mg ions rather than oxygen vacancies is thought to contribute to the formation and rupture of Mg ion-based conductive filament (CF) depending on the polarity of applied voltage pulses. In this regard, the gradual formation and rupture of CF are assumed to be visualized as potentiation and depression of mucin-based neuromorphic memristor. Based on these results, it is strongly believed that mucin-based neuromorphic memristors can be applied to future skin-attachable healthcare monitoring devices.

5:00 PM EL13.04.07
Midinfrared (MIR) Triggered Photoacoustic Film for Neuromodulation Zhiyi Du, Mingsheng Li, Guo Chen, Maijie Xiang, Nan Zheng, Chen Yang and Jixin Cheng; Boston University, United States

Photoacoustic has been shown as an emerging method for imaging and cellular modulation in biomedical applications. Up to this date generation of photoacoustic signals in photoacoustic agents and materials relies on absorption based on the electronic transitions in visible range such as gold nanoparticles or NIR range such as carbon based materials. However, operation in these wavelengthes will also interfere with other imaging modality using the same range. For example, successfully photoacoustic modulation has been achieved using carbon materials that broadly absorb while quality of Ca imaging when recording neuron responses upon modulation can be affected. Here, we show for the first time the intrinsic vibrational transition of C-H bond upon absorption of MIR can lead to efficient photoacoustic conversion. Specifically, owing to the high concentration of C-H bond in it, PDMS film was shown to generate 3 MPa photoacoustic pressure at 10 μm away from acoustic source under 2960 cm^{-1} laser illumination, corresponding to 190 N/J PA conversion efficiency. Such a high PA conversion is comparable to the widely developed CNT/PDMS PA device. Successful photoacoustic neurostimulation of GCaMP6f labeled cortical neurons cultured on PDMS film has been demonstrated and validated using Ca imaging. Taking the advantage of high transparency of PDMS film in visible and NIR range, especially at the GCaMP6f fluorescence excitation and emission wavelengths (i.e., 497 and 512 nm), Ca imaging can be performed in both epi and trans modes with substantially improved imaging quality. By focusing the illumination area, neuromodulation with high spatial resolution of 5-10 microns can be achieved to enable single neuron and subcellular stimulation. Given the fact that C-H bond is commonly existed in most of the organic materials and has the absorption far away from visible range, we herein provide a universal method to fabricate transparent photoacoustic film highly compatible with fluorescence imaging.

5:00 PM EL13.04.08
Vertical Organic Artificial Synaptic Devices with Electric Field Permeable Pinhole Electrode Nahyun Jeong[1,2] and Kyung-Geun Lim[1,2]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]University of science and technology, Korea (the Republic of)

Key Words: Artificial synapse, Vertical organic transistor, Neuromorphic electronics , pinhole metal electrode, permeable source electrode

Vertical organic field effect transistors (VOFETs) with the electric field permeable source electrode have great advantages such as low voltage operation and energy consumption due to a nano scale channel length. However, conventional electric field permeable source electrodes like silver nanowires and carbon nano tubes have a network structure which is formed by random self-assembly, hence it's difficult to control network density and position. Here, we introduced a metal thin film formed by thermal evaporation in the vacuum chamber which has a number of nanoscale pinholes that allow the electric field to pass through from gate dielectric. Also, we controlled the pinhole morphologies, such as density or size, to facilitate the electric field permeability. As a result, VOFETs with the electric field permeable pinhole metal source show high current density at low operating voltage. Moreover, the biological synapse characteristics including short term plasticity (STP), long term plasticity (LTP) and Spike-timing dependent plasticity (STDP) are stimulated by light pulse to trigger charge trapping of the active layer and the light absorbing material. Due to the novel and advanced results, the photonic synapse based on VOFETs are expected to be used as image sensing or optical communication devices.

5:00 PM EL13.04.09
Multifunctional Organic Neuromorphic Transistors by Controlling the Ferroelectricity of P(VDF-TrFE) via Photocrosslinking Young-Seok Song[1], Seungyeon Kim[1], Myeongjae Lee[2], BongSoo Kim[2] and Tae-Wook Kim[1]; [1]Jeonbuk national Univeristy, Qatar; [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

The beginning of the era of the big data, Internet of Things (IoT) and AI (Artificial Intelligence), it is necessary to process the massive amount of data. So far, many data processing method follows the classical Von Neumann's computer architecture. With this method as the data processes in series, as the amount of data increase, it is very inefficient way. So many researchers are trying to realize the neuron networking by mimicking the human brain for the parallel data processing method and it calls neuromorphic transistors. Additionally, the advantages of using organic materials like mechanical properties that match with human tissue and the working mechanisms of those devices are compatible with human physiology. [1,2]
So, in the organic neuromorphic researchers are focused on mimicking the human brain, especially synaptic function. But these transistors cannot be regarded as unique multifunctional devices because all bult-in functions are mutually combined. To address this, we focus on the separation of electrical switching and data storage functions in organic ferroelectric memory transistors [3].

This study was conducted to create a multifunctional neuromorphic device by mixing P(VDF-TrFE) (poly(vinylideneflurodie-trifluoroethylene)), a ferroelectric polymer, and various photocrosslinker 2Bx, 4Bx and 6Bx. [4] High permittivity needed for electrical switching and the ferroelectricity needed for data storage become compatible by restricting the motion of P(VDF-TrFE) via photocrosslinking. When irradiating the UV light to the photocrosslinker, compared to the reference photocrosslinker, the 4Bx and 6Bx have 2 times and 3 times more azide groups. So, with the less amount of concentration of 4Bx and 6Bx, we observed almost the same results with using more concentration of 2Bx. Additionally depend on the difference of ferroelectricity, the neuromorphic electrical properties like Short-term potentiation (STP), Long-term potentiation (LTP) and Long-term depression (LTD) etc. showed totally different results.

As a result, we realized multifunctional organic neuromorphic thin film transistors which has both switching and data storage property with the photocrosslinking of the P(VDF-TrFE) films. Also, with the various photocrosslinker, we successfully observed the increased ferroelectricity modulation efficiency of P(VDF-TrFE) films.

5:00 PM EL13.04.10
Selective Control of Supported Lipid Bilayers in a Neuromorphic OECT Ugo Bruno[1,2], Chiara Ausilio[1,2], Claudia Lubrano[3,4] and Francesca Santoro[1,3,4]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Napoli Federico II, Italy; [3]Forschungszentrum Jülich GmbH, Germany; [4]RWTH Aachen University, Germany

Neuromorphic engineering was developed to build machines able to emulate key features of the brain that allows for the fulfilment of several complex tasks at the same time, with unmatched energy efficiency. To date, hardware implementation of spiking neurons has been successfully developed, in which complex silicon-based building blocks may be combined to mimic several aspects of biological neurons[1].
Conversely, neuron-inspired devices cannot be limited to communicate through spikes, but they may require additional features like synaptic plasticity[2]. In light of this, organic neuromorphic devices and in particular PEDOT:PSS-based organic electrochemical transistors (OECTs) are emerging as ideal candidates, as their biocompatibility and soft-nature allows for the integration with living tissue[3].
In this scenario, in order to promote the seamless integration between artificial and biological neurons, the integration of neuromorphic OECTs with a supported lipid bilayer (SLB), was successfully demonstrated[4], enhancing neuromorphic features, such as short-term plasticity (STP).
While proving the possibility of integrating a biomembrane with an organic transistor, such artificial device is still far from recapitulating an actual post-synaptic neuron, hampering a proper interface with living cells. In fact, the composition of the SLB used is still far from the complex architecture of a neuronal membrane. In addition, the positioning of the bilayer between the gate and the channel of the OECT hinders the passage of ions. Furthermore, long-term plasticity (LTP) was not demonstrated.
In light of this, the present work proposes to go further, by exploiting a microfluidic module coupled to a solvent-assisted lipid bilayer[5] (SALB) technique that allows to form and confine a neuron-inspired phospholipidic membrane on the polymeric channel of a planar-gated PEDOT:PSS-based OECT, *de facto* engineering a post-synaptic artificial neurons. The correct formation and the morphological properties of the bilayer are investigated and the effect of the SLB on the electrical properties of the artificial neuron are assessed. Here, such unprecedented integration allows for the enhancement of the biomimetic potential of the transistor, while not hindering the free passage of ions. In addition, neurotransmitter-mediated LTP is demonstrated. This work ultimately paves the way towards the building of new biomimetic platforms that can be used to interface with living neurons in their native environment.

Artificial Polymer Tactile Memory Triggered by Mechanosensitive Ion Dynamics Hayoung Oh[1], Hyukmin Kweon[1], Joo Sung Kim[1], Seongchan Kim[2], Haisu Kang[3], Dong Jun Kim[1], Hanbin Choi[1], Seung Geol Lee[3,3], Jeong Ho Cho[2] and Do Hwan Kim[1]; [1]Hanyang university, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Pusan National University, Korea (the Republic of)

Tactile memory is a crucial sensory modality allowing human skin to perceive and interpret surroundings, which is vital role in practical daily activities of human. On the basis of the tactile encoding functionality, humans are able to not only identify familiar objects via touch, but also reliably and repeatedly address (e.g., gripping and lifting) them in non-destructive manners by retrieving prior acquired tactile information. This tactile recognition and memory abilities, in sensory system of human skin, are achieved by ion dynamics-based tactile signal transmission through somatosensory nerves consist of numerous synapses. Synaptic memory functions such as short- and long-term plasticity (STP, LTP) can be realized through ion-driven neural signal transfer, so that the perception and memory of tactile information proceed with extremely low energy consumption and real-time processing. To mimic the ion-based biological tactile memory processing, methodologies have been studied to integrate pressure sensors, signal converters, and ion gel-gated transistors in parallel or to make dual gated-ion gel transistors. However, these suffer from a lack of LTP capability, which is a major property to implement tactile memory. This is because without a series of voltage spikes, ion accumulation near semiconductor layer is effortlessly dissipated to achieve an ionic equilibrium state, so that programmed conductance (i.e., tactile memory level) is rapidly disappeared. Applying additional voltage pulses to the ion gel could be a plausible solution to maintain the conductance state. However, in this case, voltage input cannot be decoupled with tactile stimuli. This strongly implies that utilization of conventional ionic material design and ion dynamics is insufficient to realize ideal tactile memory in iontronic artificial tactile nerves.
Herein, we describe mechano-modulated ion dynamics, in which free ion density and migration are independently controlled by tactile stimuli and electric-field (E-field). Before applying tactile stimuli, the electrochemical property of ions is not dominated by external E-field, which is not observed behavior in conventional ion gel. Interestingly, after pressure is applied, free ion density can be increased, so that ionic conductivity and charge relaxation time are simultaneously changed. From that moment, ion transport property is dominated by external E-field. This suggests that generated free ions by tactile stimuli can render synaptic memory signals (reflecting tactile information), and the external E-field can independently control the tactile memory level. Utilizing the proposed ion behavior, we demonstrated monolithic tactile memory synaptic transistors (TMSTs), capable of perceiving tactility and augmenting the memory in a single device simultaneously. The TMSTs showed highly sensitive tactile recognition and effective tactile memory (retention time > 30 min) which can be precisely modulated by voltage pulse and tactile stimuli. We believe that the novel concept of ion dynamics will provide new insight into developing synaptic electronics for neural prosthetics and soft robotics.

5:00 PM EL13.04.12

Probing The Working Mechanism of Organic Nanowire Memristors Based On a Series of Oxocarbon Derivatives Aaron A. Cookson and James Ryan; Swansea University, United Kingdom

Neuromorphic computation is a promising way to overcome the limits of the von Neumann chip architecture in modern computing. The current problems computation faces are due to the bottlenecks in the current Von Neumann architecture. These include storage, resolution and speed in which data can be processed. Memristors (memory + resistance) have been explored as an option to replace current computing chips due to their memory storage capabilities and their ability to dynamically change their physical properties when applying a bias. [1] The memristor was mathematically derived by L. Chua in 1971 and has been demonstrated in the lab since. [2] Organic memristors have been an area of interest because of the ability to tune the structure and functional groups of a molecule to enhance the electrical performance of a device, including memory and volatility performance. [3][4]

Recently our group demonstrated a working analog memristor based on 2,4-bis[4-(diethylamino)-2-hydroxyphenyl]squaraine (SQ) nanowires on gold interdigitated electrodes. [5] The device showed exceptional analog switching behaviour with large hysteresis loops and increased conductivity with successive sweeps. The device showed non-volatile memory behaviour which can be compared and is on par with benchmark transition metal oxide devices. The working mechanism of the device, however, was seen to differ from transition metal oxide (TMO) memristors. The concentration of oxygen vacancies in TMOs is responsible for the memristive behaviour in TMO memristors. Initially we proposed that protons in SQ could be responsible for the memristive behaviour, especially as squaric acid and another oxocarbon, croconic acid, undergo inter-intra-molecular proton tautomerism. [6] To test this hypothesis, we performed a series of experiments using impedance spectroscopy and current-voltage measurements under a variety of environmental conditions. Hydration studies were employed to determine whether proton conduction occurred in SQ nanowires, which would be analogous to oxygen vacancies in TMOs. [7] Hydration studies, while ruling out intermolecular proton transport in these devices, reveal interesting observations on what controls the magnitude of hysteresis in these devices. We have since began to test alternative oxocarbon derivatives and salts in order to both develop deeper insights into the working mechanism of these devices as well as realise enhanced performance. Indeed, there are certainly a number of exciting routes to take in order to fully explore, and exploit, the potential of squaraine and related small molecule mixed conductors in the fields of bioelectronics, organic electrochemical transistors, organic batteries and neuromorphic computing.

Hydration of a Side-Chain-Free N-Type Semiconducting Ladder Polymer Driven by Electrochemical Doping Jiajie Guo[1], Lucas Flagg[2], Duyen Tran[1], Shinya E. Chen[1], Ruipeng Li[3], Nagesh Kolhe[1], Rajiv Giridharagopal[1], Samson Jenekhe[1], Lee Richter[2] and David S. Ginger[1]; [1]University of Washington, United States; [2]National Institute of Standards and Technology, United States; [3]Brookhaven National Laboratory, United States

We study the organic electrochemical transistors (OECTs) performance of the ladder polymer, poly(benzimidazobenzophenanthroline) (BBL) in an attempt to better understand how an apparently hydrophobic side-chain free polymer is able to operate as an OECT with favorable redox kinetics in an aqueous environment. We examine two BBLs of different molecular masses from different sources. Regardless of molecular mass, both BBLs show significant film swelling during the initial reduction step. By combining electrochemical quartz crystal microbalance (eQCM) gravimetry, *in-operando* atomic force microscopy (AFM), and both *ex-situ* and *in-operando* grazing incidence wide-angle x-ray scattering (GIWAXS), we provide a detailed structural picture of the electrochemical charge injection process in BBL in the absence of any hydrophilic side-chains. Compared with *ex-situ* measurements, *in-operando* GIWAXS shows both more swelling upon electrochemical doping than has previously been recognized, and less contraction upon dedoping. The data show that BBL films undergo an irreversible hydration driven by the initial electrochemical doping cycle with significant water retention and lamellar expansion that persists across subsequent oxidation/reduction cycles. This swelling creates a hydrophilic environment that facilitates the subsequent fast hydrated ion transport in the absence of the hydrophilic side-chains used in many other polymer systems. Due to its rigid ladder backbone and absence of hydrophilic side-chains, the primary BBL water uptake does not significantly degrade the crystalline order, and the original dehydrated, unswelled state can be recovered after drying. The combination of doping induced hydrophilicity and robust crystalline order leads to efficient ionic transport and good stability.

Diode Connected Organic Electrochemical Transistors—Enhanced Stability Two-Terminal High Transconductance Bioelectronic Devices and Mixed Conductor Testbeds Bryan D. Paulsen[1], Wonil Sohn[2], Emily Schafer[1], Reem Rashid[1], Dilara Meli[1] and Jonathan Rivnay[1,1]; [1]Northwestern University, United States; [2]Rice University, United States

Organic Electrochemical Transistors (OECTs) leverage the volumetric ionic-electronic coupling inherent to Organic Mixed Ionic Electronic Conductors (OMIECs) to produce low-voltage high-gain devices that can directly interface with ionic and biological media. As such OECTs are a crucial building blocks in bioelectronic and neuromorphic circuits. As said circuits advance there is a desire to simplify the implementation of OECTs while retaining their unique functionality. While normally employed as three terminal devices (3T-OECTs), here we investigate two terminal diode-connected OECTs (DC-OECTs). We show that DC-OECTs are an effective two terminal testbeds for characterizing OMIECs materials. We establish that DC-OECTs reproduce both the steady-state and frequency domain J-V behavior of saturation regime 3T-OECTs across a series of accumulation mode p-type OMIEC channel materials, from which can be extracted accurate OECT and OMIEC figures of merit: cut-off frequency, threshold voltage (V_t), device transconductance (g_m), electronic carrier mobility (μ), and μC^* (the product of mobility and volumetric capacitance). Leveraging the fact that the g_m of DC-OECTs is equally high as 3T-OECTs, we employ DC-OECTs as current amplifiers in electrocardiogram (ECG) measurements, demonstrating their effective transduction and amplification of bioelectronic signals. DC-OECTs open new opportunities for simplified cross-bar integration of OECTs in sensing arrays, and simultaneous sensing-stimulation device functionality. Beyond these application opportunities, DC-OECTs provide enhanced device stability. Voltage cycling reveals that the drain current and g_m stability of DC-OECTs is greatly enhanced compared to 3T-OECTs by avoiding deleterious drain potentials in the OFF state, and this enhancement was found to be general across all OMIECs investigated. Finally, we investigated the applicability of two terminal diode connected OECTs to neuromorphic circuits, where simple crossbar arrays are attractive.

Artificial Sense Technology Xiaodong Chen; Nanyang Technological University, Singapore

Artificial senses refer to the emulation of human's basic senses and assimilate them to functional devices and systems to help us understand and perceive the world around us. This research topic of artificial senses is transdisciplinary and lies at the confluence of materials science, bioengineering, medical sciences, electrical engineering, and computer science. Some use cases, including enhanced sensory capabilities to overcome physical human limitations, improved robotic capabilities and diagnostics with smart information processing, and prosthetics and health-monitoring devices to improve quality of life, are drawing much attention. In this talk, I will present some latest progress in artificial tactile and olfaction with the viewpoint from materials development, sensor fabrication, information processing, and system integration. Artificial senses would be a new enabling technology to construct next-generation intelligent devices and systems, paving the way for advanced soft robotic applications, rehabilitation, prosthetics, and so on.

Thiophene-Based Trimers for Evolvable and *In-Vivo*-Manufactured Electrodes and Electronics Magnus Berggren; Linkoping University, Sweden

An ensemble of different thiophene-based trimers, substituted with desired biomolecular entities, have been synthesized for neuronal and neuromorphic applications. While dissolved in aqueous and/or physiological media, the trimers aggregate and adhere to (cell and tissue) surfaces followed by enzymatic or electrochemical polymerization. Those interactions allow us to build up electrodes and electronic systems for evolvable signal processing and *in vivo*-manufactured bio-interfacing. The fundamentals of the trimer-based bioelectronics will be reported along with applications in neuromorphic and neuronal applications.

Interrogation of Brain and Peripheral Organ Neurophysiology with Multifunctional Fibers Polina Anikeeva; Massachusetts Institute of Technology, United States

Over the past decade multifunctional fibers have been applied to recording and modulation of neuronal signaling in the central nervous system in behaving rodents. In this talk, I will first touch upon translational challenges associated with applying powerful fiber neurotechnology in large animal models as a steppingstone to applications in human patients. I will then discuss our recent efforts to create fiber-based probes suitable for interrogation of neuronal signaling in peripheral organs. For instance, applications of fiber-based probes to studies of enteric (gut) circuits will be discussed along with the materials challenges posed by the anatomy and physiology of the gastro-intestinal tract. I will further describe the translational efforts in applying peripheral fiber neurotechnology in large animal models and the potential therapeutic benefits that can be delivered by these biologically informed multifunctional tools in conditions with disrupted peripheral innervation. Together, this talk will highlight the promise and challenges of preclinical implementation of fiber-based neurotechnologies.

11:00 AM *EL13.06.02
Stretchable Bioelectronic Devices for Epidermal, Retinal, and Neural Prostheses Donghee Son; Sungkyunkwan University, Korea (the Republic of)

Soft wearable/implantable bioelectronic systems capable of monitoring electrophysiological signals evoked by external mechanical/optical/electrical stimuli and delivering the feedback information have been considered essential functional components in realizing the future closed-loop prostheses. Despite such significant progress, materials fatigue and the corresponding electrical malfunction issues still remain challenging due to the lack of optimal materials/fabrication/integration/system strategies that simultaneously meet tissue-device modulus matching, electrical/mechanical durability, biocompatibility, uniformity, reproducibility, and even strain-induced error correction.
Herein, we describe optimal materials design strategies and device fabrication/integration technologies for the three different kinds of intrinsically stretchable prosthetic bioelectronics. Using various stretchable conducting/semiconducting composites, we developed damage-durable prostheses consisting of mechanical/electrophysiological/optoelectronic sensors, non-volatile resistive random access memory, and quantum dot display modules for the shape-tunable prosthetic skin, retina, and even peripheral nerve. Further, to improve the sensing accuracy of soft bioelectronic devices, electrical malfunctions originating from either repetitive stretching-induced materials relaxation or fatigue were precisely corrected by using machine learning techniques, leading to realization of the high-performance strain-insensitive soft bioelectronics.

11:30 AM EL13.06.03
Comprehensive Study on the Ion-gel Gated Organic Transistor for Next-Generation Point-of-Care Testing Dae-Gyo Seo[1], Jayoung Kim[2,3], Sunghyun Park[2], Zhenan Bao[3] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Stanford University, United States

With the growing demand for rapid clinical diagnosis and health monitoring, point-of-care (PoC) devices with high sensitivity, low-cost, high-energy efficiency, and wearable are gaining tremendous attraction.
We present the biosensor system based on ion-gel gated organic transistors (IGOTs). By tuning the gate capacitance of the IGOTs, we could modulate the device properties such as transconductance, threshold voltage, and hysteresis. Furthermore, high and commensurate capacitance made the IGOTs possible to read out the capacitance changes which cannot be detected by the MOSFET due to the relatively small capacitance as to affinity-based biosensors. Also, we revealed the relationship between the device property and the sensing ability. This resulted in outstanding biomolecule sensing performance of IGOTs. We projected a new possibility for PoC healthcare monitoring and diagnosis with high sensitivity, low-cost, high-energy efficiency, and wearable devices based on IGOTs.

11:45 AM EL13.06.04
Small Molecule Memristors for Neuromorphic Computing James Ryan and Aaron A. Cookson; Swansea University, United Kingdom

Neuromorphic computation is a promising way to overcome the limits of the von Neumann chip architecture in modern computing. Memristors can play a key role in the realization of neuromorphic devices due to their inherent memory storage and ability to dynamically alter physical properties such as resistance in response to an incoming stimulus.[1] Organic memristive devices have the potential to generate new paradigms in the memristor device field due to the inherent ability to tune the electronic properties of organic molecules for greater electrical or memory/volatility performance, which is currently a bottleneck for solid-state transition metal oxide (TMO) memristors.[2],[3] In this talk, I will highlight a new approach to fabricate high performance memristive devices based on small molecules. First, I will highlight our recent demonstration of an organic nanowire memristor based on 2,4-bis[4-(diethylamino)-2-hydroxyphenyl]squaraine (SQ) and then proceed to discuss some very recent developments in our lab.[4]

In our initial study, SQ nanowire memristors were fabricated using a very simple but effective approach whereby we deposit SQ NWs on an interdigitated gold electrode to form a lateral Au/SQ/Au architecture. These prototype devices demonstrate the hallmarks of memristor operation such as current hysteresis loops and dynamic conductivity in response to multiple voltage sweeps. The volatility of the conductivity states written to the device is also shown to have long memory retention without voltage bias, demonstrating non-volatility. These results are on par with benchmark transition metal oxide devices (TMO). These results demonstrate a straightforward and very promising approach to fabricate robust and low-cost memristive devices. The fabrication method offers an excellent platform for device prototyping and high-throughput screening of potential memristive materials.

Following on from our initial study, we are looking into the working mechanism of SQ NW memristors via a suite of electronic and electrochemical techniques applied under varying temperature and environmental conditions, exploring alternative molecules and developing a more scalable approach to fabricate organic memristors based on small molecule semiconductors. All of these topics will be highlighted and an up-to-date summary of the progress we are making will be provided.

Electronic and Photonic Neuromorphic Device Concepts Based on Organic and Hybrid Materials Systems Emil J. List-Kratochvil[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Artificial neural networks (ANN), inspired by biological nervous systems, enable signal processing beyond the capabilities of von Neumann computer architectures. Through dynamically adapting the connectivity (synaptic weights) in individual devices and by applying learning algorithms ANNs can offer in memory and tensor computing capabilities. Yet, to fully unleash the potential of hardware ANNs there is still a need for neuromorphic device concepts, which properly emulate all necessary synaptic functions adequately and allow for an easy integration into large scale hardware ANNs. In this contribution we will demonstrate organic ionic/electronic [1] as well as plasmonic/photonic [2] neuromorphic device concepts using different types of hybrid material systems. We will show that all presented devices concepts can be used to mimic fundamental functions of a synapse, such as long-term plasticity showing potentiation and depression, spike-time or spike-rate dependent plasticity or may be trained to realize AND- or OR logic gate operations and well as small scale photonic ANNs.

Neuromorphic Organic Electrochemical Transistors, Neurons and Robotics in Hybrid Self-Learning Platforms Ugo Bruno[1,2], Daniela Rana[3,4], Chiara Ausilio[1,2], Ottavia Bettucci[1], Claudia Lubrano[3,4] and Francesca Santoro[1,3,4]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Napoli Federico II, Italy; [3]Forschungszentrum Jülich GmbH, Germany; [4]RWTH Aachen University, Germany

Neuromorphic platforms are emerging as new computational paradigm[1], with the ultimate goal of building artificial neural system, by replicating the efficiency of the brain in terms of parallel computation.
Such technologies can mirror several aspects of the brain, by exploiting complex circuits[2] or by exploiting unique features of innovative materials[3]. Among the plethora of the available materials and structures, organic electrochemical transistors (OECTs) have emerged as ideal candidates in the building of complex neuromorphic systems, able to interface with living organisms[4] and to learn autonomously[5].
Notably, PEDOT:PSS-based OECTs have been employed in the implementation of the first biohybrid synapse. Here, cells cultured *in vitro* could directly communicate with such artificial neurons by means of neurotransmitters, emulating a biological chemical synapse[6].
In this scenario, such devices may offer the possibility of merging electronic devices and biological neurons in an unprecedented way, addressing challenges that current technologies are not able to face, such as EMG-based prosthetics limbs failures[7] and treatment of symptoms in neurodegenerative diseases[8].
The present work demonstrates an artificial post-synaptic neuron that drives a prosthetic hand, coordinating its grasp with the activity of pre-synaptic biological cells cultured inside the microfluidic channel of the device itself.
The artificial neuron can communicate with its biological counterpart, by oxidizing neurotransmitters directly secreted by neuronal cells resulting in an update of its synaptic weight, as a stable conductive state of the polymeric channel that is then used to tune the movement of the artificial hand. In a physiological condition, such synaptic weight allows for the complete closure of the hand. Conversely, when a dysregulation of the neurotransmitter secreted by the pre-synaptic cells occurs, emulating a pathological condition, the post-synaptic neuron loses the control of the prosthetic limb. Here, a feedback controller is introduced, regulating its synaptic weight and allowing for the recovery of the physiological condition. Such result is achieved by introducing hydrogen peroxide inside the microfluidic chamber that can reverse the neurotransmitter mediated synaptic weight update. Furthermore, the neuromorphic core of such platform is exploited to achieve reinforcement learning, ultimately paving the way towards a novel generation of hybrid devices able to combine decades of development of silicon-based technologies with innovative features of organic neuromorphic devices.

Neurorobotic Approaches to Emulate Human Motor Control with the Integration of Artificial Synapse Seonkwon Kim[1], Seongchan Kim[2], InCheol Kwak[1], Soo Young Cho[1], Dong Gue Roe[1], Yonghyun A. Kwon[1], Jung Woo Moon[1], Seonmi Eom[1] and Jeong Ho Cho[1]; [1]Yonsei University, Korea (the Republic of); [2]The Pennsylvania State University, United States

The advancement of electronic devices has enabled researchers to successfully emulate human synapses, thereby promoting the development of the novel research field of artificial-synapse-integrated soft robots. This paper proposes an artificial reciprocal inhibition system that can successfully emulate the human motor control mechanism through the integration of artificial synapses. The proposed system is composed of artificial synapses, load transistors, voltage/current amplifiers, and a soft actuator to demonstrate the muscle movement. The speed, range, and direction of the soft actuator movement can be precisely controlled via the preset input voltages with different amplitudes, numbers, and signs (positive or negative). The artificial reciprocal inhibition system can impart lifelike motion to soft robots and is a promising tool to enable the successful integration of soft robots or prostheses in a living body.

2:30 PM *EL13.08.02
Molecular-Scale Hardware that Mimic Synapses Christian A. Nijhuis; University of Twente, Singapore

Inspired by the energy efficiency of brains and the ever-increasing demand for miniaturised electronics, there is a drive to develop devices that mimic the dynamic character of neurons and synapses to realize, for instance, non-von Neumann neuromorphic computing. Mostly, such operations are realized with energy inefficient and complex silicon-based circuits or with mesoscale memristors, but molecular hardware for doing so is not available yet [1]. In this context, molecular switches are an interesting approach, but so far molecular switches lack the dynamical, time-dependent character inherent to synapses [2,3]. It has been notoriously difficult, however, to reversibly address molecular switches in solid-state tunnel junctions.[3,4,5]. Recently, we developed a new type of an electrically driven molecular switch that can toggle between two different functionalities.[5] By coupling fast electron transport to slow proton addition steps, we created dynamic molecular switches that show large hysteretic negative differential conductance [6]. These switches mimic basic spike-rate dependent plasticity, Pavlovian learning, and emulate all Boolean logic gates. These molecular switches are promising to develop spiking neural networks and open new ways to design molecular-electronic devices.

8:30 AM *EL13.09.01
Biorealist Organic Electrochemical Neurons Simone Fabiano; Linkoping University, Sweden

Future brain-computer interfaces will require local and highly individualized signal processing of fully integrated electronic circuits within the nervous system and other living tissue. Due to their poor biocompatibility, circuit complexity, low energy efficiency, and operating principles fundamentally different from the ion signal modulation of biology, traditional neuromorphic implementations based on silicon have limited bio-integration potential. Organic mixed ionic-electronic conductors (OMIECs) are in a stage of rapid development as novel applications that use these versatile materials continue to emerge. In OMIECs, the strong coupling between ions and electrons enables efficient signal transduction, making these materials ideal for interfacing electronics with biological systems. Here, we will use OMIECs to develop organic electrochemical neurons and synapses with ion-modulated spiking. We will discuss their facile integration with biological nerves and demonstrate simple neurosynaptic circuits with neurotransmitter-/amino acid-/ion-based spiking modulation capabilities. These soft and flexible organic electrochemical neurons and synapses operate at low voltage and respond to multiple stimuli, defining a new era for bio-integrable artificial neuronal systems.

Skin-Like Neuromorphic Devices for Intelligent and Personalized Wearable Technology Sihong Wang; University of Chicago, United States

For leveraging wearable technologies to advance precision medicine, personalized and learning-based analysis of continuously acquired health data is indispensable, for which neuromorphic computing could provide the most efficient implementation of artificial intelligence (AI) data processing. For realizing on-body neuromorphic computing, skin-like stretchability is required to be combined with the suite of desired neuromorphic metrics. In this talk, I will introduce our research in developing new electronic materials, device designs, and fabrication processes for imparting intrinsic stretchability onto neuromorphic devices that can provide state-of-the-art computing performance. I will also show the practical applicability of this device for implementing machine-learning computing and algorithms for health data analysis, when the computing hardware is under human-body-induced deformation.

9:30 AM EL13.09.03
Organic Neuromorphic Spiking Circuits—From Sensory Coding and Neurotransmitter-Mediated Plasticity to Retina-Inspired Computing Functions Giovanni Maria Matrone[1,2], Eveline van Doremaele[2], Sophie Griggs[3], Gang Ye[4], Iain McCulloch[3,5], Francesca Santoro[6,7] and Yoeri van de Burgt[2]; [1]Northwestern University, United States; [2]Technische Universiteit Eindhoven, Netherlands; [3]University of Oxford, United Kingdom; [4]Shenzhen University, China; [5]King Abdullah University of Science and Technology, Saudi Arabia; [6]Istituto Italiano di Tecnologia, Italy; [7]RWTH Aachen University, Germany

The fundamental mechanisms of signal communication within the human body rely on the spiking frequency of action potentials.[1] Through biological receptors and afferent neuronal cells, stimuli from the external world are encoded into a spiking pattern and transmitted to the central nervous systems where they are processed via interneurons. Indeed, the direct dependence of spikes frequency on the magnitude of the stimulus is generally referred to as “sensory coding”.
Neuromorphic electronics is currently experiencing a huge increase in research activity, aiming to mimic the architecture of the human brain to enable parallel computing with high energy efficiency[2] and local processing, thus advancing intelligent systems interfacing with the human body[3].
Replicating the interdependent functions of receptors, afferent neurons and interneurons with spiking circuits, sensors and biohybrid synapses is an

essential first step towards merging neuromorphic circuits and biological systems, crucial for computing at the biological interface.
Moreover, establishing an active interaction with biological tissues, especially with the central nervous system, requires adaptive computing systems that are not only able to receive biologically encoded inputs but also to process and communicate these.
Recently, organic materials have been employed to build electronic circuits that mimic the spiking behaviour of neurons[4,5]. Despite processing complex sensorial input, these systems still lack mechanisms to modulate the encoded signal[6].
However, a combination of bioelectronic devices may recreate a "neuronal pathway" that in nature relies on the cooperation of spiking (neurons and interneurons) and non-spiking elements such as mechano-chemical sensors (receptors), as well as neuromodulator junctions (chemical synapses).
Here it is presented a novel adaptive spiking circuit that replicates afferent neurons "sensory coding" from external physical stimuli. The neuromodulatory activity of interneurons is emulated by associating the spiking circuit with biohybrid synapses demonstrating an interdependent chemical synaptic connection. To establish a full neuronal pathway, these key biological functions are combined, showing the signal transduction from light stimulus to spiking frequency and to dopamine-mediated plasticity: a retinal pathway primitive.
This circuit constitutes a fundamental building block for programmable neural pathways that are able not only to perform "sensory coding", transducing both physical as well as physiological environmental information, but also to locally execute bio-inspired pre-processing functions: an essential step towards realizing processors dynamically communicating with the nervous system.

Non–Von Neumann Multi-Input Spike Signal Processing Enabled by an Artificial Synaptic Multiplexer Dong Gue Roe, Dong Hae Ho, Soo Young Cho, Yonghyun A. Kwon, InCheol Kwak, Seonkwon Kim, Jung Woo Moon, Seonmi Eom and Jeong Ho Cho; Yonsei University, Korea (the Republic of)

Multiplexing is essential for technologies that require processing of a large amount of information in real time. Here, we present an artificial synaptic multiplexing unit capable of realizing parallel multi-input control system. Ion gel was used as a dielectric layer of the artificial synaptic multiplexing unit because of its ionic property, allowing multigating for parallel input. A closed-loop control system that enables multi-input–based feedback for actuator bending control was realized by incorporating an ion gel–based artificial synaptic multiplexing unit, an actuator, and a bending angle sensor. The proposed multi-input control system could simultaneously process input and feedback signals, offering a breakthrough in industries in which the processing of vast amounts of streaming data is essential.

Large-Scale Organic Electronics for Neural Signal Acquisition and Processing Jennifer Gelinas; Columbia University Irving Medical Center, United States

Analysis and modulation of neurophysiological signals are increasingly leveraged to understand brain functions and treat neuropsychiatric disorders. Deriving more usable information from neurophysiologic methods could accelerate progress toward these goals, but current approaches are hampered by a trade-off of resolution and invasiveness. Our approach is to design and develop organic electronics that permit large-scale acquisition and manipulation of brain activity patterns to the resolution of individual neurons. Leveraging the conformability and volumetric capacitance of these materials, we have created devices that permit high spatiotemporal resolution interaction with in vivo neural networks. Furthermore, we investigate the capacity of fully implantable integrated circuits based on internal ion-gated organic electrochemical transistors (IGTs) to process neural data in real-time and enable physiologically relevant manipulation of these signals.
These devices enabled us to identify novel network properties in epilepsy models that are amenable to targeted therapeutic interventions. We were able to effectively detect and modulate pathologic signals to prevent disease progression. Such studies have set the foundation for translation of these devices in human subjects, where we have characterized cortical microcircuits in patients undergoing neurosurgical procedures. Our results highlight the potential for organic electronics to safely enhance our ability to acquire, interpret, and modify neural signals, with the goal of facilitating discovery of biomarkers and therapies for patients with neuropsychiatric disorders.

11:00 AM EL13.10.03
Graphene-Edge Neuroelectronics for Ultrahigh-Density Subcellular Single-Unit Recording Yunxia Jin[1,1,1], Chne-Wuen Tsai[2,1], Sippanat Achavananthadith[2], Dat T. Nguyen[3], Jerald Yoo[2,1], Yuxin Liu[1,1,1] and John S. Ho[1,2,1]; [1]National University of Singapore, Singapore; [2]Department of Electrical and Computer Engineering, National University of Singapore, Singapore; [3]Integrative Sciences and Engineering Programme, National University of Singapore Graduate School, Singapore

Single-unit electrophysiological recording at electrode density comparable to neural density is critical to interrogate the function of the brain and the study of neurological diseases. In addition, three-dimensional triangulation of neuron location by spatially oversampled multiple single-unit recording requires closely-packed ultrahigh-density electrodes. However, the electrode spatial density is currently limited by high electrochemical impedance and availability of interfacing materials and fabrication method. Here, we propose and demonstrate a graphene-edge neuroelectronics with a density of more than 2000 electrodes/mm^2, exceeding the neural density in the brain. By exposing nanotextured graphene edges on the cross-section of the probe, each channel of dimensions less than 12 μm achieves an impedance of less than 1 MΩ and a charge injection capacity of more than 1 mC/cm^2. Notably, the probe records neural activity with high action potential amplitudes approaching 1 mV and allows reliable detection of multiple single-units in cortical areas. We further show that chronically implanted probes exhibited stable electrochemical impedance, high signal-to-noise ratio of more than 20 dB, and single-unit tracking capabilities over 3 months. This work paves the way for ultrahigh-density chronic neural recording for closely-packed neurons in the brain.

11:15 AM EL13.10.04
A Redox-Reversible Switch of DNA Bonding and Structure Jason D. Slinker[1] and Robert Kuchta[2]; [1]The University of Texas at Dallas, United States; [2]University of Colorado Boulder, United States

A controlled interface with nanotechnology is key to progressing interests in adhesion, photonics, electronics, energy harvesting and storage, sensing, and thermal management. Electrically reconfigurable biological materials open pathways for advancing these broad interests and enhancing current efforts to leverage biological self-organization to generate novel materials with designer medical, mechanical, optical, and electrical properties. We have identified DNA base surrogates with redox-reconfigurable hydrogen bonding behavior based on alloxazine, the redox-active moiety of the biological flavin cofactors. Alloxazine DNA base surrogates were synthesized and incorporated into DNA duplexes as surrogate bases that function as a redox-active switch of hydrogen bonding. Circular dichroism revealed that 24-mer DNA duplexes incorporating one or two alloxazines exhibited spectra and melting transitions like DNA with only canonical bases, indicating the constructs adopt a conventional B-form conformation. Thiolated DNA duplexes incorporating alloxazines were self-assembled onto multiplexed gold electrodes and probed electrochemically. Square wave voltammetry revealed a redox peak near −0.27 V versus a Ag/AgCl reference, consistent with the reduction of the alloxazine moiety. Furthermore, alternating between alloxazine oxidizing and reducing conditions modulated the redox peak consistent with the formation and loss of hydrogen bonding, which disrupts the base pair stacking and charge transport efficiency. These alternating signals support the assertion that alloxazine can function as a redox-active switch of hydrogen bonding, useful in controlling DNA and bioinspired assemblies.

11:30 AM EL13.08.03
Sensing Drug-Induced Blockage of Voltage-Gated Calcium-Ion Channel from Differentiated Neuronal Membrane Monitored via Organic Microelectrode Array Zixuan Lu[1], Chiara Barberio[1], Aimee Withers[1], Anna-Maria Pappa[1,2], Alexandra Wheeler[1], Konstantinos Kallitsis[1], Eleonora Martinelli[1], Achilleas Savva[1], Walther Traberg-Christensen[1] and Róisín Owens[1]; [1]University of Cambridge, United Kingdom; [2]Khalifa University of Science and Technology, United Arab Emirates

Neuronal ion-channel proteins are crucial membrane components directly related to neuron electrical activities. Disturbance of neuron signals and natural toxin effects caused by Ion-channel dysfunctional diseases still burden the global healthcare system. The study of native ion channels from cell membranes provides a simplified and direct model to study the drug and toxin effects on targeted ion-channels.[1] Microelectrode arrays were fabricated and coated with conducting polymer poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) as the active interfacing layer.[2] SH-SY5Y neuroblastoma cells was chemically differentiated with a 10-day process, and significant increase of neuronal marker expression was detected by immunofluorescence imaging and Western blot. Differentiated cells show a drastic increase of neurite outgrowth, which is an important benchmark of mature neurons. Further, native-neuronal membrane vesicles (also called blebs) were chemically induced from SH-SY5Y. By vesicle-fusion process, the SH-SY5Y membranes were successfully integrated onto the organic microelectrode arrays (OMEAs) and characterized by electrical (electrochemical impedance spectroscopy (EIS)) and optical (fluorescent recovery after photobleaching (FRAP)) methods. Then, calcium-ion channel blocking-effects with an antiarrhythmic drug, verapamil, were detected and analyzed by EIS. The calcium ion-channel protein was more than 50% upregulated after differentiation, and this difference was proved by a dose-response of the ion-channel blocking assay via electrical monitoring. Our neuronal membrane-on-chip system provides a time-efficient, cell-free, and label-free platform for pharmacology study and drug discovery on native ion-channel activities.

1:30 PM *EL13.11.01
Near-GHz Switching in Polymer-Based Artificial Synapses—Characterization and Switching Mechanisms Alberto Salleo; Stanford University, United States

In this talk I will describe an organic electrochemical neuromorphic device that switches at record-low energy (<0.1 fJ projected, <10 pJ measured) and voltage (< 1mV, measured), displays >500 distinct, non-volatile conductance states within a ~1 V operating range. Our organic neuromorphic device works by combining ionic (protonic) and electronic conduction and is essentially similar to a concentration battery. Our synapses display outstanding speed (<20 ns) and endurance achieving over 10^9 switching events with very little degradation all the way to high temperature (up to 120°C). These performance metrics are impressive yet very surprising for polymers that are usually perceived as slow and subject to degradation. In this talk I will describe the unique structural properties that lead to such fast switching and high endurance which we deduce from *operando* electrochemical characterization using synchrotron radiation.

2:00 PM *EL13.11.02
Two-Terminal Neuromorphic Devices Based on Organic Electrochemical Diodes Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Although various types of neuromorphic devices base on memristive, phase-change, and ferroelectric characteristics are proposed, there exist few examples of two-terminal neuromorphic behaviors driven by ion-intercalated modulation. Herein, we report the organic electrochemical diode (OECD)-based two-terminal neuromorphic device architecture. The proposed devices operate via key principles based on polarity-dependent current-rectification and activity-dependent electrochemically-floated potential shift of organic mixed ionic-electronic conductors with low oxidation potentials. The actual potential of a given active channel layer could be effectively modulated by repeated electrical stimulations through the input node so that the non-conductive channel became conductive under the forward bias below 0.8 V and vice versa. We also demonstrated that patterned devices in series/parallel could show the behaviors of programmable AND or OR logic gates as a proof-of-principle of integrated digital circuits.

2:30 PM EL13.11.03
Organic Electrochemical Transistor-Based Immunosensor for Sars-Cov-2 Spike Protein Detection Renan Colucci, Dimitrios Koutsouras, Paschalis Gkoupidenis, Paul W. Blom and Ulrike Kraft; Max Planck Institute for Polymer Research, Germany

With rapidly increasing transmissions of the severe respiratory syndrome coronavirus 2 (SARS-CoV-2), the World Health Organization (WHO) classified the SARS-CoV-2 outbreak as a global pandemic in March 2020.[1] Since then, SARS-CoV-2 has severely impacted society and health globally. To break the spread of such a virus, quick, reliable, easy to handle, point-of-care testing strategies with low detection limits are crucial. Currently, there are two standard tests, reverse transcription–quantitative polymerase chain reaction (RT–qPCR) and viral antigen test (rapid test). Both do not fulfill the demand completely: The first one provides high sensitivity but requires trained personal, high sample quality and specialized equipment. The second one provides a rapid result (~30 min) and is suited for point-of-care testing, but lacks sensitivity.[2] Hence, novel approaches and methodologies for low-cost and precocious-stage diagnosis are needed. Devices able to address these demands are electronic biosensor. A typical biosensor is composed of a bioreceptor that interacts with the analyte and a transducer that converts the resulting biological incident into a measurable signal.[3] Organic electrochemical transistors (OECT) are excellent transducers for the conversion to electronic signals, since they operate well in aqueous (biologic) environments at low potentials (usually < 1 V). Furthermore, they provide self-signal amplification.[4] Here, we present an organic electrochemical transistor (OECT)-based biosensor that allows the detection of SARS-CoV-2 spike protein down to concentration levels of 10^{-15} M (equivalent to 10^{-13} g*mL^{-1}). The OECTs are modified with SARS-CoV-2 immunoglobulin G (IgG) and the SARS-CoV-2 spike protein biorecognition results in a shift of the transfer curves. The proteins incubation time is 30 min, which is equivalent to the standard antigen tests. In summary, we have successfully developed a promising immunosensing platform based on OECTs with a highly sensitive diagnostic method for COVID-19, suitable for point-of-care testing.

2:45 PM EL13.11.04
Photo-Enhanced Output in Highly Transparent Thin Film Transistors Based on Organic/Inorganic Hybrids for Neuromorphic Synapses Xiaojuan Fan; Marshall University, United States

We report that highly transparent thin film transistors were built on glass substrates based on amorphous metal oxide and polymer hybrid structures through solution processing at room temperature. UV-Vis-NIR microscopic spectroscopy measurements were conducted on organic/inorganic hybrid materials. Thin films on Si wafers show optical interference fringes, indicating that the as-prepared samples are of high quality, i.e., smooth and uniform, from which thin film thicknesses can be derived. The transistors consist of a layer of metal oxide/PEG mixture as the active semiconductor and a layer of PMMA as dielectric materials on transparent conductive ITO contacts. Source and drain electrodes were deposited by an e-beam evaporator of 4 nm thick Cu and 200 nm thick Au in various combinations of channel length and width. The 4-probe station *IV* characteristics display a depletion mode for *p*-type transistors. Such transistors can undergo an unusual conversion from depletion mode to enhancement mode by photo-stimulation without switching the polarity of gate voltage. The mechanism is attributed to dramatic photo-current generations in amorphous metal oxide-embedded polymer hybrids under light irradiation. The selected polymers are biocompatible, enabling the fabricated transistor devices applicable to the research of neuromorphic synapses.

Designing Bioelectronic Materials for Regenerative Medicine Molly Stevens; Imperial College London, United Kingdom

This talk will provide an overview of our work on chemical modification and functionalisation strate-gies to obtain designer polymers for bioelectronic applications in regenerative medicine and therapeutics. We introduce moieties to the polymer backbone to obtain tunable properties such as semi-conductivity [1], self-immolation [2] and light sensitivity [3]. Our bioconjugate capture probes allow for multiplexed high-dimensionality biosensing [4]. I will also discuss the opportunities presented by organic bioelectronics as tissue and cell interfacing materials for stimulating regeneration [5], with examples of our current research in cardiovascular and neurological therapies. Finally, I will discuss how we are actively engaging in efforts towards the democratisation of healthcare innovations [6].

Soft Self-Healable Actuatable Electro-Luminescent Materials Benjamin C. Tee; National University of Singapore, Singapore

Neuromorphic architectures can enable significant power efficiencies in machine learning tasks[1,2]. The use of soft, organic materials can allow for integration of sensing, actuation and data transmission onto neuromorphic platforms. In this talk, I will share our recent work on developing asynchronous data transmission systems2 for neuromorphic in combination with soft flexible electronic materials and devices3. Using such systems, we can generate unique datasets containing high speed sensory data, for e.g., a MNIST like tactile dataset[4] and apply them to use cases in robotics5.

8:15 AM *EL14.01.01
Rational Design and Investigation of Catalysts for Sustainable Resources Hannah N. Barad; Bar-Ilan University, Israel

As a major part of trying to mitigate global climate change and improve sustainable resources, discovery of new, stable, and highly active catalyst materials is a pressing issue. There are several reasons for this, first, currently the most efficient and stable catalysts for the chemical processes that we use to transform raw resources into products with the desired functions (chemicals or energy), *e.g.*, H_2 evolution and CO_2 reduction, contain expensive rare and precious elements such as Pt and Ir. This explains the efforts to find abundant, accessible, low-cost, stable alternatives that will yield process efficiencies comparable or better than those we have today. For example, for water splitting, many new materials with different compositions have shown promising results as catalysts. However, they are mostly prepared by wet chemical synthesis, which results in chemical waste and can be too slow for industrial use. Second, the morphology of the catalysts is important because it affects their catalytic properties as higher surface areas yield more catalytically active sites, surface energetics change, leading to improved reaction rates, etc. These reasons emphasize the motivation to accelerate the process of finding new materials with varying nanostructures and optimized functionality, by systematic exploration of several parameter spaces.
In recent years, artificial intelligence, namely by machine learning (ML) tools, has gained prominence in the field of materials science. The use of ML accelerates new material predictions and assists with finding unexpected correlations between the process-structure-function relations of materials, which leads to a better understanding and focus of the vast parameter spaces that exist in materials science. Rational design by ML in conjunction with combinatorial materials science promotes the rapid discovery and analysis of new materials, and enables breakthroughs in materials science, which would otherwise not have been possible.
Here we present the progress in the development of electrocatalysts using rational design with ML in conjunction with combinatorial synthesis and high-throughput characterization. We investigate changes in composition and nano-morphology on material libraries and their effects on the catalysis of reactions such as O_2 evolution, CO_2 reduction, and CH_3OH oxidation. The different nanostructures and compositions show high activity and stability as electrocatalysts. The insights gained, indicate a dependence of catalytic activity on composition and nanostructuring, which the standard experimental techniques cannot achieve or explore, thus illustrating the importance and impact that composition and structure have, and will have, on developing sustainable catalysts. This can only be done by high-throughput experimentation design, combined with machine learning tools, which will assist with appropriate path directions and ensure rational studies on catalysis in the future.

8:45 AM EL14.01.02
Harnessing Non-equilibrium Syntheses to Develop New High Throughput Approaches for Highly Efficient Oxide Thin-Film Semiconducting Photoelectrodes Ronen Gottesman[1,2]; [1]The Hebrew University of Jerusalem, Israel; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

A unique approach to exploring non-equilibrium synthesis parameter spaces of oxide thin film photoelectrodes will be presented, broadening the pathway toward discovering new chemical spaces inaccessible through conventional solid-state reactions.
There is an increasingly urgent need for disruptive and innovative materials that satisfy the chemical and physical requirements to reduce global warming through sustainable development. Fortunately, only a fraction of the possible combinations were studied, making it likely that the best materials are still awaiting discovery. However, designing controlled synthesis routes of single-phase oxides with low defects concentration will become more difficult as the number of elements increases;[1,2] and there are currently no robust and proven strategies for identifying promising multi-elemental systems.
These challenges demand an initial focus on synthesis parameters of novel non-equilibrium synthesis approaches rather than chemical composition parameters by high-throughput combinatorial investigations of synthesis-parameter spaces. This would open new avenues for stabilizing metastable materials, discovering new chemical spaces, and obtaining light-absorbers with enhanced properties to study their physical working mechanisms in photoelectrochemical energy conversion.
Using two non-equilibrium synthesis tools: pulsed laser deposition and flash photonic sintering can form gradients in synthesis parameters without modifying composition parameters, which enables reproducible, high-throughput combinatorial synthesis over large-area substrates and high-resolution observation and analysis. Even minor changes in synthesis significantly impact material properties, physical working mechanisms, and performances, demonstrated by the relationship between synthesis conditions, crystal structures of α-SnWO$_4$,[3] and properties over a range of thicknesses of CuBi2O$_4$,[1] both emerging light-absorbers for photoelectrochemical water-splitting used as model multinary oxides. Our approach addresses an immediate need by focusing on novel non-equilibrium synthesis approaches of disruptive and innovative materials that meet the chemical and physical requirements for reducing global warming through sustainable development.

9:00 AM EL14.01.03
High Throughput Discovery of Photoelectrode Assemblies for Solar Fuels Generation Joel Haber; California Institute of Technology, United States

The development of efficient, stable photoelectrodes remains a primary materials challenge in the establishment of a scalable technology for artificial photosynthesis. The typical photoelectrode architecture consists of a semiconductor light absorber coated with an auxiliary material that serves a combination of functions, including corrosion protection, electrocatalysis, light trapping, carrier transport, and elimination of deleterious surface recombination sites. We describe high throughput investigations of alloying of metal oxide light abosrbers and the variation in performance and photo-response of integrated photoelectrode libraries. Photoelectrode assemblies based on promising coating compositions and loadings were investigated in detail.

9:15 AM *EL14.01.04
Towards Self-Organizing Two-Dimensional Hybrid Perovskites—Machine Learning Driven Co-Navigation of Chemical and Compositional Spaces Jonghee Yang[1], Benjamin Lawrie[2], Amirhossein Rahimi[1], Sergei Kalinin[1] and Mahshid Ahmadi[1]; [1]University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Two-dimensional (2D) hybrid perovskites combine the richness of physical functionalities of inorganic materials and complexity and stimulus responsiveness of organic molecules in a single bulk dynamic material. The unique aspect of these materials is the thermodynamic (meta) stability, allowing for self-organized formation of complex large-period structures. Combined with the ease of fabrication, these materials not only have extensively demonstrated state-of-the-art high-performance optoelectronics but also offer the pathway towards versatile applications including sensors, electronic and neuromorphic devices as well as their cost-effective mass production. However, discovery and optimization of these materials require joint optimization of the composition of the inorganic components and selection of the molecular moieties, to harness the phase formation and self-assembly processes on the material level, and extend it to the micro- and macro scale functional devices. In this talk, I will discuss the potential of machine learning driven high throughput automated experiments to accelerate the discovery of 2D and quasi 2D hybrid perovskites, optimize the processing pathways, and understand the kinetics of their formation. I will also discuss how the high throughput liquid and solution-based synthesis can be transitioned into the thin film formation for functional applications.

9:45 AM BREAK

10:15 AM *EL14.01.07
Combinatorically Inkjet-Printed Metal Halide Perovskite Optoelectronic Devices Emil J. List-Kratochvil[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Beyond the use in home and office-based printers, inkjet printing has become a popular structuring and selective deposition technique. More recently great interest also exists in emerging industrial areas like in the manufacturing of printed circuit boards, solar cells, flexible organic electronic and medical products.
Metal halide perovskites (MHP) have received great attention in recent years, predominantly due to the high performance of perovskite solar cells. The versatility of the material has also allowed its use in light-emitting diodes and photo detectors, amongst other optoelectronic device applications. In these device applications the tunability of the energy bandgap is of particular importance. In contrast to other semiconducting material classes the energy bandgap in MHPs can be easily tuned by controlling the halide ratio in the compositions using pure and mixed halide gradients ranging from pure MAPbI3 via MAPbBr3 to MAPbCl3. Moreover, the drop-on-demand capabilities of inkjet printing enable the deposition of the MHP inks in a precise ratio to produce specific perovskite compositions with dedicated energy bandgaps in the printed thin film. By this means we can fabricate multiple perovskite compositions absorbing or emitting light at specific wavelengths in a single printing step. Using various mixed halide perovskites, we will show the fabrication of combinatoricallyprinted photodetector arrays [1,2] as well as large area multi color light emitting devices [3].

10:45 AM EL14.01.06

High-Throughput Analysis of Combinatorial Metal Halide Perovskite Libraries, a FAIR Dataset in NOMAD Hampus Näsström[1], Pascal Beblo[2], Fatima Akhundova[2], Oleksandra Shargaieva[2], José M. Prieto[1], Hannes Hempel[2], Claudia Draxl[1], Eva L. Unger[2,1,3] and Thomas Unold[2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [3]Lund University, Sweden

Machine learning and artificial intelligence claims to offer a paradigm shift in how experimental materials research is performed. However, these methods often require uniformly labeled and very large datasets, something that is not traditionally available in experimental materials research. One way to begin obtaining the necessary data volumes is by applying high-throughput technologies.
In this work, we present a high-throughput investigation of metal halide perovskites for the use in optoelectronics. Combinatorial libraries of $Cs_yPb_{1-y}(Br_xI_{1-x})_{2-y}$ perovskites were fabricated by thermal co-evaporation and investigated using contact-less high-throughput characterization such as hyperspectral photoluminescence imaging, time-resolved photoluminescence mapping and grazing-incidence wide-angle X-ray scattering mapping. The high-dimensional datasets of each sample were reduced and combined to zero-dimensional descriptors using automated analysis. These descriptors were used to show how the theoretical photovoltaic power conversion efficiency depends on the Br to I and Cs to Pb ratios in a previously unexplored range of the $Cs_yPb_{1-y}(Br_xI_{1-x})_{2-y}$ solid solution. A generalized data schema for combinatorial thin films was developed in order to disseminate the dataset in a Findable, Accessible, Interoperable and Reusable (FAIR) way within the Novel Materials Discovery (NOMAD) repository. Through NOMAD, the labeled data of the 3456 individual samples of this dataset can be combined with others to provide the volume of experimental data needed for applications in machine learning and artificial intelligence.

11:00 AM EL14.01.08

High-Throughput Synthesis and Characterization of Ternary Nitride Perovskites Rebecca Smaha[1], Rachel Sherbondy[2], Kevin Talley[1], Sage Bauers[1], Geoffrey L. Brennecka[2] and Andriy Zakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Oxide perovskites are robust, stable, and display a wide range of functional properties, and halide perovskites have made a significant impact in photovoltaics and other optoelectronics. The greater covalency of nitrogen than oxygen and halogens makes nitrides attractive for semiconducting and other functional applications in renewable energy. Recent advances in experimental methods, particularly combinatorial methods, for synthesizing nitride materials have led to a rapid increase in the number of known ternary nitride phases. We recently experimentally realized $LaWN_3$ in thin film form as the first oxygen-free nitride perovskite, a goal that has long presented a synthetic challenge due to the difficulty of completely excluding oxygen during synthesis and the high oxidation states required for the *A* and/or *B*-site cations. $LaWN_3$ crystallizes in polar space group R3c and exhibits a large piezoelectric response,[1] opening a host of possible avenues to target novel compounds for functionalization, including as potential multiferroics for spintronic applications.

Here we present the high-throughput synthesis and detailed investigation of new *RE*-*M*-N (*RE* = La, Ce; *M* = W,Mo) ternary nitrides via RF sputtering. This phase space is nearly unexplored, and the combinatorial synthesis and high-throughput characterization methods used here allow rapid exploration, accelerating the discovery of novel materials and pinpointing which have promising properties for functional applications. We report on a detailed investigation of the structure, optoelectronic properties, and crystallization dynamics of thin film $LaWN_3$. The optoelectronic properties are found to be highly sensitive to stoichiometry. In addition, we discuss the recent discovery and characterization of two new Ce-based nitride perovskites, $CeMN_3$ (*M* = W, Mo), which display low-temperature magnetic frustration.[2] Recent work on new phases obtained with other *A*- and *B*-site cations is also discussed.

11:15 AM EL14.01.09

Combinatorial Vacuum-Deposition of Metal Halide Perovskite Films and Solar Cells Isidora Susic[1], Adi Kama[2], Lidón Gil-Escrig[1], Chris Dreessen[1], Francisco Palazon[3], David Cahen[4,2], Michele Sessolo[1] and Henk J. Bolink[1]; [1]University of Valencia, Spain; [2]Bar-Ilan University, Israel; [3]Universidad Politécnica de Cartagena, Spain; [4]Weizmann Institute of Science, Israel

The development of vacuum deposited perovskite materials and devices is partially slowed down by the minor research effort in this direction (at least when compared with the field of solution-processed perovskites), but also from one of its intrinsic characteristics: long timeframe for the optimization of even a single perovskite composition since in one deposition run only a single set of parameters can be used (i.e. set of deposition rates for a certain set of precursors). Combinatorial materials science (CMS) is a method that can be used to accelerate the study of compositionally varying perovskites. When CMS is applied to thin-films, a compositional gradient is deposited on purpose on a single large area substrate, referred to as a library, forming many different compounds or materials in a single deposition run. Here we report the combinatorial vacuum-deposition of wide bandgap perovskites of the type $FA_{1-n}Cs_nPb(I_{1-x}Br_x)_3$, by using 4 sources and a non-rotating sample holder.[1] From initial deposition rates calculated based on stoichiometry and properties for each precursor, we run a combinatorial deposition and high throughput characterization. By using small pixel substrates, we are able to produce >100 solar cells with different perovskite absorbers in a single deposition run. The materials are thoroughly characterized by spatially resolved and/or high throughput techniques, including optical, morphological and structural techniques. By subsequent fine tuning of the deposition rates, we can alter the gradient and reproduce the best performing formulations in standard depositions with rotation. We extended the method for optimizing wide bandgap CsMAFA triple-cation perovskite solar cells, which are found to be efficient but not thermally stable. With the aim of stabilizing the perovskite phase, we add guanidinium (GA^+) to the material formulation, and obtained CsMAFAGA quadruple-cation perovskite films with improved thermal stability, as observed by X-ray diffraction and rationalized by microstructural analysis. The corresponding solar cells showed similar performance with a remarkable thermal stability, when compared to the triple-cation perovskite devices.[2] We believe this approach can encourage the discovery of materials, and serve as a basis to prototype other compositions (low bandgap, lead- free) overcoming the current limitations of vacuum deposition as a research tool for perovskite films.

11:30 AM EL14.01.10

High Throughput Exploration of Novel Perovskite-Inspired Materials Using Combinatorial Inkjet Printing Allan Starkholm[1], Vincent Schröder[2], Hampus Näsström[2], Emil J. List-Kratochvil[2] and Eva L. Unger[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Humboldt-Universität zu Berlin, Germany

Perovskite solar cells (PSCs) have since 2012 attracted considerable attention, which can be attributed to the facile synthesis and thin film deposition, as well as to high power conversion efficiencies. However, there are two major challenges that currently hinder the commercialization of PSCs, and therefore need to be addressed; poor stability and the presence of toxic lead. Perovskites have a large structural and compositional space and research during the last decade has resulted in several new perovskite and perovskite-related materials with suitable properties for utilization as energy materials.[1] This, in turn, has further expanded the chemical and structural space of potentially interesting perovskite-inspired materials, which requires the use of suitable, scalable, high-throughput methods for the discovery of new candidate materials. This is crucial in order to swiftly identify new materials for energy applications to accelerate the transition towards a more sustainable economy. The time-consuming materials discovery process combined with the historically long implementation time of new photovoltaic technologies[2] is, as of today, limiting the possibility to speed up this important transition. Inkjet printing is a scalable fabrication technique that has been proven valuable for the deposition of perovskites as large area modules. Furthermore, inkjet printing has been demonstrated as a potentially interesting tool for combinatorial, high-throughput, deposition of numerous perovskite compositions with potential for solar cell application.[3] In this work, the use of combinatorial inkjet printing to screen a large compositional space of novel perovskite and perovskite-inspired materials for optoelectronic devices is presented. We developed direct and high-throughput analysis strategies to evaluate the performance potential of these materials in operando.

11:45 AM EL14.01.11
High-Throughput Energy Materials Discovery Udo Bach; Monash University, Australia

The effects of global warming are calling for a rapid transition from fossil to renewable energy sources. New materials for energy generation and storage are required to enable this transition. In this presentation we will introduce a new research tool which introduces elements of automation and artificial intelligence to the field of materials discovery. The new research platform will be hosted at the Melbourne Centre for Nanofabrication and is part of the Australian Centre for Advanced Photovoltaics. The main purpose of this installation is to accelerate the development of novel printable photovoltaic materials such as lead halide perovskites and their lead-free analogues, it is however also applicable towards the discovery of energy materials more broadly. It entails three integrated robotic sections. The first allows to formulate inks from liquid and solid chemical precursors, the second section allows to produce thin films from these inks via solution processing techniques and the third section hosts a number of characterization tools to determine the optical, electronic and structural properties of these films. The entire system operates under inert gas atmosphere with a clock speed of 5 minutes and the ability to operate autonomously for 24 hours.

SESSION EL14.02: Robots and Automated Experimentation
Session Chairs: Udo Bach, Emory Chan and Carolin Sutter-Fella

Towards Stable Hybrid Perovskites: High-Throughput Characterization and a Machine-Learning-Assisted Analysis Marina S. Leite; University of California, Davis, United States

Hybrid organic-inorganic perovskites (HOIPs) represent a promising class of material for next-generation optoelectronics. Yet, their long-term stability must be established prior to commercialization. Edisonian, traditional trial-and-error methods for material screening, development, and stability testing are slow considering the vast hyper-parameter space entailing chemical composition and the potential influence of environmental stressors when acted in combination. To overcome this bottleneck towards the identification of stable HOIPs, we realize automated experimentation and machine learning (ML) to gain physical understanding of how these materials' behavior is affected by environmental stressors, such as relative humidity and temperature. We apply ML models to analyze high throughput, *in situ* steady-state photoluminescence and predict the changes in $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ perovskites while exposed to relative humidity cycles. We compare linear regression, echo state network, and seasonal auto-regressive integrated moving average with eXogenous regressor algorithms, and attain consistent accuracy of >90% for the latter, while following long-term changes for 50 hours. Our accurate time series predictions showcase the promise of ML to mimic non-linear response from a series of hybrid perovskite compositions.

2:00 PM EL14.02.02
AI-Guided Autonomous Materials Discovery for Organic Photovoltaics Seungjoo Yi[1], Nicholas Angello[1], Tiara Torres-Flores[1], Edward Jira[1], David Friday[1], Austin Cheng[2], Riley Hickman[2], Changhyun Hwang[1], Alan Aspuru-Guzik[2], Ying Diao[1], Nick Jackson[1], Martin Burke[1] and Charles M. Schroeder[1]; [1]University of illinois at Urbana Champaign, United States; [2]University of Toronto, Canada

In this work, we are pursuing an AI-guided, closed-loop approach to discover new organic photovoltaics (OPVs) with high device performance. Our work integrates autonomous synthesis, automated materials characterization, and AI-based molecular prediction methods in a closed-loop manner to discover new high-performance OPV molecules. We use a Bayesian optimization framework in which physicochemical descriptors of OPV candidates guide the search through a large molecular combinatorial space while maintaining a customizable tradeoff between exploitative and explorative sampling. Candidate OPV molecules suggested by the AI framework are prepared via automated synthesis methods using a "Lego-like" molecular building block-based approach relying on an iterative Suzuki cross-coupling reaction scheme. Following synthesis, the physical properties of candidate OPV molecules are characterized using an automated workflow, with experimental results passed back to the Bayesian optimizer for subsequent rounds of closed-loop materials discovery. Using this approach, our team has uncovered new high-performing OPV molecules after multiple rounds of AI prediction, synthesis, and materials characterization. Overall, our work aims to fill key knowledge gaps in understanding how molecular structure and properties encode OPV device performance. Moreover, our work is advancing the science of closed-loop autonomous discovery by learning how to synergistically integrate AI, automated synthesis, and automated testing and characterization into a common workflow. We aim to meet the "10-10" target (10% efficiency and 10-year stability for OPV materials) to make organic photovoltaics a commercial reality for next-generation energy capture applications.

2:15 PM EL14.02.03
Integrating Robotic High-Throughput Processing with Synchrotron Based *In Situ* Multimodal Analysis—Homogenous Crystallization of Mixed Br-I Perovskites Jiatu Liu[1], Matteo Ciambezi[1], Mahesh Ramakrishnan[1], Jinzhao Li[2], Eva L. Unger[2] and Justus Just[1]; [1]Lund University, Sweden; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Optoelectronic material properties and especially conversion efficiencies of next-generation semiconductors are a result of the complex interplay between precursors, intermediates, spectators and products during synthesis processes. Therefore, the discovery of optimized synthesis processes has become an important part in material discovery approaches. A knowledge based discovery and tuning of synthesis processes requires a fundamental understanding of its systematics, pathways and kinetics. Due to the complexity of synthesis interactions, a multitude of experiments with a wide variation of parameters, investigated from complemental perspectives, is required.

To this extend we developed a platform (*in-FORM*), which integrates robotic high-throughput solution processing with synchrotron based in-situ multimodal process analysis. It is based on a small-footprint, robotic, roll-to-roll slot-die coating system, which is fully integrated into a hard X-ray beamline for real-time in-situ process analysis at the MAX IV synchrotron. We measure simultaneously and at the same spot from the same incident X-ray beam a combination of X-ray spectroscopy (X-ray absorption and fluorescence), X-ray diffraction (XRD) and X-ray excited optical luminescence (XEOL). This allows for a complementary investigation of the local structure, crystalline phase, chemical composition, oxidation states, and optoelectronic properties, unraveling formation and evolution processes during and after slot-die ink deposition.
Aiming to optimize the synthesis of mixed bromide-iodide metal-halide perovskites for a wide range of resulting absorber band-gaps while achieving high opto-electronic material quality, we utilized our in-situ platform. We investigated the full formation process, from precursor solutions to final films, under a wide range of synthesis parameters using a combinatorial approach. Our results show how the choice of solvents and co-solvents determines Br/I intermixing and segregation during the synthesis process. Measurements with high-temporal resolution (10ms) during rapid gas quenching reveal how rapid quenching processes can be utilized to achieve homogenous Br/I distributions. By enabling a fundamental understanding of the complex interplay between solvents and intermediates, we pave the way towards the development of greener solvent processes and environmental friendly up-scaling.

2:30 PM *EL14.02.04
Closing the Loop to Automate and Optimize the Synthesis of Halide Perovskites Simon Arnold[1,2], Corneel Casert[1], Edward Barnard[1], Stephen Whitelam[1] and Carolin M. Sutter-Fella[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Organic-inorganic halide perovskites have excellent optoelectronic properties which enables their application for example in photovoltaics, light emitting diodes, and detectors. The field is plagued by the fact that subtle variations in the synthetic protocol can lead to significant reproducibility challenges. In addition, the parameter space to optimize for desirable optoelectronic properties and stability is very large. Therefore, automation of halide perovskite synthesis at high throughput presents an attractive route to identify synthesis parameter-structure-function properties.
In this talk I will describe our joint effort in setting up a robotic platform, SpinBot One, to synthesize and characterize $FAPbI_3$ films. SpinBot One is coupled to neural networks which are trained using evolutionary reinforcement learning to realize time-dependent processes that optimize the optical properties of the material under study. SpinBot One fabricates halide perovskite thin films via spin coating and thermal annealing followed by optical characterization (UV Vis, photoluminescence) on the platform and external X-ray diffraction measurements. SpinBot One performed experiments to rationalize the influence of spin speed, spin duration, MACl content, and annealing profile on crystal phase formation and phase stability. The first part of this talk will describe the more technical/ engineering aspects of building our closed loop system while the second part discusses scientific findings enabled by the closed loop.

3:00 PM BREAK

3:30 PM *EL14.02.05
Robot-Accelerated Exploration of Perovskite Crystallization and Reaction Networks Emory Chan; Lawrence Berkeley National Laboratory, United States

Hybrid inorganic/organic materials offer modular platforms for generating libraries of custom materials, whose properties can be tailored to applications in lasers, photovoltaics, and other optoelectronic devices. The large number of components in these complex materials, and the numerous parameters that specify their synthesis, result in an experimental space that is challenging to explore with conventional laboratory techniques. I will discuss the development of data-enabled strategies for discovering new materials through the combination of robotic synthesis, physical models, and machine learning. I will discuss our Robot-Accelerated Perovskite Investigation and Discovery (RAPID) workflow, which has performed over 15,000 distinct reactions. We used these large datasets to train machine learning classification models for the crystallization of metal halide perovskites and to validate new software pipelines for experimental design and capture. We demonstrate how such robotic techniques have accelerated the application of data approaches such as meta-learning, active learning, and model fusion to perovskite crystallization. Finally, we discuss how expansive robotic datasets allowed us to uncover the dual roles of water in perovskite crystallization and to elucidate the reaction networks that govern chemical transformations of perovskites.

4:00 PM EL14.02.06
Accelerated Discovery of Ligand Molecules for Perovskite Nanocrystals via Machine Learning Guided High-Throughput Experimentation Min A Kim[1], Qianxiang Ai[2], Sandra Bueno[1], Joshua Schrier[2] and Emory Chan[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Fordham University, United States

Surface binding ligands are critical component in nanoparticle studies, from growth to post-synthesis treatment process. Especially for particles with low chemical stabilities, ligands could act as a barrier preventing defect formations to prolong their intrinsic properties. Given vast chemical space available for ligand molecules, successful search will likely discover unseen ligands for the desired effects on nanoparticles. However, searching such large and complex pool of molecules requires high experimental cost and time, while still practically impossible to explore every candidate available. We combined high-throughput (HT) experimental workflow with machine learning model to accelerate exploration of ligand molecules. We implemented automated liquid handing robots to screen surface treatment reactions by exposing $CsPbBr_3$ perovskite nanocrystal solution to a library of ligands across a range of concentrations. We used perovskite nanocrystals as a model system; Our machine learning guided framework can be easily adopted to screen molecules and their surface interactions with other nanoparticles. Our developed workflow successfully screened 500 reactions in one 8-hour workday demonstrating high efficiency of our experimental method. Each reaction was characterized by HT absorption/fluorescence measurements to observe the change in photoluminescence (PL) intensity as they are exposed to various ligand molecules. Utilized optical measurements provided HT screening tool to correlate the ligand environment and luminescence of nanocrystal solution over time. The surface binding strength of ligand molecules were compared based on the relative change in PL intensity. Ligand selection in HT reactions was prioritized by an active learning (AL) approach with uncertainty quantified by twin regressors. Our model successfully found high performance ligand molecules with initial teaching dataset. Identified surface binding ligand molecules enhanced emission efficiency and chemical stability of perovskite nanocrystals. Feature importance analysis on our models helps the future investigations on uncovering fundamental correlations between molecular properties and their effects on the nanocrystal surface.

4:15 PM EL14.02.07
In-Loop X-Ray Phase Fraction and Structure Analysis for High-Rate Closed-Loop Autonomous Experimentation Ming-Chiang Chang[1], Sebastian Ament[1], Duncan Sutherland[1], Maximilian Amsler[1], Lan Zhou[2], John M. Gregoire[2], Carla P. Gomes[1], R. Bruce van Dover[1] and Michael O. Thompson[1]; [1]Cornell University, United States; [2]California Institute of Technology, United States

Recent advances in autonomous closed-loop experimentation have created new opportunities in high-throughput material discovery research. However, quantitative phase and phase fraction identification from x-ray scattering at speeds commensurate with synchrotron-based measurements remains challenging and limits full exploitation of autonomous searches. To address this challenge, we have developed a probabilistically quantitative, multi-phase labeling algorithm that provides in-loop full structural information for AI agents controlling high-throughput autonomous experiments; data include quantitative lattice strains, peak broadening and grain size effects, and probability estimates for likely multi-phase combinations. In conjunction with non-equilibrium laser spike annealing of compositional libraries to explore composition and processing spaces, we demonstrate the ability of the autonomous agents to utilize the additional data from x-ray scattering to implement a two-stage objective function, switching between *exploration* and *exploitation* modes based on uncertainty of the whole material processing space with structurally labeled phase fields. By providing in-loop data at rates commensurate with the laser spike annealing and synchrotron measurements, we allow active learning AI agents to explore the phase space efficiently and to identify optimal conditions to synthesize high phase-purity structures. With further design of targeted acquisition functions and incorporating additional property measurements, we expect to extend this method for on-the-fly modeling of structure-property relationships and enable practical multi-objective optimization.

4:30 PM *EL14.02.08
A Robotized Screening Platform for Renewable Energy Materials—Building a Pipeline and Proof of Principle Studies Per H. Svensson[1,2], Allan Starkholm[3] and Lars Kloo[2]; [1]RISE - Research Institutes of Sweden, Sweden; [2]KTH Royal Institute of Technology, Sweden; [3]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Novel materials constitute the core challenge for all ambitions towards new technologies in the field of renewable energy. A grand challenge for humanity is sufficiently fast discovery of new sustainable materials to solve many of the existing societal challenges. In general, it takes an alarmingly long time to screen and discover new materials, and the time to implement new energy technologies into the commercial market from the time of discovery is in the realm of decades. This is very problematic considering the immediate demand of novel materials and efficient energy storage technologies. Consequently, accelerated discovery and development of new systems/devices are urgently required and robotized materials screening represents a promising tool to accelerate this process significantly.

To meet these challenges, society requires new methodologies and techniques. Our group has for many years been working on an initiative to develop a robotized platform, Poseidon, for the discovery of new materials in different application areas. This talk will present the developed robot pipeline and workflows for solar cells and batteries, as well as results from the screening.

SESSION EL14.03: High Throughput Characterisation
Session Chairs: Hannah Barad and Emil List-Kratochvil
Tuesday Morning, April 11, 2023
Moscone West, Level 3, Room 3014

10:30 AM *EL14.03.01
Model Supported In-Line Characterizaton of Roll-to-Roll Coated Solar Cells Jens W. Andreasen[1], Michael K. Sørensen[2], Anders S. Gertsen[1], Marcial F. Castro[3], Moises E. Rodriguez[2], Suraj Manikandan[1] and Luise T. Kuhn[1]; [1]Technical University of Denmark, Denmark; [2]FOM Technologies, Denmark; [3]CIC energiGUNE, Spain

The application of scalable processing methods like roll-to-roll coating is being adopted with increasing intensity in the field of organic and hybrid perovskite solar cells. This development calls for characterization methods matching the speed and volume of such deposition techniques. One such method is *in situ* X-ray scattering which has followed step, allowing high-throughput analysis of the effect of fine-grained variation of processing parameters and inline analysis of the kinetics of structure formation.
Analyses of non-crystalline nanostructure in thin films coated on flexible substrates are still few and low in detail. The analysis is complicated by the overlapping contributions of scattering from substrate and other nanostructured layers, but there are also considerable advantages by working with coatings on a flexible substrate. Besides studying the coated thin films under the actual processing conditions that allow scaling to mass production, it also facilitates large scale analysis of processing parameters with high resolution. Böttiger *et al.*[1] demonstrated this as a structural analysis extension to an earlier large scale solar cell device analysis experiment, where constituent concentration ratio and film thickness was varied over tens of meters of roll-coated devices[2]. In this manner, "recording" thousands of experiment variations along the substrate foil, high-resolution analysis of parameter space is allowed by "playing back" the coating, either on a fast testing device to record solar cell device parameters (IV-curves), or through a high-flux X-ray beam to record the small- and wide-angle scattering from the coated film. Acquisition times down to a few hundred milliseconds can be realized corresponding to a spatial resolution along the coated foil of a millimeter to a centimetre for foil speeds between 0.5 to 5 m/min[3]. For an experiment where a component concentration is varied from 0% to 100%, this corresponds to a resolution in concentration parameter space of better than 0.01%, or better than 0.001% for the case of additive concentration, varied from 0% to 5%[1]. This is well below what can be expected in mixing accuracy from syringe pumps and uncertainties in the flow dynamics of the microchannel solution mixing structure. With fewer measurements along the coated foil and thus a lower resolution of parameter space similar experiments can be completed in a few days with an optimized laboratory instrument where acceptable counting statistics can be achieved in 100 s exposures[4-6].
We have focused on developing an in-line methodology that is supported by molecular dynamics simulation[7] in order to disentangle the scattering fingerprints that may eventually be used to steer mesoscale structure formation to achieve the optimal photovoltaic performance of a bulk heterojunction. As will be shown, the methodology may be applied both on laboratory scale setups[8] as well as on synchrotron beam lines, and may even be used in conjunction with coating conditions far removed from ambient, i.e. with fully heated solution, coating head and substrate to handle materials that otherwise quickly aggregate and gelate. In combination with optical probes and machine learning techniques, the methodology is expected to close the lab-to-fab gap

that continues to hold back the commercial breakthrough of organic solar cells.

11:00 AM EL14.03.02
Automatic Identification by Deep Learning of New Hybrid Perovskites from X-ray Diffraction Patterns Florian Massuyeau and Romain Gautier; CNRS-IMN, France

Hybrid lead halides of perovskite type have recently shown a great potential in optoelectronic applications. For this reason, many research groups are currently exploring this chemical system to discover new low dimensional hybrid perovskites. However, discovering such materials is challenging as the necessary structure determination by X-ray crystallography is time consuming and non-perovskite compounds are very often synthesized instead of the more interesting perovskites. In this context, we developed a deep learning approach, which automatically and accurately assign the structure type from the X-ray diffraction patterns of new hybrid lead halides.[1] The models could automatically identify new hybrid perovskites with an accuracy as high as 92%. Interestingly, we were able to identify and explain the key features in the diffraction patterns, which allow the machine learning algorithms to discriminate between perovskites and non perovskites. From this information, the scientists' ability in discriminating the different structure types is largely augmented and such algorithms could be included in autonomous materials discovery cycles in the future.

Automating 4D-STEM Data Acquisition for Perovskite Imaging Alexander J. Pattison[1], Wolfgang Theis[2] and Peter Ercius[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of Birmingham, United Kingdom

Scanning transmission electron microscopy is a key tool for characterizing the structure and composition of optoelectronic materials at atomic scales [1]. More recently, the advent of high-speed pixelated electron detectors has enabled the collection of full 2D convergent beam electron diffraction patterns for every scan position in a normal 2D raster scan, producing 4D datasets. As well as being used to generate standard STEM images with variably defined collection angles, new 4D-STEM techniques such as center-of-mass [2], ptychography [3], nanoscale strain mapping [4] and STEM holography [5] are now also available.

Despite its widespread usage, however, taking STEM data remains a mostly manual process, which limits the efficiency of microscope sessions and introduces subjective bias into the selection of regions of interest (ROI). With the processing power of modern desktop computers and the availability of open-source computer vision and image analysis software, it is now feasible for computers to decide which ROIs are worth interrogating during an experiment and where to move a microscope stage next to take more useful data. A major challenge is developing workflows that are sufficiently customisable for the range of samples and experiments conducted in EM investigations.

In this presentation, we demonstrate the operation and applications of a custom-built automation program to acquire data on an aberration corrected STEM. This program is integrated with a high speed direct electron detector capable of acquiring large 4D-STEM scans with 87,000 frames per second. The program's pipeline architecture allows rapid development of custom workflows based on basic methods, making it highly customisable for different samples and experiments. We demonstrate its use in acquiring 4D-STEM data sets of many regions of interest suitable for atomic resolution phase contrast STEM of dose sensitive materials. This shows the potential to study large amounts of materials such as perovskites at high resolution without human intervention leading to statistically meaningful results.

A High-Throughput, Multi-Approach Platform for Discovery of Phosphosulfide Semiconductors Andrea Crovetto; Technical University of Denmark, Denmark

Despite the success of Group III phosphides as optoelectronic semiconductors, phosphorus-containing materials for optoelectronics are still largely unexplored. This is unfortunate, because phosphorus is one of the most versatile elements in the periodic table, as it can take a range of positive and negative oxidation states giving countless possibilities for materials discovery.

One of the many intriguing possibilities is to explore P-containing materials containing both a more electropositive and a more electronegative species than phosphorus. Very interesting materials (phosphosulfides) can be obtained using sulfur as the electronegative species. Many phosphosulfides are predicted to be semiconductors with band gaps in the visible. Yet, there are less than 5 five reports of phosphosulfides in thin-film form and hardly any optoelectronic characterization. Phosphosulfides with phosphorus in the -3 oxidation state are completely unexplored by experiment, although recent calculations show direct band gaps, disperse bands, and a high degree of versatility.

To try to harness some of these possibilities in a time- and resource-efficient manner, I propose an integrated platform for discovery of phosphosulfide materials. This platform includes:
- High-throughput/high versatility modular synthesis apparatus for combinatorial growth of inorganic phosphosulfide thin films. This includes sulfur- and phosphorus partial pressure control (both at atmospheric and low total pressures), separate chambers for volatile metal incorporation, and creation of perpendicular combinatorial gradients in the metal-to-metal ratio as well as in the S/P ratio.
- High-throughput characterization apparatus, focusing on the properties that are expected to be correlated with the final optoelectronic performance and are difficult to simulate with sufficient accuracy.
- A tiered approach to material property simulation, which complements the information available from experiment. The simulation tools can be roughly

divided into first-principles quantum mechanical methods, semiclassical methods, and classical “rule-of-thumb“ methods.
- Data management tools to accommodate both experimental and simulation data
- Various artificial intelligence tools to be used both for decision-making in the lab and for understanding complex composition-structure-process-property-performance relationships.
- Public access to the data generated by the tools listed above

To make the presentation more concrete, I will show preliminary optoelectronic characterization of a new phosphosulfide thin-film material to demonstrate the general potential of phosphosulfides for optoelectronics. Finally, I will show recent results on Cu_3P thin films, where a similar (integrated) approach resulted in discoveries that could not have been made by a single-methodology approach.

11:45 AM EL14.04.09
Design Optimization of Bifacial Perovskite Minimodules for Improved Efficiency and Stability Hangyu Gu and Jinsong Huang; The University of North Carolina-Chapel Hill, United States

Bifacial solar modules can produce more energy than monofacial ones, but efficient bifacial perovskite modules have not been demonstrated yet. Here we report bifacial perovskite minimodules with front efficiency comparable to that of the best opaque monofacial minimodules while gaining additional energy from albedo light. The addition of hydrophobic additive in bottom hole transport layer surprisingly protects the perovskite films from moisture damage during atomic layer deposition. Integrating silica nanoparticles with proper size and spacing in perovskite films recovers the absorption loss induced by the absence of reflective metal electrodes while maintains the charge collection properties of perovskites. The small-area single-junction bifacial cells have an equivalent stabilized efficiency of 26.4% at an albedo of 0.2. The bifacial solar minimodules show front efficiency of over 20% and bifaciality of 74.3%, and thus an equivalent efficiency of over 23% at an albedo of 0.2. The bifacial minimodule retained 97% of its initial efficiency after light soaking under one simulated sun for over 6000 hours at 60±5 °C.

Interweaving Synthesis, Theory, Experiment, Devices, Data Tools and Machine Learning for Exploring Materials—Example of Halide Perovskites Claudia Draxl; Humboldt-Universität zu Berlin, Germany

Every material or material class comes with its individual properties and functions that may be useful for a certain type of application. Understanding the respective peculiarities, is particularly interesting from a fundamental point of view. Employing first-principles theory, one can explore the relevant interactions on the electronic scale. A broad variety of available experimental probes allows for in-depth characterization. Bringing both together, often highlight discrepancies between computational results, typically obtained for perfect crystals, and measurements performed on real materials. Moreover, uncertainties may arise coming from the preparation and/or treatment of the investigated samples. On top of all this, every technique – be it experimental or theoretical – comes with its own subtleties. Taking the halide perovskites as an example, for instance, a reliable calculation of the electronic structure even with forefront methodology is still a remarkable challenge [1]. This makes it even more challenging to relate these results to real-world halide perovskites used in state-of-the-art devices. This is also in part due to the sample quality, concerning structural disorder, instability issues, and complex compositions.

Augmented datasets that combine knowledge derived from all perspectives – sample synthesis, experiments, devices, and *ab initio* calculations – have the power of overcoming this barrier and answering scientific questions that cannot be resolved from their individualistic perspectives. Within the FAIRmat consortium [2] (https://fairmat-nfdi.eu), the NOMAD Laboratory [3] (https://nomad-lab.eu), originally developed for computational materials science, is now adapting towards managing experimental material-science data and their various applications, one of them being solar cells.

In this presentation, we demonstrate with the example of organic-inorganic halide perovskites how NOMAD enables the exploration of materials in an interoperable manner from both, the theoretical and the experimental perspective, including synthesis, characterization, and device properties. This enables not only scientific insight through in-depth comparison and analysis but provides also a basis for employing novel artificial-intelligence based workflows and tools. For example, users may train their machine-learning models with theoretical results or experimental data either coming from NOMAD or from their own labs, or from curated datasets like the Perovskite Database Project [4], or with a combination of all of them.

Work carried out in collaboration with J. Márquez Prieto, E. Unger, T. Unold, L. Himanen, M. Scheidgen and the entire FAIRmat team.

High-Throughput Optical Absorption Spectra for Inorganic Semiconductor Ruoxi Yang, Matthew Horton, Jason Munro and Kristin A. Persson; Lawrence Berkeley National Laboratory, United States

An optical absorption spectrum constitutes one of the most fundamental material characteristics, with relevant applications ranging from material identification to energy harvesting and optoelectronics. However, the database of both experimental and computational spectra are currently lacking. In this study, we designed a computational workflow for optical absorption spectrum and integrated the simulated spectra into the Materials Project. Using density-functional theory, we computed the frequency dependent dielectric function and the corresponding absorption coefficient for more than 1000 solid compounds of varying crystal structure and chemistry. The computed spectra show excellent agreement, as quantified by a high value of the Pearson correlation, with experimental results when applying the band gap correction from the HSE functional. The demonstrated calculated accuracy in the spectra suggests that the workflow can be applied next-generation perovskite materials for optoelectronic applications.

2:15 PM EL14.04.03
Computational Discovery of Novel $Ln_2M_2O_5Ch_2$ Materials for Photocatalytic Water Splitting Katarina Brlec, Joe Willis and David O. Scanlon; University College London, United Kingdom

Worldwide, 96% of all hydrogen is produced from fossil fuels in steam methane reforming or coal gasification processes, leading to large greenhouse gas emissions.[1] In addition to fossil fuels, another major source of hydrogen on Earth is water. Hydrogen can be sustainably produced using photocatalytic water splitting – a biomimicry of photosynthesis. TiO_2 and other d^0 oxides have been extensively studied over the last 50 years, however their electronic band structure with low-lying oxygen-dominated valence band prevents efficient hydrogen evolution photocatalysis.[2]

Mixed anion systems (ON, OX, OCh systems) opened a new paradigm in the search for better photocatalysts, as the second anion can be engineered to have a higher-lying p orbital to optimise the band edge positions for water redox. A series of $Ln_2Ti_2O_5S_2$ (Ln=Y, Sm, Gd, Tb) compounds exhibited visible-light photocatalytic water splitting, with $Y_2Ti_2O_5S_2$ showing simultaneous O_2 and H_2 evolution.[3,4]

In this work we explore the 26 previously unknown members of the $Ln_2M_2O_5Ch_2$ (Ln = Sc, Y, La; M = Ti, Zr, Hf; Ch = S, Se, Te) series using state-of-the-art density functional theory (DFT). In total, 289 competing phases of the entire Ln-M-O-Ch chemical space were evaluated at hybrid-DFT level to accurately determine the thermodynamic stability of the proposed materials. Phononic stability of the systems was confirmed using the supercell lattice dynamics approach, with any instabilities mapped out to obtain the true ground state structure. Finally, the relevant optoelectronic properties and bulk band alignments were calculated at hybrid-DFT level to assess the suitability of materials for photocatalytic applications.

Machine Learning to Investigate Material Properties—Autoencoders as a Powerful Tool to Reveal Material Properties Alessio Gagliardi; Technische Universitat Munchen, Germany

Machine learning (ML) is emerging as a new tool for many different fields which now span, among the others, chemistry, physics and material science [1,2]. The idea is to use ML algorithms as a powerful machinery to identify, starting from big data analysis, subtle correlations between simple elemental quantities and complex material properties and then use these to predict them. This approach can help to screen many material properties directly *in-silico* avoiding more computational expensive ab-initio calculations and experimental measurements.
However, adapting existing ML architectures to problems in chemistry, physics and material science is not straightforward. Several aspects need to be addressed to improve machine performance which can be summarized into prediction accuracy and generalization skills. Improving these aspects require to go into the details of the machine and analyze the way they learn from a training dataset. This allows to identify which architecture, training algorithm and dataset are relevant for the problem at hand.
In the present talk I will discuss about the use of a special class of algorithms, i.e. Autoencoders, and how their latent space can be directly used to understand structure-to-property relations in materials and boost numerical simulations.

4:00 PM EL14.04.07
Forbidden Optical Transitions—A New Design Metric for Transparent Conductors Rachel Woods-Robinson; Lawrence Berkeley National Laboratory, United States

Many semiconductor materials have weak or forbidden transitions at their fundamental band gaps, as is the case in many high-performing n-type transparent conductors (TCs) including Sn-doped In_2O_3 (ITO) and which induces a widened region of transparency. Finding a high-performing p-type TC could enable breakthroughs in optoelectronic devices such as photovoltatics and several high-throughput screenings have been performed. However, most of these screenings assume that the direct fundamental band gap is a good proxy for absorption edge energy, and so far the presence of forbidden transitions has been overlooked in searches for new p-type TCs. To address this, we compute absorption spectra across a set of ~18,000 semiconductors from the Materials Project database, demonstrating that over half have forbidden or weak optical transitions at the band gap and nearly 10% have at least 0.5 eV between their direct gap and allowed gap (a descriptor we call "forbidden energy difference"). We show that compounds with highly localized states at the band edges (as determined by the inverse participation ratio) are most likely to have forbidden transitions, and for these compounds high orbital overlaps correlate with large forbidden energy differences. Next, we use this data set to perform a screening for p-type and n-type TCs that may have been previously overlooked due to the forbidden nature of their band gap, and defect calculations yield a set of new promising candidate ambipolar TCs, p-type TCs, and n-type TCs. Notably, the two best known n-type TCs, In_2O_3 and SnO_2, would have been filtered out in previous screenings, yet we show they emerge successfully from our screening. We have shared our data set via the MPContribs platform, and we recommend that future screenings for optical properties use metrics representative of absorption features rather than band gap alone.

4:15 PM EL14.04.08
High-Throughput Computing and Screening Thermodynamic and Phonon Transport Properties of 13,205 Dynamically Disordered Perovskites Ming Hu; University of South Carolina, United States

Although first-principles based anharmonic lattice dynamics method coupled with the phonon Boltzmann transport equation has been developed to obtain the phonon properties including lattice thermal conductivity at highest accuracy ever, the costly and time-consuming nature of the required interatomic force constants calculations renders high-throughput infeasible when facing tens of thousands of new materials. Here, a high-dimensional multi-element deep neural network is trained, dubbed Elemental Spatial Density Neural Network Force Field (Elemental-SDNNFF), achieving a competitive force root mean square error and a speed-up of 3 orders of magnitude in comparison to first-principles. The effectiveness and precision of the Elemental-SDNNFF approach is demonstrated on a set of >100,000 inorganic crystalline structures spanning 63 elements in the periodic table by prediction of complete phonon properties such as phonon dispersions and lattice thermal conductivity. We then use our trained neural network model to predict and screen full phonon properties of 13,205 perovskite structures. Due to the inherent structural feature of dynamical disorder, the perovskite structures have shown diverse thermodynamic and phonon transport properties. Thermodynamic stability of all 13,205 perovskite structures is predicted by screening negative frequencies in the Brillouin zone. Four-phonon scattering and two-channel thermal transport are also analyzed and screened. The underlying mechanism is analyzed in deep at the electronic level. This study demonstrated that our algorithm is very powerful for predicting phonon properties of large-scale inorganic crystals and is also promising for accelerating high-throughput search of novel phononic materials for emerging applications.

4:30 PM EL14.04.10
Combinatorial Slot-Die Coating of Metal Halide Perovskite Semiconductors Jinzhao Li, Natalia Maticiuc and Eva L. Unger; Helmholtz-Zentrum Berlin, Germany

Metal-halide perovskite semiconductors are of interest for various optoelectronic devices: photovoltaics, light-emitting diodes, lasers, and photodetectors.[1] In order to explore the vast compositional space of perovskite materials, high-throughput approaches are of strong interest. Current, the approach to compositional engineering is based on manually mixing perovskite precursor inks and fabricate samples individually. To more efficiently fabricate a large amount of perovskite compositions in a single deposition or automizable step, high-throughput fabrication methods based on scalable methods such as slot-die coating, inkjet printing, and evaporation have been developed. Among them, slot-die coating is a promising technique for solution fabrication of high-efficiency perovskite solar cells. This method can be easily modified to make combinatorial sample by implementing a differential feed of two or more precursor inks into the slot-die head, which we refer to as combinatorial slot-die coating. As we will present in this talk, this generic methodology offers very interesting opportunities for high-throughput screening of the of perovskite compositions.
Here, we demonstrate the use of combinatorial slot-die coating to fabricate perovskite semiconductors varying the compositions from $FAPbI_3$ to $MAPbBr_3$. It provides a direct method for synthesis and mixing of perovskite compositions by varying the pump rate. We fabricated solar cell devices and found devices with the composition $FA_{0.8}MA_{0.2}Pb(I_{0.8}Br_{0.2})_3$ yielded the best performance, which is consistent with the previously published result.[2] To characterize the homogeneity and quality of samples, we carried out morphological, optical and crystallographic measurements on thin-films. We found that the coverage of high bromine samples is poor, which is due to the different crystallization pathways of bromide compared to iodide-based perovskite.[3] The $FAPbI_3$-rich devices give better performance due to the improved morphology, which suggests the combinatorial slot-die coating method is suitable for fabrication of solar cells. This work highlights both the potential and obstacles using a high-throughput strategy for screening and exploring the compositional and structural properties of metal halide perovskite semiconductors.

5:00 PM EL14.05.02
SnF_2-Doped Cs_2SnI_6 Ordered Vacancy Double Perovskite for Photovoltaic Applications Rubaiya Murshed, Sarah Thornton, Curtis Walkons and Shubhra Bansal; University of Nevada Las Vegas, United States

Cs_2SnI_6, an emerging inorganic perovskite variant is considered an environmentally benign lead-free option for photovoltaic application. Cs_2SnI_6 offers favorable optoelectronic properties as well as high stability due to the presence of the tetravalent oxidation state. Owing to its p-type semiconducting nature, Cs_2SnI_6 has previously been reported as an efficient hole transport material. However, its candidacy as a potential light absorber is still being explored in different strategical investigations. In this study, for the first time, Cs_2SnI_6 has been used in a superstrate *n-i-p* planar device structure enabled by a spin-coated absorber thickness of ~2 mm on a chemical bath deposited Zn(O,S) electron transport layer. The crystalline Cs_2SnI_6 phase is obtained with CsI, SnI_2, and SnF_2 salts in a solvent mixture of Gamma-Butyrolactone (GBL) and N, N-Dimethylformamide (DMF) and a bandgap of 1.6 eV has been demonstrated. The best device power conversion efficiency reported here is 5.18% with V_{OC} of 0.81 V, J_{SC} of 9.28 mA/cm^2 and a fill-factor of about 68%. The devices exhibit a high V_{OC} deficit, and higher device efficiency can be expected by improvement of material quality, charge transport and device engineering.

5:00 PM EL14.05.04
0D–2D Hybrid Photodetectors using Multilayer MoS_2 and Lead Halide Perovskite Quantum Dots with Tunable Bandgap SeockJin Jeong and Jong-Soo Lee; Daegu Gyeongbuk Institute of Science & Technology (DGIST), Korea (the Republic of)

We report high-performance 0D–2D hybrid photodetectors integrated with tunable band gap perovskite ($CsPbI_3$, $Cs_XFA_{X-1}PbI_3$, and $FAPbI_3$) quantum dots and MOCVD-grown bilayer MoS_2. In our hybrid structure, the lead halide PQDs can be utilized as an absorbing layer of the light of specific wavelengths and transfer the photogenerated carriers to the MoS_2 transport layer. With tunable wavelength lead halide PQDs, the 0D–2D hybrid photodetector shows a high responsivity up to 10^7 AW^{-1} and high specific detectivity exceeding 10^{13} Jones due to the difference in the built-in potential between PQDs and multilayer MoS_2 layers. This work proposes the possibility of fabricating high-performance photodetectors by hybridizing PQDs of various band gaps with 2D materials.

5:00 PM EL14.05.05
High Throughput Screening of Composition in Multicomponent Organic Based Photovoltaics Mariano Campoy-Quiles; ICMAB-CSIC, Spain

Combining two acceptors and one donor in the active layer of organic solar cells, also referred to as ternary blending, has become a very important strategy in this field in order to improve light harvesting, as well the preventing morphological evolution. The efficiency strongly depends on the exact ternary composition, as the optimum mixing will be a compromise between transport and optical properties. Despite its importance, predicting how the final efficiency of a system depends on composition has been, thus far, elusive [1].
In this talk, we will first describe a novel methodology for the fast evaluation of binary and ternary systems for photovoltaics. The new approach is based on the fabrication of samples with gradients in the relevant parameters of interest that represent a large fraction of the corresponding parameter space. In particular, we fabricate gradients in thickness, microstructure, and composition, and apply hyperspectral imaging to correlate material and device properties [1]. Then, we will show how this machinery, which is ca 100 faster than conventional optimization protocols [2], can be used to cartograph the complex composition phase diagram for ternary organic solar cells based on a single polymer donor (such as P3HT, PTB7-Th or PM6) and two acceptors (e.g. IDTBR, IDFBR, Y6, ITIC, PCBM, etc.) [3,4]. We find that, depending of the specific system, the ternary land scape can exhibit either one or more efficiency maxima. We also observe that the optimum composition is often found outside the 1:1 donor:acceptor ratio trajectory. Finally, we will discuss different options to choose the third material in the ternary, including the use of an experimental genetic algorithm method that we have developed.

5:00 PM EL14.05.06
Metal-Organic Chemical Vapor Deposition of Hybrid Perovskites Alicia Bryan, Jonathan Meyers, Lorenzo Serafin and James Cahoon; University of North Carolina at Chapel Hill, United States

Hybrid perovskites (HPs) have become widely recognized in the chemistry and materials science communities as a promising candidate for the next generation of efficient optoelectronic and photovoltaic devices. Their unique hybrid organic-inorganic nature affords HPs an exciting blend of electronic and structural properties, and yields both advantages and challenges in fabrication. The vast majority of HP fabrication methods to date have focused on simple solution processing, while comparatively few vapor-phase HP deposition methods have been developed, and these broadly rely on single-source evaporation of solid HP perovskite crystals or dual-source coevaporation of precursor salts. However, these methods suffer from limited control over reactant vapor pressures and temperatures that in turn lead to limited control over final film composition and morphology. In light of this, we have developed a metal-organic chemical vapor deposition (MOCVD) method for HP fabrication to enable precise control of composition, stoichiometry, and film morphology. Using our custom-built reactor equipped with vapor precursors including methylamine, tetraethyllead, and hydrogen halide gasses, we have successfully deposited $CH_3NH_3PbI_3$ and $CH_3NH_3PbBr_3$ perovskites as confirmed using X-ray diffraction, UV-visible spectroscopy, and scanning electron microscopy. We have further probed deposition on a variety of substrates including silicon oxides, glass, and organic-functionalized materials to investigate the vital relationship between substrate identity and film nucleation and growth dynamics.

Materials Screening of Interface Passivation Layer in Perovskite Photovoltaic Devices Using Machine Learning Zhe Liu, Chongyang Zhi, Suo Wang and Zhen Li; Northwestern Polytechnical University, China

Machine learning (ML) has increasingly gained attention in the field of materials science, especially to accelerate the development of new energy materials. Particularly, we tackle the materials screening challenge of interface passivation layers in perovskite solar cells (PSC). Perovskite solar cells with quasi-2D passivation layers is known to be effective to achieve record-high efficiencies (*e.g.*, 2D/3D PSCs). However, the large number of available organic compounds has made the trial-and-error experimental approach very inefficient. In this study, we demonstrated a materials screening framework using ML methods, with experimental validations using new data collected from our lab as well as scientific literature. The ML method is applied to investigate the relationship between the molecular features of ammonium salts and the PCE improvement ratios. We establish an accurate predictive model with a dataset of 19 ammonium salts via the following two methodological innovations: (1) data-bias correction by adding diversely sampled data in the material feature space, and (2) ensemble ML learning with five base learners of distinct model architectures. Along with the Shapley Additive Explanations (SHAP) analysis method, four molecular features (*i.e.*, hydrogen atom, hydrogen bond donor, partition coefficient, and complexity) are identified as the most important, having suitable value ranges for screening the ammonium salts for a better passivation effect. Therefore, the molecular feature criteria are used to downselect 10 candidates from a pool of approximately 112 ammonium iodides available in the PubChem database. Finally, PSCs are fabricated using the predicted ammonium iodides for the model validation. We demonstrated efficient PSCs with a 3-phenylpropan-1-aminium iodide (PPAI) induced interface layer, achieving PCEs of 21.87% and 24.32% in PSCs with $(FA_{0.83}MA_{0.17})_{0.93}Cs_{0.07}Pb(I_{0.83}Br_{0.17})_3$ and $FA_{0.92}MA_{0.08}PbI_3$ absorber layers, respectively. We believe that ML-assisted material screening can help us interpret the crucial molecular features for perovskite interface passivation, and effectively predict the materials candidates. The proposed ML workflow can be easily adapted for screening a wide range of organic molecules to improve the performance and stability of optoelectronic devices.

9:15 PM EL14.06.02
High-Throughput Screening of Organic Solar Cells Based on PTQ10:NFA to Determine the Best Compromise Between Efficiency and Stability
Sergi Riera-Galindo[1], Arnau Guiteras[1], Marta Sanz[2], Laura López-Mir[2] and Mariano Campoy-Quiles[1]; [1]ICMAB-CSIC, Spain; [2]Eurecat Technology Center, Spain

High power conversion efficiency (PCE) and stability are essential for the industrial viability of organic photovoltaic (OPV). The optimization of device

PCE and stability is a multi-parameter complex system. High-throughput screening offers tremendous opportunities to accelerate the discovery of optimal material composition and structure of efficient and stable organic solar cells.

In this work, we present the stability of organic solar cells based on PTQ10 with different acceptors. First, we evaluate the impact of the molecular weigth (MW) of the PTQ10 donor polymer blended with three differente non-fullerene acceptors (NFAs) (ie. IDIC, Y6 and Y12) on the performance of organic solar cells. By increasing the MW from 10 to 147 kDa, the efficiency improves by one order of magnitude, from around 2% up to 12%. The devices with higher molecular weights also show better thermal stability. We also characterized the active layer materials by photoluminicence, Grazing-Incidence Wide-Angle X-ray Scattering (GIWAXS) and charge carrier mobility.

Moreover, we explore by combinatorial screening the dependence of the stability with the active layer thickness following ISOS protocols, in order to determine if the optimal thickness for power conversion efficiency matches the thickness of the most stable devices.

As a result, we report stable and promising systems of organic solar cells for industrialisation of low cost organic photovoltaics.

9:30 PM *EL14.06.03
Accelerating Perovskite R&D Using Direct Multi-Material Printing Tonio Buonassisi, Alexander E. Siemenn and James Serdy; Massachusetts Institute of Technology, United States

In this study, we present a hardware and software platform that could accelerate deposition and characterization of perovskite solar cell materials by a factor of >1000x relative to spin coating. The hardware is a “direct multi-material printing” method known as “chemjet.” We utilize multiple positive-displacement fluid dispensers, combine fluids using a joiner valve, and dispense the mixture *via* a nozzle onto a substrate at a rate of up to 2000 unique formulations per minute.

It is natural to ask, to what extent perovskite materials deposited *via* chemjet are similar to those deposited via spin coating or slot-die coating methods. To build trust, we demonstrate the equivalence of X-ray diffraction patterns and optical absorption (UV-Vis) profiles between perovskite materials in the $(MA,FA)PbI_3$ family with both chemjet and spin coating.

We discuss the machine-learning control loops employed to optimize for materials properties, and aid the researcher in extracting scientific insights. This presentation concludes with a prospectus of the scientific questions currently being addressed using this platform, as well as an overview of the future strengths and challenges of chemjet.

*credit to Aldair Gongora for introducing Buonassisi to the term “direct multi-material printing.”

1:30 PM *EL15.01.01
Perovskite and Organic Solar Cells for Space Applications Peter Muller-Buschbaum; Technical University of Munich, Germany

Due to massive research, the champion devices for perovskite solar cells have passed the 25% device efficiency threshold and organic solar cells approach

20%. In general, perovskite and organic solar cells only require comparatively thin absorber layers on the order of 100 nm, which enables a reduction in device thickness of the total solar cells well below 1 µm. Moreover, processing of the perovskite and organic layer can be done from solution on flexible substrates at low temperatures via potential scalable methods like printing and spray coating. Thereby, flexible solar cells can be fabricated. Combining these advantageous factors, enables fundamentally higher specific energy densities compared to the classical solar cell types used in space so far. Moreover, it will open up new possibilities in transport, deployment, and application of perovskite and organic solar cells in space. However, so far, performance data of perovskite and organic solar cells in space environment is very limited. Besides promising laboratory experiments that can never capture the full set of ambient conditions present in space, some near-space experiments have been performed in the upper atmosphere with appealing results regarding the performance and stability.
Here, we present the first electrical characterization of perovskite and organic solar cells at orbital altitudes [1]. Space flights are an ideal platform to investigate the behavior of solar cells in conditions that are characterized by ultra-high vacuum, strong UV solar irradiation, and the absence of oxygen or water outside Earth's atmosphere. During a suborbital rocket flight, we measured the voltage-current response of perovskite and organic solar cells under different illumination conditions. The combination of the solar cell measurements with irradiance data obtained from simultaneous light sensor measurements allows for deducing the performance parameters. Our results show that the solar cells survived the harsh conditions during transport, the start preparation procedure, and the rocket launch, where the best solar cells reached power conversion efficiencies of more than 10% for perovskite-based solar cell modules. Our results show the versatility of perovskite solar cells for application in various environmental conditions, with promising potential to revolutionize future renewable energy production in space.

X-factors that Might Determine How Perovskite Solar Cells are Deployed Michael D. McGehee; University of Colorado, United States

Metal halide perovskite solar cells might be deployed as single junctions or in tandems that could consist of wide bandgap perovskites paired with silicon, copper indium gallium dye selenide or a narrow-bandgap perovskite. Modules might be made with singulated cells that are connected by wires or ribbons or in a monolithically integrated architecture made with several laser scribes. Researchers often discuss the efficiency, stability under standard operating conditions and cost of the various options when making the case that one approach is the most attractive. These factors are indisputably important, but there are other factors that do not get as much attention, but could end up determining which approach is the best one. We will discuss reverse bias degradation that can occur when a panel is partially shaded and comment on which architectures are likely to be the most resistant to this type of degradation. We will discuss why some architectures are likely to have higher yield than others and point out that laser scribing along with metal vias could introduce degradation mechanisms that are not seen in the cells that are frequently put through accelerated lifetime testing.

Radiation Effects in Quantum Well Multi-Junction Solar Cell Seth Hubbard, Stephen Polly and Brandon Bogner; Rochester Institute of Technology, United States

The space III-V photovoltaic industry relies on multijunction solar cell technology meeting high-efficiency, low weight, and radiation tolerance metrics. Incorporation of nanostructures in the current-limiting subcell of the III-V multijunction solar cells has been shown to be an efficient way to achieve current matching between the subcells. Adding QWs to the intrinsic region of the limiting GaAs subcell of a standard triple junction InGaP/GaAs/Ge solar cell, on the one hand, enables absorption of the sub-band edge photons, effectively lowering the bandgap of the middle cell, and at the same time can allow for efficient carrier extraction. Engineering of the energy states in the strained QWs for enabling carrier escape via tunneling and thermalization can be approached by tuning the width of the QWs, as well as by changing the separating energy barriers height and width. Increasing the number of strained QWs strongly impacts the absorption in the QWs, however, the strain energy accumulation in the QWs has to be carefully balanced with appropriate and oppositely strained barrier material to maintain low non-radiative recombination. Alternatively, using rear-side distributed Bragg reflectors (DBR) structures, the optical thickness of the QW region can be nearly doubled.

In this talk, I will demonstrate development of both single-junction GaAs and tandem InGaP/GaAs solar cells incorporating $In_{0.08}Ga_{0.92}As$ strain balanced quantum wells. This work builds on previous reports of the integration of InGaAs quantum wells in an InGaP/GaAs heterojunction solar cell with minimal loss in Voc, as well as significant effort to understand the growth conditions required for strain compensation with GaAsP including the effects of phosphorus content, growth temperature, gas switching sequence, and substrate orientation. Up to 50 layers of strain balanced QWs have been added to a single junction device with minimal degradation in Voc and monotonic increase in Jsc. A distributed Bragg reflector (DBR) was added below the structure centered at the collection energy of the QWs to increase the optical path length of the QW region and further increase subgap current collection. Finally, these components were assembled into dual-junction device comprised of an InGaP homojunction and InGaP/GaAs heterojunction optimized with and without the incorporation of 50x QWs and a DBR for AM0 and AM1.5G spectra. These developments have resulted in radiation tolerant 2-junction solar cells incorporating QWs, with a 27.5% AM0 (>30% AM1.5G) efficiency, representing a 2.5% absolute efficiency increase over a control 2-jucntion solar cell without QWs. Radiation testing is currently ongoing.

In addition, we have also investigated the impact of integrating advanced textured photonic structures to increase the optical path length (OPL) in thin and ultra-thin GaAs and $In_{0.3}Ga_{0.7}As$. In particular, we have demonstrated a facile *in situ* method for back surface textures that can be accomplished using standard metal organic vapor phase epitaxy. The textured films were characterized using specular and diffuse reflectance measurements as an indicator of improved angular reflectance.

Development of Electronics Technologies for Space Radiation Environments Jesse Mee; Air Force Research Laboratory, United States

The United States Space Force (USSF) space systems are growing rapidly in complexity to meet the needs of the future Department of Defense (DoD) space architecture. These national assets provide surveillance, communications, navigation, positioning and timing functions for both the DoD and commercial sectors, and all ultimately rely on advanced electronics circuits, systems and devices. Operation in a space radiation environment puts unique constraints on the types of electronics that can be deployed into these systems depending on the orbit altitude, inclination and mission duration. Adding to the complexity, the future USSF architecture is envisioned to include a hybrid mix of large, long-lived, high-value assets augmented by a layer of smaller, shorter-duration, satellite constellations. This creates a spectrum of space radiation tolerant and radiation hardened electronics needs to support these systems. It is the mission of the Air Force Research Laboratory Space Vehicles Directorate (AFRL/RV) Space Electronics Technology (SET) team to provide trusted, affordable, radiation hardened/tolerant, high-performance, and reliable electronics for future USSF space systems. This presentation will discuss the trade-space in electronic components development to meet "new-space" requirement for high-performance with good-enough radiation tolerance, while continuing to support legacy radiation hardened electronics needs for long lived systems.

Ultra-high Properties of Carbon and Boron Nitride Nanomaterials toward Space Materials Jun Kyung Kim, Se Gyu Jang, Hyeonsu Jeong, Seokhoon Ahn, Bon-Cheol Ku, Seung Min Kim and Jin Sang Kim; Korea Inst of Science and Technology, Korea (the Republic of)

The space elevator is an earth-to-space transportation system, and carbon nanotube (CNT) fibers and boron nitride nanotubes (BNNTs) which can protect CNT fibers from the space environment have been considered as core materials. To develop core technologies for these materials, Korea Institute of Science and Technology (KIST) has been carrying out the "4 Ultrahigh-performance Composites Development Project" since 2017, where 4U stands for ultra-light weight, ultra-high strength, conductivity, and shielding. In this presentation, we will share major achievements through the 4U project.
For high-performance CNT fibers, we have developed various techniques based on both the direct and wet-spinning methods. The main achievement among the direct spinning-based techniques is the fast densification method derived from the principle of wet-spinning method [1]. Directly-spun CNT fiber usually possesses poor internal structure with less aligned CNTs and lots of voids, which critically limits the properties of directly-spun CNT fiber. To overcome this issue, we developed the method in which swollen CNT fiber by chlorosulfonic acid was stretched and coagulated. This method allowed us to fabricate highly-aligned and densified CNT fiber with excellent properties in a minute. Furthermore, the high-performance CNT fibers by wet-spinning technique were fabricated after optimizing fiber orientation and defects. The highly oriented and densified CNT fibers were then thermally treated, which resulted in producing ultra-high strength and modulus CNT fibers with high electrical and thermal conductivity [2].
For BNNTs, we have intensively studied the synthesis, purification, dispersion, and fibers of BNNTs. For example, the growth mechanism of BNNTs was identified through the discovery of open tip growth mode by radicals, and BNNT purification and dispersion technology was developed through polymer functionalization.

Radiation Tolerance of $GaAs_{1-x}Sb_x$ Solar Cells—A Candidate III-V System for Space Applications Hadi Afshari[1], Brandon Durant[1], Tristan Thrasher[1], Logan Abshire[1], Vincent R. Whiteside[1], Shun Chan[2], Dongyoung Kim[2], Sabina Hatch[2], Mingchu Tang[2], Jeremiah McNatt[3], Huiyun Liu[2], David Smith[4] and Ian R. Sellers[1]; [1]University of Oklahoma, United States; [2]University College London, United Kingdom; [3]NASA Glenn Research Center, United States; [4]Arizona State University, United States

The high radiation tolerance of $GaAs_{0.86}Sb_{0.14}$ based solar cells with a bandgap suitable for PV is demonstrated at the low intensity low temperature (LILT) conditions. This system shows remarkable radiation hardness at AM0, and more prominently, at the conditions of several outer planetary targets. The photovoltaic behavior of the system after electron irradiation is attributed to an irradiation induced change in the absorber bandgap due to local heating and strain relaxation, and the generation of less prohibitive shallow Sb-based defects in the $GaAs_{1-x}Sb_x$ absorber.
Both high efficiency and radiation tolerance are the two essential factors required for solar cells working in space. While III-V multi-junction solar cells are used ubiquitously in space, the radiation tolerance of such systems, particularly in deep space brings added complexity to their design since there is large variability in the sub cell radiation tolerance. Although, numerous studies have been performed to improve radiation resistance of the tandem structures; still thick cover glass is required, which increases the weight and reduces the specific power of the systems. GaAs as one of the most successful PV technologies has now reached record PCE levels, but its response to high radiation levels under LILT conditions is concerning (particularly around Jupiter and its moons) requiring very thick cover glass which removes the ability for compact stowage and deployment. Recently, ultrathin GaAs has been shown to offer potential as a more radiation hard system for space, if appropriate optical management can be designed to improve the absorption. Here, we propose GaAsSb as an alternative candidate system for space power applications, particularly in the regions of harsh radiation conditions of outer space and under LILT conditions. We show remarkably radiation tolerant performance in optically thick optimized $GaAs_{0.86}Sb_{0.14}$ without encapsulation suggesting this material should be further considered for hostile space missions including those to Jupiter or for satellite applications in Highly Eccentric Orbits (HEO) being considered to provide better internet coverage which require more robust systems than are currently available.

SESSION EL15.02: Perovskite Photovoltaics for Space Applications

Moscone West, Level 3, Room 3000

8:30 AM *EL15.02.01
Perovskite Solar Cells a New Horizon for Space Power Systems? Ian R. Sellers; University of Oklahoma, United States

In this presentation the potential of metal halide perovskite solar cells for space power applications will be presented. This discussion will focus on recent work at the University of Oklahoma, which includes the assessment of the systems in low-intensity-low-temperature (LILT) conditions for outer planetary missions, in addition to exposure to high temperatures and variable radiation conditions that directly and independently impact the absorber material and transporting layers of the solar cells. This presentation will discuss a number of perovskite systems including mixed Pb-Sn systems and the FAMACs family of metal halide perovskites. It will be shown that perovskites display remarkable tolerance to high radiation exposure and that while measurements *do* suggest high energy radiation negatively affects the transporting layers and interfaces in the devices: the perovskite absorber *is not affected* in any significant way. Moreover, these systems are observed to self-heal under ambient conditions in the dark demonstrating the unique behavior of perovskite solar cells and their potential for future space applications. This is further substantiated by high temperature measurements that indicate specific triple cation perovskites displays no appreciable or permanent degradation up to 500 K, supporting in particular their potential as candidate systems for future lunar missions.

9:00 AM *EL15.02.02
Perovskites and Other Emerging Photovoltaic Technologies for Space Applications Michael Kelzenberg, Phillip Jahelka and Harry A. Atwater; California Institue of Technology, United States

Perovskite solar cells have emerged as promising candidates for space applications owing to their high absorption coefficient, which allows for sub-micron cell thicknesses, and to their promising radiation tolerance. They have been fabricated on thin (<2 µm) flexible polymer superstrates, allowing for specific power up to ~30 kW/kg at the cell level, dramatically higher than other cell technologies. However, the space environment subjects solar cells to ionizing radiation and elevated operating temperatures, which for conventional space photovoltaics, requires the addition of radiation shielding coverglass for radiative cooling and to prevent premature degradation of the efficiency. Conventional coverglass typically ranges from 70—200 µm in thickness, and would substantially erode the specific power advantage of ultrathin perovskites. It is thus of interest to study the stability of perovskite solar cells in the space environment, to determine how much shielding or cooling materials would be necessary for use in various orbits or mission lifetimes. We will present the results of prior and ongoing radiation studies including high-energy electrons and low-energy protons, and discuss the viability of thin polymer substrates and shielding materials. Our research also includes other emerging photovoltaic technologies for space applications, including luminescent solar concentrators, nanostructured III-Vs for improved radiation hardness, and low-cost diffused-junction GaAs cells. We will discuss developments in these cell technologies and our present effort to measure the behavior of research devices in low-earth orbit.

Radiation Tolerance Testing and Materials Analysis of Perovskite Solar Cells Utilizing a Versatile Ion Beam Facility at the University of North Texas Bibhudutta Rout; University of North Texas, United States

Recently, several groups have shown that perovskites based solar cells show significant tolerance to proton radiation, however, perovskites also suffer from beam-induced damage in simple SEM characterization. Understanding the full extent of the various radiation-induced effects will greatly de-risk the perovskites for various non-terrestrial as well as terrestrial PV applications. Recently, we have performed several studies on the effects of proton and alpha irradiance at various fluences and energies, enabling the comprehensive assessment of the relative contribution of both nuclear and electron ionization losses in these materials. Using the stopping range of ions in matter simulations (SRIM) and damage displacement dose analysis in conjunction with targeted experimental irradiation energies and fluences we have developed a semi-empirical approach to evaluate the performance, radiation tolerance, and self-healing of solar cells. The correlation between the structural evolution of materials and device performance under irradiation can be estimated before the experiments by calculating the contributions to the total vacancies by the individual constituent elements.
At the University of North Texas, Ion Beam Laboratory, we have two dedicated accelerator facilities providing proton beams of energies from a few tens of KeV to several MeV enabling targeted irradiation of various layers of the devices. We have also a novel and powerful set of integrated in-situ analytical techniques for defect characterization in PV devices along with simultaneously performing irradiation of targeted layers of the devices.
In this presentation, we will provide updated results of these ion irradiation tolerance testing, radiation induced defect generation, as well as an in-situ elemental and charge collection analysis of the various layers of the perovskite-based solar cells.

10:15 AM EL15.02.04
Low-Cost and Lightweight Oxide Barriers for Space and Terrestrial Perovskite Solar Cells Ahmad R. Kirmani; Rochester Institute of Technology, United States

With parallel improvements in device efficiency and operational stability of perovskite solar cells, efficient and lightweight packaging schemes become the next frontier of research in this direction. Such schemes are also important for deployment of perovskite photovoltaics in aerospace applications, given their promising radiation hardness.[1] I will present our latest metal oxide based ul1tralight barrier layers that can be deposited using low-cost scalable techniques atop perovskite solar cells. 1-micron thick silicon oxide (SiO_X) will be shown to improve device tolerance against the most critical space and terrestrial stressors including low- and high-energy protons, alpha particles, atomic oxygen, moisture, and polar solvents (DI water, and dimethylformamide, DMF).[2] The barrier layer is electrically insulating, mechanically dense, crack-free, uniform, and chemically inert to the perovskite device stack. Based on these experiments, the calculated lifetime of the device in the low-Earth orbit (LEO) increases from ~0.3 years for bare cells to ~6 years after SiO_X encapsulation. The technology is attractive simultaneously for terrestrial and space applications, minimizing packaging costs and module weights, and maximizing specific power.

Sublimed Perovskite Based Photovoltaics for High Altitude and Space Applications Henk J. Bolink[1], Javier Sebastián[1], Claus Zimmermann[2] and Michele Sessolo[1]; [1]University of Valencia, Spain; [2]Airbus Defense and Space, Germany

Metal halide perovskite solar cells (PSCs) are of interest for high altitude and space applications due to their lightweight and versatile form factor. However, their resilience toward the particle spectrum encountered in space is still of concern. For space cells, the effect of these particles is condensed into an equivalent 1 MeV electron fluence. The effect of high doses of 1 MeV e-beam radiation up to an accumulated fluence to 1016 e� cm�2 on methylammonium lead iodide perovskite thin films and solar cells is probed. By using substrate and encapsulation materials that are stable under the high energy e-beam radiation,
its net effect on the perovskite film and solar cells can be studied. The quartz substrate-based PSCs are stable under the high doses of 1 MeV e-beam irradiation. Time-resolved microwave conductivity analysis on pristine and irradiated films indicates that there is a small reduction in the charge carrier diffusion length upon irradiation. Nevertheless, this diffusion length remains larger than the perovskite film thickness used in the solar cells, even for the highest accumulated fluence of 10E16 e� cm�2. This demonstrates that PSCs are promising candidates for space applications.

11:00 AM EL15.02.06
Stress Testing of Perovskites Solar Cells For Stable Operation in Space Kaitlyn VanSant[1,2], Ahmad Kirmani[3], Kyle Crowley[1], Xiaopeng Zheng[2], Joseph Luther[2], Timothy Peshek[1] and Lyndsey McMillon-Brown[1]; [1]NASA Glenn Research Center, United States; [2]National Renewable Energy Laboratory, United States; [3]Rochester Institute of Technology, United States

Perovskite solar cells (PSCs) could transform space energy generation by providing a low-cost alternative to existing space photovoltaic (PV) technologies. They exhibit promising radiation tolerance, high specific power and low costs could be obtained with high volume manufacturing. NASA has significant interest in designing a PSC resilient to stress conditions relevant to the lunar surface, with a specific focus on understanding contacts and barrier layers to maximize stability.

To achieve this goal, the cell must be able to withstand extreme ultraviolet light, harsh radiation, hard vacuum and temperatures up to 75°C, assuming thermal management will protect the cells from the lunar ambient temperature extremes.[1] In order to be a viable space PV technology, the perovskite solar cells will also need to be space-qualified, which will require either encapsulation or a barrier layer to protect the cells from the terrestrial environment (prior to launch) and on the lunar surface. Space-qualified cells must also meet NASA's strict out-gassing requirements.[2]

In our research, we focused on the down-selection of both the contacts and the barrier layers for solar cells designed to operate in the lunar environment. We used a p-i-n device architecture, with a triple cation perovskite absorber.[3] We explored contacts composed of bathocuproine (BCP)/Ag, BCP/Au and a contact consisting of SnO_x/Indium tin oxide (ITO)/Au, referred to as ITO contacts.[4] For the barrier layers, we investigated a SiO barrier layer alone; a space-grade two-part silicone, DC93-500, with cover glass; and a combination of these two schemes (i.e. SiO/DC93-500/cover glass). Preliminary results from stressing the cells at 75°C under modest vacuum conditions (10 – 20 mTorr) were used to select the most thermally robust combination of contacts and barrier layers. We then used a cryostat to apply light, heat and vacuum conditions simultaneously to these selected cells. To augment these cell-level stress studies, synchrotron X-ray diffraction data was measured as a function of temperature at SLAC to assess the crystallographic structural stability of the full cell stack, over a similar temperature range to that used for the thermal vacuum stress testing.

In this presentation, we will summarize the optimal combination of contacts and barrier layer(s) that we devised, based on the results of this stress testing. We will also report on how cells with the selected architecture performed, when exposed to electron-beam irradiation.

SESSION EL15.03: Radiation Tolerance of Perovskite Photovoltaics
Session Chairs: Bibhudutta Rout and Ian Sellers
Wednesday Afternoon, April 12, 2023
Moscone West, Level 3, Room 3000

1:30 PM *EL15.03.01
Perovskites Built for Space—Radiation, Thermal Cycling, Cell Design and Packaging Joseph Luther; National Renewable Energy Laboratory, United States

The space power market is now undergoing rapid growth with many more small satellites to be launched over the coming years with significant cumulative power requirements. Perovskites offer a unique potential alternative to both Silicon photovoltaics and III-V multijunction technology used today due to perovskites unique defect/radiation tolerance, packaging/lightweight configurations coupled with their low cost. However, they must first be shown to withstand the harsh environments which can involve proton, electron, neutron, and alpha particle irradiation, coupled with rapid and extreme thermal cycling, and high temperatures reached under the more powerful AM0 spectrum (1347 W/m2 vs 1000 W/m2 for AM1.5G) Perovskites devices offer many design flexibilities which can be exploited to construct devices specifically for space conditions but must each be tested for nuances in stability and performance. One such example is that perovskite cells with "PIN" geometry (which is defined as a structure with hole contact deposited before the Perovskite and electron contact after the perovskite) can be designed to operate with a temperature coefficient as low as 0.08 %/K, which is among the best in all photovoltaics, whereas other configurations show much more undesirable decrease in performance at high temperature. Thus, when designing a cell specifically for space application, it is critical to explore each of the space stressors as a function of the layers, compositions, and packaging. Here, I will discuss guidelines and initial testing results for perovskites using earth-based radiation sources for evaluation radiation tolerance in various space orbits. These results will be discussed with the community at MRS to better understand the feasibility of perovskite technology and potential collaboration opportunities for space applications.

2:00 PM *EL15.03.02
Scalable Halide Perovskites—Radiation Tolerance and Processing Sensitivities Samuel D. Stranks; University of Cambridge, United Kingdom

Halide perovskites have opened up a new world of semiconductors that can be processed inexpensively by solution or vapour yet perform exceptionally well. These materials are realising new paradigms for solar cell manufacturing at high throughput, including lightweight, high power modules that could enable new applications in space, aerial communications and electric vehicles. Here, I will show new results in which we have vapour-deposited tunable halide perovskite absorbers, which we in turn use in high-performance tandem cells. I will show how sensitive the fabrication can be to processing conditions, and how to control such parameters to realise high performance including with passivation approaches. I will also show tests of halide perovskite devices for proton radiation hardness required for space applications, and characterise the devices on different length scales. The materials demonstrate extremely good resilience to proton radiation even at very high doses. However, I will also show their limitations when bombarded with electrons or X-rays.

We propose the recently expanding field of hybrid organic-inorganic metal halide perovskites solar cells to offer avenues to achieve high specific power (power/mass) needed for space-based power systems. These perovskites present tuneable band gaps ideal for a solar cell absorber layer, when combined with their favourable carrier diffusion lengths arising from high carrier mobility and lower ease of formation of deep-band defects, have thus far resulted in single-junction record efficiencies of 25.7% -perovskite solar cell have over taken efficiencies of thin-film Silicon solar cells. The ability to process the perovskite family of materials at temperatures below 473K via solution processing techniques such as spin-coating, spray coating, and even printing offers avenues for low-cost fabrication of perovskite solar cells. Moreover, work has been done to investigate the viability of perovskite solar cells on a flexible substrate, and it has been shown to be robust enough for flexible and ultralightweight cells, achieving power densities as high as $23Wg^{-1}$ [1]. As such, perovskite solar cells present themselves as a potential candidate for the high specific power technology necessary to enable space based solar power. More critically, perovskites are sensitive to oxygen and water vapor, both of which are not present in space and hence they inevitably become an extremely important opto-electronic energy materials to investigate for space applications.

Hybrid organic-inorganic lead halide perovskite solar cells and their constituent device material layers were irradiated to examine their viability for space energy applications. Perovskites cells, hole and electron transport material films, and transparent conducting films were irradiated with 30keV and 75keV protons at fluences ranging from 4.3×10^{13} p^+ cm^{-2} to 1.7×10^{14} p^+ cm^{-2}. The optical transmission and electrical resistances of the charge-transport material films were characterized before and after irradiation to deconvolve and assess the individual contribution of these materials on the degradation of perovskite devices. We conclude, some materials like PEDOT do become more opaque. Apart from these, electrically, the damage to many of these materials is low enough that there is only a small impact on the perovskite cell performance. The results of this proton irradiance study can serve as material selection guide for space cells. Furthermore, we characterized the perovskite solar cells through light-IV curves and EQE spectra before and after irradiation. Further to our initial study [2], we observed large scale degradation trends post large doses of proton irradiation. However, we demonstrate temperature-dependent anneal recovery post irradiation. We note that while heating a cell can recover most of its performance, this recovery peaks at 80°C and this reversible recovery starts reaching its limit when proton irradiation energy gets high, up to 75KeV.

Radiation Tolerance, High Temperature Stability and Self-Healing of Triple Halide Perovskite Solar Cells Hadi Afshari[1], Sergio Chacon[1], Brandon Durant[1], Rose Crawford[1], Bibhudutta Rout[2], Giles Eperon[3] and Ian R. Sellers[1]; [1]University of Oklahoma, United States; [2]University of North Texas, United States; [3]Swift Solar, United States

$FA_{0.8}Cs_{0.2}PbI_{2.4}Br_{0.6}Cl_{0.02}$ triple halide perovskite solar cells are studied for potential space power applications including exposure to high temperatures and variable radiation conditions. The radiation tolerance of these devices is investigated in response to increasing levels of proton irradiation and fluence. Parameters were chosen to investigate the relative effects of nuclear displacement and electron ionization processes upon the solar cells being assessed. The change in the photovoltaic (PV) parameters was monitored with regards to energy and fluence of irradiation at various temperatures. The experimental results indicated a considerable reduction in the PV parameters affecting *Jsc* and FF with minimal effect on *Voc* as the energy and fluence of the irradiation increased. However, a suite of complementary measurements suggests that while the irradiation negatively affects the transporting layers and interfaces in the devices: the perovskite absorber is not affected in any significant way. Moreover, these systems were observed to self-heal under ambient conditions in the dark demonstrating the unique behavior of perovskite solar cells and their potential for future space power systems. This is further substantiated by high temperature measurements that indicate that the system under investigation displays no appreciable loss up to 490 K, supporting in particular their potential as candidate systems for future lunar missions.

3:30 PM *EL15.03.05
Potential, Radiation Tolerance and Damage Mechanisms of Perovskite Multijunction-Based Space PV Felix Lang[1], Giles Eperon[2], Jarla Thiesbrummel[1], Eike Köhnen[3], Francisco Pena-Camargo[1], Heinz-Chris Neitzert[4], Steve Albrecht[3], Samuel D. Stranks[5], Dieter Neher[1] and Martin Stolterfoht[1]; [1]Universität Potsdam, Germany; [2]Swift Solar, United States; [3]Helmholtz-Zentrum Berlin fuer Materialien und Energie GmbH, Germany; [4]Salerno University, Italy; [5]University of Cambridge, United Kingdom

Perovskite multijunction-based space PV systems promise excellent power conversion efficiencies beyond the detailed balance limit of their single junction counterparts while requiring only ultra-thin absorber layers. Their high power-weight (W/g) potentials consequently make them a dream power source for private-driven space exploration, planned satellite mega-constellations, and future habitats on Moon and Mars. Yet there are still questions regarding their long-term stability under light, bias, and ambient conditions, and application outside Earth’s protective atmosphere place even more extreme demands on material and device stability.

In this presentation, I will review lessons learned during various high-energy proton irradiation experiments we conducted on perovskite single-junctions, as well as perovskite/Silicon, perovskite/CIGS, and perovskite/perovskite tandem PV. [1–4] With perovskite subcells being highly radiation tolerant perovskite/perovskite tandems, even exceed commercially available, industry-standard III-V semiconductors on Ge triple-junction space solar cells in terms of radiation tolerance.

To enable a deeper understanding of potential degradation mechanisms, I will present various subcell-specific characterization techniques that allow disentangling of the different losses and limiting factors in monolithic interconnected perovskite-based multijunction solar cells. Contrary to standard *JV* characterizations, this approach allows us to assess the performance and loss mechanisms of the individual subcells, even after their assembly in a monolithic tandem stack. I will begin with subcell-specific characterizations after high energetic irradiation mimicking the harsh radiation environment in space and then continue with various examples in which we identify limiting loss mechanisms and efficiency potentials in perovskite/silicon and perovskite/perovskite tandems.[5,6,7] After all, such deep understanding is pivotal to further optimizing the efficiency as well as the stability for space applications.

Impact of the Ionizing Radiation on the Halide Perovskite Crystal, Thin Films and Devices Aldo Di Carlo[1,2], Arthur Istheev[3,4,5], Danila Saranin[3], Fabio Matteocci[1], Daniele Trucchi[2] and Marco Girolami[2]; [1]CHOSE - Univ of Rome Tor Vergata, Italy; [2]ISM-CNR, Italy; [3]Laboratory of Advanced Solar Energy (LASE), NUST-MISIS, Russian Federation; [4]Moscow Center for Diagnostics & Telemedicine, Russian Federation; [5]N. Semenov Federal Research Center for Chemical Physics, RAS, Moscow, Russian Federation

Halide perovskites (HP) have demonstrated great potential for photovoltaics and detector applications, due to the strong absorption, large mobility lifetime product, structural defect tolerance, and wide range of chemical compositions with high Z atoms. Ionizing radiation sensing is one of the emerging directions for the use of halide perovskites, which already demonstrated high radiation hardness. Indeed, the progress in the development of the HP science can demonstrate potential technological breakthrough for ionizing radiation detectors in terms of detection performances, stability, low-temperature processing and conformable lightweight integration thanks to its possible flexibility. The typical composition of HP contains heavy elements (Cs, Pb, Ag, Bi, Sn, I, Br) with atomic numbers in the range of 47-82, which is even larger in comparison to widely used X-ray absorber - CZTS (max atomic number is 52). Moreover, in contrast to state-of-art materials for ionizing radiation detection, the band gap of HP can be easily varied, through cationic and/or anionic substitution, between 1.2 to 2.8 eV. One principal technological advantage of the halide perovskite technology is a low-temperature (100°C) solution processing, that permits the fabrication of devices with various printing methods, such as ink-jet, slot-die, spray etc., all are compatible to flexible substrates (plastic and glass).

In this talk we will discuss the radiation properties of some members of the halide perovskite family, such as $MAPbBr_3$ and in single crystals and in thin film $FAPbBr_3$ and $CsFAPbI_{3-x}Cl_x$ configuration under inizing radiation such as E-beam and X-ray. We investigate the changes in structural and optical properties of perovskite crystals induced by e-beam irradiation with high flux (10^{15} electrons per cm^2, energy 5 MeV) and an extremely high dose (25 MRAD). Ellipsometry measurements demonstrated a strong increase of the Urbach tails related to radiation-induced defects. A trap-induced Fermi level pinning at +0.56 eV was observed by Kelvin probe microscopy analysis of the irradiated $MAPbBr_3$ monocrystals with respect to pristine crystals. However, X-ray diffraction analysis and optical depth analysis with two-photon excitation microscopy photoluminescence reveal that, despite the large irradiation dose, the structural and optical properties are stable. This clearly shows that $MAPbBr_3$ crystals are stable for high energy applications. To evaluate defects related parameters such as activation energy and density we fabricated HP Schottky diodes with rectifying electrodes and we performed deep level transient spectroscopy at different absorbed dose of the radiation. DLTS analyses clearly demonstrated the self-healing properties of halide perovskite to the radiation damage.
X-ray photocurrent measurements, performed on $FAPbBr_3$ thin films, highlight their outstanding properties in terms of signal stability with time, high bulk specific sensitivity, excellent linearity with dose-rate, all extremely desirable properties for a detector conceived for X-ray imaging or radiotherapy applications. In addition, the possibility of working in photovoltaic mode (i.e., at zero-bias), is an added value, making $FAPbBr_3$ thin films appealing for the fabrication of portable detectors with no need for power supply.

Monolayer-Modified Hole Transporter Improves Space Compatability for Perovskite Photovoltaics Calton J. Kong[1,2,3], Mohin Sharma[4], Mritunjaya Parashar[4], Kaitlyn VanSant[3,5], Brian Wieliczka[3], Bibhudutta Rout[4], Joseph Luther[3] and Ahmad R. Kirmani[3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]National Renewable Energy Laboratory, United States; [4]University of North Texas, United States; [5]NASA Glenn Research Center, United States

Perovskite solar cells demonstrate great promise as the next generation photovoltaic technology and interest is also rising in their operation under harsh environments such as near-Earth orbits and deep space. In this talk, we develop one of the most space tolerant perovskite solar cell device designs reported to date. To achieve this, we first modify the commonly used poly[bis(2,4,6-trimethylpheneyl)amine] (PTAA) hole transporter with a self-assembled monolayer of 2-(9H-carbazol-9-yl)ethyl]phosphonic acid (2PACz) molecules. This monolayer-modified charge transporter results in columnar perovskite grain growth minimizing grain boundaries, suppressing bulk defects, and increasing open-circuit voltage by ~40 mV. Compared to control devices based on PTAA hole transporter, these cells remarkably show a 22% radiation tolerance increase when irradiated with 10^{13} cm^{-2} fluence of 75 keV protons, and a 18% increase in thermal tolerance when aged at 110 °C, conditions commonly experienced during space operation. Replacing silver with ITO as a back contact further boosts tolerance to these stressors due to its encapsulation benefits. The wide-ranging advantages offered by this low-cost device design make it appealing for terrestrial and space photovoltaic applications.

4:45 PM EL15.03.08
Probing the Ion Migration and Radiation Tolerance of Triple-Cation Perovskite Solar Cells via Rutherford Backscattering Spectrometry
Mritunjaya Parashar[1], Mohin Sharma[1], Darshpreet Kaur Saini[1], Todd Byers[1], Ahmad Kirmani[2], Joseph Luther[3], Ian R. Sellers[4] and Bibhudutta Rout[1]; [1]University of North Texas, United States; [2]Rochester Institute of Technology, United States; [3]National Renewable Energy Laboratory, United States; [4]University of Oklahoma, United States

Mixed organic-inorganic halide perovskites (OIHPs) based solar cells have attracted the interest of researchers in recent years due to their potential for both terrestrial and space applications. As a result of the photovoltaic community's ongoing efforts, the triple-cation perovskite photoabsorber, ($Cs_{0.05}(MA_{0.17}FA_{0.83})_{0.95}Pb(I_{0.83}Br_{0.17})_3$) has emerged as one of the most promising compositions for perovskite solar cells (PSCs) in terms of stability and power conversion efficiency (PCE). Ion migration of the various cations/anions in OIHPs is considered one of the possible reasons for device degradation and hysteresis in the PSCs. Furthermore, PSCs are becoming viable candidates for space photovoltaic applications thus, it is critical to investigate the impact of radiation-induced degradation in PSCs. Ion beam techniques such as Rutherford backscattering spectrometry (RBS) can be a useful method to probe the elemental depth profile of multilayer PSCs as well as to study the inter-diffusion of various ionic species of OIHPs between the different interfaces. In the present work, we have used a 2 MeV He^+ beam to probe the evidence of ion migration between different interfaces in a state-of-the-art PSC having a device architecture as: Glass/ ITO/ SnO_2/ $Cs_{0.05}(MA_{0.17}FA_{0.83})_{0.95}Pb(I_{0.83}Br_{0.17})_3$/ Spiro-OMeTAD/$MoO_3$/ Au. During the analysis, the active area of the device were exposed up to irradiation equivalent to 5.5×10^{15} He^+/cm^2 which is orders of magnitude higher than the annual proton fluence (~10^{10}-10^{14} p^+/cm^2) in various outer space trajectories, and still any measurable evidence (with a depth resolution ~1 nm) of ion migration was not observed which suggests that the perovskite solar cells with the above device architecture have a high tolerance to the radiation. We will be presenting elemental compositional depth profiles as well as any beam-induced diffusion of the elements.

SESSION EL15.04: Radiation Detection Using Perovskite and Organic Semiconductors
Session Chairs: Felix Lang and Kaitlyn VanSant

Spectroscopic Radiation Detection Using Perovskites Jinsong Huang; University of North Carolina-Chapel Hill, United States

Metal halide perovskites are promising candidates for room temperature gamma-ray spectrum detectors, however, it is challenging to grow high-quality single crystals under operation conditions to make them performance competitive to existing materials. I will report the growth of centimeter-size organic-inorganic lead halide single crystals at high yield from low purity precursors using a relatively low-temperature solution method. By identifying the defects in these materials, a method will be presented to make most perovskite composition to have spectroscopic detection capability. We will report the application of perovskites for both direct and indirect detection. Finally the radiation hardness of these materials under X-ray and gamma-ray will be briefed.

8:45 AM *EL15.04.02
Radiation Monitoring with a Dosimeter Conformal to the Human Body Oana D. Jurchescu; Wake Forest University, United States

Radiation is used extensively in healthcare both for establishing diagnostics and as a powerful treatment tool. From visualizing features within bones, tissues, and organs to treating cancer, the radiation dose and point of contact to the human body are tailored to each patient’s needs. Administration of the correct dose is critical to the outcome of the procedure, and precise control of its path prevents serious damage that the ionizing radiation can induce to the healthy tissues surrounding the target volumes. Conventional dosimetry techniques used in clinical settings, however, are limited to providing only the absolute radiation dose a patient receives, and accurately measuring variations in its value over large areas remains a challenge. In this presentation I will discuss radiation detectors based on large area arrays of organic field-effect transistors (RAD-OFETs) that allow for high-resolution *in vivo* dosimetry at the skin surface. These dosimeters absorb radiation similar to the tissue, are low-cost, mechanically flexible and conformal to the human body, allowing for direct measurement of the radiation dose without the need for extensive data processing faced by current technologies. The mechanism responsible for radiation detection, as well as the sensitivity of the devices, are discussed. 2D-mapping the spatial distribution of the dose revealed non-uniformities in the received dose, with hotspots near the center beam. Our results are important because they provide the much-needed tools that can generate the information on the variations in the radiation dose over a large area, relevant to diagnostics and therapy in a clinical setting. The spatial control over the administered dose would allow for maximizing the target dose, while minimizing normal tissue dose when planning a patient’s radiation regimen.

This work has been performed in collaboration with Derek Dremann, Dr. Andrew Zeidell, Prof. James D. Ververs, Prof. J. Daniel Bourland, and Prof. John E. Anthony.

9:15 AM EL15.04.03
***Ab initio* Molecular Dynamics Calculations of Threshold Displacement Energies in Halide Perovskites** Mario F. Borunda[1], Rosty B. Martinez[1], Ahmad Kirmani[2] and Ian R. Sellers[3]; [1]Oklahoma State University, United States; [2]National Renewable Energy Laboratory, United States; [3]The University of Oklahoma, United States

Ab initio molecular dynamics (AIMD) simulations have been performed for different halide perovskites to investigate their response to low-energy radiation. The threshold displacement energy (E_d) is the minimum amount of transferred kinetic energy to an atom so that it generates a stable defect in the lattice of a particular material. The E_d is a critical physical parameter for simulating non-ionizing radiation damage in materials, the primary degrader of optoelectronic properties under radiation environments. AIMD allows us to probe atoms in different lattice directions and establish the E_d of the species in the halide perovskite. These efforts would allow for a better understanding of the radiation hardness of materials.

Fully Organic Thin Film Based Dosimeters for High Energy Ionizing Radiation Beatrice Fraboni[1,2]; [1]Univ of Bologna, Italy; [2]INFN, Italy

The development of novel high performing, thin and flexible sensors for the detection of ionizing radiation in real-time at affordable costs is rapidly increasing, as the technology currently available still fails to address the requirements of large-area, conformability and portability, lightweight and low power operation.
Organic small molecules and polymers are promising active layers for advanced dosimetry purposes, as their mechanical features allow the development of devices able to adapt to complex contoured surfaces, with outstanding portability (low power operation) and lightweight. Organic semiconductors can be processed from solution and deposited at low temperature (<150 °C), leading to the possibility to realize 2D matrices of pixels onto flexible and large-area substrates. They also provide the unique possibility to develop human-tissue-equivalent detectors, thanks to their density and composition, which makes

them ideal candidates for medical dosimetry applications. Their low average atomic number and density also grants a low absorption of the incoming radiation, making them extremely radiation-tolerant. The physical process of radiation detection for organic thin- film based detectors will be discussed in two different configurations: 1) the direct one, based on a simple planar device with an organic thin film as active conversion layer, and 2) the indirect one, based on a polysiloxane-based scintillating layer effectively coupled to an organic phototransistor (OPT)

Both configurations are thus fully organic devices and have been assessed for flexibility and operation at low power. We report on their performance under exposure to intense photons and MeV protons radiation fields, to evaluate their suitability as space crew members personal dosimeters. The direct configuration (planar 2-terminal device) can quantitatively and reliably measure the dose of protons impinging on the sensor both in real-time and in integration mode. This contribution will discuss how to detect and exploit the energy absorbed both by the organic semiconducting layer and by the plastic substrate, allowing to extrapolate information on the irradiation history of the detector. Their measured sensitivity S = (5.15 ± 0.13) pC Gy-1 and limit of detection LOD = (30 ± 6) cGy s-1 assess their efficacy and their potential as proton dosimeters in several fields of application. As for the indirect configuration, we will present its stability and operation for biases as low as 1V we will discuss a new kinetic model, developed to describe the detector response mechanism, able to precisely reproduce the dynamic response of the device under proton irradiation and to provide further insight into the physical processes controlling its response.

10:30 AM *EL15.04.05
Solution Preparation of Optical and Electronic Metal Halides Bayram Saparov[1], Zheng Zhang[1], Mehran Amiri[2] and May Nyman[2]; [1]University of Oklahoma, United States; [2]Oregon State University, United States

Perovskites and perovskite-inspired halides are continuing to attract the interest of a broad community of researchers as prospective materials for optoelectronic applications. In addition to their outstanding optical and electronic properties, the solution-processability of metal halides is among their greatest advantages. Low-temperature solution preparation not only reduces the processing cost but is also partly responsible for the remarkable diversity in chemical compositions and crystal structures of this class of materials. However, the solution chemistries of most metal halide systems and their relationship with the observed structural and chemical diversity are poorly understood. This is exemplified by the great variety of solution processing conditions reported for both new materials synthesis and solution deposition of thin films reported in the literature. In this talk, our ongoing research efforts to study and develop understanding of several metal halide systems will be summarized. Our combined computational and experimental approach includes UV-vis spectroscopy and electrospray ionization mass spectrometry (ESI-MS) measurements, small-angle X-ray scattering (SAXS) and density functional theory (DFT) calculations. Our early success in several pseudoternary systems will be described along with the outstanding challenges in studying more complex multicomponent systems will be discussed. This study shows that understanding the solution chemistry of multinary metal halide systems could be a valuable tool for discovering new functional materials for practical applications.

11:00 AM EL15.04.06
Direct Detection of 5 MeV Protons by Mixed 3D-2D Perovskite Flexible Films Laura Basiricò[1,2], Ilaria Fratelli[1,2], Matteo Verdi[1,2], Andrea Ciavatti[1,2], Luisa Barba[3], Olivia Cesarini[2], Giorgio Bais[4], Maurizio Polentarutti[4], Massimo Chiari[2] and Beatrice Fraboni[1,2]; [1]University of Bologna, Italy; [2]National Institute for Nuclear Physics, Italy; [3]National Council of Research, Italy; [4]Elettra-Sincrotrone Trieste, Italy

The development of detectors for protons and heavy particles is a long-lasting research topic not only for fundamental applications, but more recently, in the medical field for hadron therapy of cancer. In this application, ion beams are used for the controlled treatment of cancer by focusing them onto small volumes, to avoid the spreading of the radiation to healthy tissues. For this reason, there is an increasing demand of systems optimized for the accurate in-situ, real-time recording and mapping of the dose delivered during a treatment plan.
Metal halide perovskites are rapidly emerging as active materials in low cost high performing ionizing radiation detectors thanks to strong absorption of ionizing radiation, high charge carrier mobilities, long exciton diffusion, long charge carrier lifetime, and excellent optical properties. [1] Further, they combine the high performance of traditional inorganic semiconductors with the low cost, large area scalable, deposition methods (i.e., printing technologies) typical of organic semiconductors. However, the direct proton beam detection or dose-monitoring by perovskite based devices has not been explored yet and only one paper has been published so far on direct proton detection, implemented by fully organic flexible devices.[2]
In this work, we propose a novel flexible proton detector based on mixed 3D and 2D perovskites films deposited from solution. Mixed 3D-2D perovskites are formed by mixing 3D (based on methylammonium (MA) cations) and 2D (based on larger organic ammonium (OA) cations) structure perovskites. Their employment has been reported as an effective strategy to retain the exceptional transport properties of 3D perovskites and the high stability induced by the layered structure of 2D perovskites. By adding the 3D phase ($MAPbBr_3$) we here aim to enhance the radiation absorption of protons by the perovskite film, thanks to the higher density of $MAPbBr_3$ and to the higher thickness of the active layer for mixed compounds.
The here proposed devices demonstrate an accurate monitoring of proton dose with instant feedback and low limit of detection, and provide a stable response even after hard and long-lasting proton irradiation.
In fact, the detector exhibited a stable response to repetitive irradiation cycles with sensitivity up to (290 ± 40) $\text{nC Gy}^{-1}\text{mm}^{-3}$ and a radiation tolerance is also assessed up to a total of $1.7 * 10^{12}$ protons impinging on the beam spot area, with a maximum variation of the detector's response of 14%.
The presented results provide an effective solution to the challenge of identifying novel functional materials and portable devices for real-time accurate monitoring of proton dose, addressing the quest for radiation hardness, low-cost scalability over large areas and mechanical flexibility, still unsolved for a range of application which span from personal dosimetry to large area and lightweight detectors for large accelerators facilities and space missions.

11:15 AM EL15.04.07
Record Stability for Fully Passive Perovskite-Based X-Ray Detectors Using Starch as Polymeric Template Andrea Ciavatti[1,2], Antonella Giuri[3], Matteo Verdi[1], Aurora Rizzo[3], Laura Basiricò[1], Silvia Colella[3] and Beatrice Fraboni[1]; [1]DIFA - University of Bologna, Italy; [2]INFN - Bologna, Italy; [3]CNR NANOTEC, Italy

Lead-Halide hybrid Perovskites are recently emerging as promising materials for high energy radiation detection thanks to the combination of excellent transport properties, even in polycrystalline films, and their solution processability. Since 2015 hybrid lead-halide perovskites have attracted increasing attention as an interesting alternative to traditional semiconductors used for radiation detection. The presence of heavy elements inside the atomic structure ensures a high X-ray absorption coefficient, together with the high crystal density, make them ideal for direct detection of ionizing radiation. High performance detectors were demonstrated in both polycrystalline and single crystal forms [1], outperforming traditional Si- or CZT-based sensors. Despite top performance of perovskite single crystals, they do not fully exploit the solution processability on flexible substrates, the deposition over large area and the low-voltage operation, typical of thin-film devices. Flexible thin-film perovskite X-ray detectors have been recently reported [2,3]; however, low operational and environmental stability is limiting their further development toward commercialization.
Here we report a strategy based on using starch as a polymeric template for the fabrication of stable thin film perovskite direct X-ray detectors, which confers to the film a series of characteristics that cannot be achieved with pristine perovskites, in particular higher stability in ambient conditions, improved

homogeneity of the film also at greater thicknesses, enhanced mechanical flexibility and robustness. The approach is highly reliable and versatile, in fact, we demonstrate it in this work for different perovskite compositions, namely $MAPbI_3$ and $FA_xMA_{1-x}PbI_3$. Moreover, the starch polymer allows excellent tuning of the active layer thickness, since acting as a rheological modifier enhances the viscosity of perovskite precursors' ink.
The proposed p-i-n photodiodes can operate with no external bias applied (fully passive devices), thus strongly improving the operation stability by decreasing the ion migration. We monitored the current response at 40kVp of X-ray radiation for detectors with different active layers compositions and thicknesses. We found that a 20 wt% starch concentration in the perovskite precursor solution, corresponding to 1050 nm thick perovskite layer provides the best trade-off between X-ray absorption, charge collection efficiency and performance stability. We measured an X-ray sensitivity of 5.5±0.2 $\mu C\ Gy^{-1}\ cm^{-2}$ (at 0 V), with no degradation on the electric characteristic after 9.4 Gy irradiation.
The device degradation was monitored for samples stored in air for a time window of 630 days. During this period, the samples were subjected to temperatures and relative humidity as high as 30°C and 70% respectively during summer times. After 1.7 years the films retained their dark color and nice dynamics curves under X-rays were measured, demonstrating an exceptional stability: 97% of the initial sensitivity was retained for the best perovskite-starch composite formulation making it the most stable unencapsulated perovskite X-ray detector reported so far.

SESSION EL15.05: Wide Bandgap Lightweight Electronics for Harsh Environments
Session Chairs: Bayram Saparov and Kaitlyn VanSant
Thursday Afternoon, April 13, 2023
Moscone West, Level 3, Room 3000

1:30 PM *EL15.05.01
Novel AlGdN Alloys for Integrated Detection in Radiation Environments Nancy Haegel; NREL, United States

Metastable ternary nitrides are a growing class of materials that offer broad potential for both new functionality and heterogenous integration. In this work, we are synthesizing $Al_xGd_{1-x}N$ as a radiation hard ultrawide bandgap semiconductor, with potential for integrated detection high energy particles including neutrons and gamma rays. Metastable $Al_{1-x}Gd_xN$ alloys have been synthesized via non-equilibrium radio frequency co-sputtering in a combinatorial system allowing exploration of a range of Gd compositions. First-principles calculations show that the limiting critical composition for a wurtzite to rocksalt phase transition is $x_c = 0.82$. Theory suggests that at temperatures below 1000 K there is a large miscibility gap limiting Gd incorporation in AlN to only a few percent. However, by accessing higher effective temperature through non-equilibrium growth we have achieved Gd concentrations up to 24%, the highest Gd^{3+} incorporation into the wurtzite phase reported to date. Single-phase compositions up to $x \approx 0.24$ are confirmed by high resolution synchrotron grazing incidence wide angle X-ray scattering and transmission electron microscopy (TEM).
These new materials have been characterized using a range of analytical tools, including X-ray diffraction, Rutherford Backscattering Spectroscopy, cathodoluminescence, temperature dependent X-ray, ellipsometry, and transmission electron microscopy with high resolution energy dispersive X-ray. Energy dispersive X-ray (EDX) imaging in the scanning electron microscope and cathodoluminescence, monitoring an internal UV transition within the Gd atoms, indicate uniform distribution of Gd in thin films with columnar grains. High resolution EDX in the TEM shows homogeneous incorporation of Al, Gd and N in films on the order of ~ 200 nm in thickness, and TEM imaging indicates a wurtzite structure based on fast Fourier transform (FFT) analysis, consistent with the synchrotron grazing incidence wide angle X-ray scattering.
Because $Al_{1-x}Gd_xN$ is a heterostructural alloy (AlN is a wurtzite structure, GdN is a rocksalt structure), a key part of the project is to explore the fundamental science to enable stable integration of new tunable metastable nitride materials into thin film structures for high radiation and high temperature environments. Interfacial understanding and control are critical and could potentially provide both enhanced structural stability for these metastable alloys (e.g., via designed lattice matching) and tunable electronic functionality (e.g., ohmic to rectifying behavior). We will review the status of contact materials for high resistivity high energy particle detectors and discuss paths to device integration.

2:00 PM *EL15.05.02
Influence of Mechanical Hotspots on Radiation Susceptibility of GaN HEMTs Md Rasel[1], Nahid Al-Mamun[1], Sergei Stepanoff[1], Aman Haque[1], Khalid Hattar[2], Douglas Wolfe[1], Fan Ren[3] and Stephen Pearton[3]; [1]The Pennsylvania State University, United States; [2]Sandia National Laboratories, United States; [3]University of Florida, United States

Performance and reliability of microelectronic devices are governed by the mechanical strain. Typically, strain engineering implies uniformly distributed strain. However, we offer a different perspective by hypothesizing that very small but localized strain (or stress) may have significant impact on the overall behavior of AlGaN/GaN high electron mobility transistors (HEMTs). Micro to nanoscale confined mechanical stress fields may develop unavoidably and are ignored because their spatial average is insignificant. We exploit high resolution techniques such as transmission electron microscopy (TEM) and micro-Raman spectroscopy to spatially resolve the stress field in GaN HEMTs to demonstrate the stress localization and then radiation effects.

To study stress localization effects on the global electrical characteristics, we introduced a highly localized strain relief by milling a 20×30 μm^2 micro trench about 70 µm deep on the backside of an 800×840 μm^2 size HEMT die. The resulting local relaxation of in-plane residual strain was mapped using micro-Raman technique. Our results show that a decrease of only 0.02% strain can decrease the overall output saturation current up to ~20 %. The drop of output current is attributed to reduced two-dimensional electron gas (2DEG) sheet carrier density and electron mobility due to the strain relief in the device layers. However, the mechanistic process of strain relief also causes defect generation at the interfaces, which increases leakage current. Our technique for localized strain re-distribution could be an effective tool to surrogate the influence of inherent localized strain build-up across the channel of electronic devices.

To study radiation effects, we exposed the HEMTs to gamma rays (up to 10 megaRads dose at 180 kiloRads per hour). We report the thermal and mechanical responses in terms of the changes in lattice strain and temperature, which were simultaneously characterized by changes in phonon frequency of E2 (high) and A1 (LO) from on- state and unpowered/pinched off reference states. Lower doses of radiation improved the electrical properties, however degradation initiated at about 1 megaRads. We observed about 16% decrease in saturation current and 6% decrease in transconductance at the highest dose. However, leakage current increase by 3 orders of magnitude was the most notable radiation effect. We observed temperature increase by 40% and mechanical stress increase by a factor of three at dose of 10 megaRads compared to the pristine devices. Spatial mapping of mechanical stress along the

channel identifies the gate region as mechanically affected area, whereas the thermal degradation was mostly uniform. Transmission electron microscopy showed contrast changes reflecting high vacancy concentration in the gate region. These findings suggest that localized stress (mechanical hotspots) may increases vulnerability to radiation damage by accommodating higher concentration of defects that promote leakage current.
Finally, we present experimental results on a novel concept of electron wind force driven room temperature annealing of GaN and SiC devices. This technique was applied on Gamma irradiated HEMT and SiC diodes. We demonstrate full recovery of the HEMTs irradiated to 10 mega-Rads gamma radiation. About 200% performance improvement was recorded for the SiC diodes. Our hypothesis is that mechanical stress waves are instrumental in eliminating interfacial defects.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

3:30 PM EL15.05.03
Chemical Modifications of Low-dimensional MoS$_2$ in Radiation-Harsh Environments Kory D. Burns[1], Christopher M. Smyth[2], Alex M. Boehm[2], Eric Lang[3], Taisuke Ohta[2], Jordan A. Hachtel[4] and Khalid Hattar[5]; [1]University of Virginia, United States; [2]Sandia National Laboratories, United States; [3]The University of New Mexico, United States; [4]Oak Ridge National Laboratory, United States; [5]The University of Tennessee, Knoxville, United States

The resilience of MoS$_2$ to energetic particles and understanding the chemical modifications induced are of great interest for the realization of long-term space-based electronics incorporating low dimensional materials. In this contribution, we probe these properties in MoS$_2$ using 10 keV He$^+$ ion irradiation to alter the chemical composition of MoS$_2$ enabling selective alterations of the work function. By combining photoemission electron microscopy (PEEM), optical spectroscopy, X-ray photoelectron spectroscopy (XPS), structural characterization, and monte carlo simulations we unveil the role of structural defects in the band onset potential, work function, electron binding energy (E_B) of the occupied states, and ionization energy. Here, we assess the influence of layer number and substrate interactions in the defect formation process at different fluences. Ultimately, we provide an avenue for efficient testing of the radiation tolerance of low-dimensional materials and analyze the defect-property relationship progression in extreme environments. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Negative Capacitance HfO$_2$-ZrO$_2$ Superlattice Gate Stack Towards High-Performance Radiation-Hard Electronics Nirmaan Shanker[1], Suraj Cheema[1], Li-Chen Wang[1], Sergei Stepanoff[2], Douglas Wolfe[2] and Sayeef Salahuddin[1,3]; [1]University of California, Berkeley, United States; [2]The Pennsylvania State University, United States; [3]Lawrence Berkeley National Laboratory, United States

There is an increasing demand for high-performance, low-power microelectronics that can operate in extreme radiation environments for space, nuclear, and avionic applications [1]. One route towards high-performance, low-power transistors is to increase the gate capacitance, i.e. lower equivalent oxide thickness (EOT), which reduces the operating voltage and therefore power. However, EOT scaling has been stagnant since the adoption of the high-κ metal gate SiO$_2$/HfO$_2$ gate stack [2], as conventional EOT scaling approaches, such as SiO$_2$ interlayer (IL) scavenging, in which the IL EOT contribution is reduced, result in significantly degraded gate leakage, carrier mobility, and reliability characteristics due to the closer proximity of the Si channel to the high-κ dielectric [2]. In contrast, integrating a ferroelectric negative capacitance (NC) gate oxide [3] can scale EOT while maintaining gate leakage, mobility, and reliability, as the IL thickness is no longer reduced [3]. We have previously demonstrated a 1.8 nm ferroelectric-antiferroelectric HfO$_2$-ZrO$_2$ superlattice (HZH) gate stack boasting a capacitance enhancement over the 8 Å SiO$_2$ IL layer via the NC effect [3]. Furthermore, once the HZH gate stack was integrated into 90 nm L_g silicon-on-insulator (SOI) nMOS transistors, gate leakage, electron mobility, and the PBTI reliability were unchanged relative to a conventional high-κ dielectric HfO$_2$ gate stack [3, 4], while maintaining the capacitance enhancement and demonstrating a 14% and 25% increase in ON current (I_{on}) and transconductance (g_m) at the same operating voltage, respectively [3, 5].
In this work, we investigate the total ionizing dose effect (TID) of gamma radiation (^{60}Co source) up to 10 Mrad on the NC HZH gate stack integrated into bulk metal-oxide-semiconductor (MOS) capacitors and 90 nm L_g SOI (~20 nm) nMOS transistors. In the bulk MOS capacitors, both EOT and gate leakage are maintained up to 10 Mrad dose with negligible flatband voltage shifts, suggesting minimal charge trapping within the NC HZH gate stack. In the 90 nm L_g SOI (~20 nm) nMOS transistors, the only significant change was a dose-dependent negative threshold voltage (V_T) shift (-250 mV at 10 Mrad), while changes in transistor metrics such as EOT, I_{on}, g_m, and subthreshold swing were negligible. The negative V_T shift was attributed to electrical coupling to trapped charges in the buried oxide (BOX) layer of the SOI substrate, consistent with previous reports of TID effects on short-channel SOI transistors incorporating conventional high-κ dielectrics [1] and can be mitigated by employing an ultrathin BOX layer (~10 nm) [1]. Overall, we demonstrate that the NC HfO$_2$-ZrO$_2$ gate stack can be integrated into radiation-hard electronics and serve as an avenue for next-generation high-performance radiation-hard electronics in extreme environments.

A High-Detectivity, Fast-Response, and Radiation-Resistant TiN/CdZnTe Heterojunction Photodiode Mykhailo Solovan[1], Andriy Mostovii[1], Hryhorii Parkhomenko[1], Marat Kaikanov[1], Nora Schopp[2], Ernest Asare[1], Taras Kavalyuk[3], Dmytro Korbutyak[4] and Viktor Brus[1]; [1]Nazarbayev University, Kazakhstan; [2]University of California, Santa Barbara, United States; [3]Charles University, Czechia; [4]National Academy of Sciences of Ukraine, Ukraine

Photodiodes have found wide practical applications as sensing and information transmission technology. However, some fields of their possible applications require added features besides excellent performance characteristics. For instance, the rapid development of commercial and scientific space programs and large-scale nuclear safety efforts in radioactively contaminated areas considerably demands next-generation radiation-resistant optoelectronic materials and devices. The heterojunction photodiode device concept opens a broad range of possibilities in combining different semiconductor materials with unique properties resulting in added functionalities, but with the price of detectivity and response time compared to conventional silicon photodiodes.
In this work, we proposed a novel *high-performance and radiation-resistant* UV-vis-NIR (300 – 820 nm) heterojunction photodiode based on radiation-resistant functional semiconductor materials: titanium nitride (TiN) 'window' layer and cadmium zinc telluride solid solution (CdZnTe) photoactive layer. The developed TiN/CdZnTe heterojunction photodiodes **concurrently revealed outstanding detectivity D^* = 4.14×10^{12} Jones @ -0.2 V and rise/fall response times of 3.5/3.8 μs @ -1.5 V** outperforming existing similar heterojunction optoelectronic devices based on photoactive compound semiconductor materials.[1] Moreover, the added feature of the proposed heterojunction photodiodes is their **advanced radiation resistance**,

experimentally demonstrated under *extreme conditions* of short impulse proton irradiation (170 keV) with an accumulated fluence of 2×10^{12} proton/cm^2. This unusual synergy of high performance and radiation resistance of the TiN/CdZnTe photodiodes is crucial for their reliable, long-term operation under the detrimental influence of ionizing radiation in extreme environments like space or radioactively contaminated zones.
We have a strong belief that our work is of interest to a broad range of material scientists and device engineers, as it pushes the current detectivity-response time boundaries, defined by the long-standing materials science and device engineering problems in developing **simultaneously highly sensitive, fast-responding, and radiation-resistant optoelectronic devices** based on compound semiconductors.

Fast Engineering Models for Radiation-Induced Defect Production in Thin Materials Henry R. Little, Christopher Lenyk, Darren Holland, Adib Samin and Whitman Dailey; Air Force Institute of Technology, United States

Due to the rapid evolution of electronic devices based on advanced lithography techniques and the commercialization of space, methods are needed to assess and predict performance in adverse radiation environments of both the transient and long-term response to irradiation. Experimental measurements of radiation damage generally exist on the order of hours after irradiation, and simulations are able to provide detailed predictions of damage out to the order of picoseconds. Additionally, radiation damage and interactions at depths below the mean free path of radiation in a particular material have long proven difficult quantities to measure and challenging to predict. A potential method is explored for predicting the concentration of defects in a material resulting from neutron irradiation, and the method's output is compared against experimental results for the well-studied material, MgO. The Monte Carlo Neutral Particle transport code (MCNP), leveraging the PTRAC module, is used to simulate irradiation of MgO samples with dimensions that are sub-mean free path, in the Oak Ridge National Laboratory's High Flux Isotope Reactor (HFIR). Cluster dynamics results and atomic displacement theory are used to compute the total number of defects in transient phase and account for the effects of defect saturation and thermal annealing. Comparison of the long-term response is then compared against actual experimental results of MgO irradiation in the HFIR and shown to agree within a factor of two. The method is then broadened to examine the spatial distribution of defects in the sample. Other materials are also explored for comparison including Si and GaN.

In-situ and ex-situ Spectral Response Characterization of the Radiation Damage and subsequent Recovery during Proton Irradiation of Silicon and Perovskite based Solar Cells Heinz-Chris Neitzert[1], Felix Lang[2], Andrea Denker[3], Juergen Bundesmann[3], Lucio Gialanella[4], Paola Delli Veneri[5], Lucia Mercaldo[5], Maryamsadat Heydarian[6], Alexander J. Bett[6] and Martin Schubert[6]; [1]Universita di Salerno, Italy; [2]University of Potsdam, Germany; [3]Helmholtz Zentrum Berlin fuer Materialien und Energie GmbH, Germany; [4]Universita della Campania "Luigi Vanvitelli", Italy; [5]C.R. ENEA Portici, Italy; [6]Fraunhofer Institute for Solar Energy Systems ISE, Germany

The dynamics of the radiation induced degradation of space solar cells is complex and often degradation and annealing are competing processes, in particular if elevated solar cell operation temperatures are reached. In-situ characterization of the degradation process during exposure of the solar cells to high energy particles can be simply performed by monitoring of the radiation-induced current, that is strongly correlated to the photoelectric properties of the solar cells. In order to detect also fast annealing processes, however, the in-situ monitoring of the photocurrent is needed. Spectrally resolved measurements of the photocurrent allow to distinct between different degradation and annealing mechanisms, like bulk effects and interface modifications, but are usually only performed ex-situ due to the bulky equipment.
A very simple and compact measurement setup will be shown, that enables the spectral response measurement with good temporal resolution also in a vacuum system without the need of optical windows already during irradiation. It is based on the pointwise photocurrent generation with LEDs with different emission wavelength and a detection unit, that converts the small resulting photocurrents directly into a proportional frequency, that can then easily be monitored for example by using the audio card of a PC [1].
First measurement during the degradation of conventional single junction monocrystalline silicon solar cells with protons are reported, confirming the good temporal resolution and the excellent signal-to-noise ratio even in the complex environment of a high energy particle accelerator. In a further evolution the setup has been modified for the characterization of Tandem type solar cells and the, in this case ex-situ, characterization of a micromorph silicon Tandem cell (2) has been successfully demonstrated. By comparing ex-situ photocurrent spectra of these micromorph cells to the spectra of all-perovskite Tandem cells it is shown, that the micromorph cell can be used as a stable reference cell for the calibration of the in-situ setup, that will in future be used for the in-situ characterization of all-Perovskite or Perovskite/CIGS cells. These both types of Perovskite cells have been already shown to be very stable under proton irradiation [3,4]. For this latter types of thin film solar cells with very promising properties for space applications the in-situ photocurrent monitoring, with excitation with a simpler two-LED irradiation system will be reported and also compared to the radiation induced current monitoring results.

5:00 PM DISCUSSION TIME

5:30 PM *EL15.06.03
Proton Radiation Hardness of Organic Photovoltaics Harrison Ka Hin Lee[1], Katherine Stewart[2], Declan Hughes[1], Jérémy Barbé[1], Adam Pockett[1], Rachel Kilbride[3], Keith Heasman,[4], Zhengfei Wei[1], Trystan Watson[1], Matthew Carnie[1], Ji-seon Kim[2] and Wing Chung Tsoi[1]; [1]Swansea University, United Kingdom; [2]Imperial College London, United Kingdom; [3]The University of Sheffield, United Kingdom; [4]Surrey university, United Kingdom

Recent developments of solution-processed bulk-heterojunction organic photovoltaic (OPV) cells have demonstrated power conversion efficiencies (PCEs) as high as 18.7% for single-junction devices. Such a high PCE in addition to its desirable lightweight property and high mechanical flexibility can realize high specific power and small stowed volume, which are key considerations when choosing PV for space missions. To take one important step forward, their resilience to ionizing radiation should be well studied. Herein, the effect of proton irradiation at various fluences on the performance of benchmark OPV cells is explored under AM0 illumination. The remaining device performance is found to decrease with increasing proton fluence, which correlates to changes in electrical and chemical properties of the active layer. By redissolving the devices, the solubility of the active layer is found to decrease with increasing proton fluence, suggesting that the active materials are likely cross-linked. Additionally, Raman studies reveal conformational changes of the polymer leading to a higher degree of energetic disorder. Despite a drop in performance, the retaining percentage of the performance is indeed higher than the current market-dominating space PV technology—III–V semiconductor-based PV, demonstrating a high potential of the OPV cell as a candidate for space applications.

Radiation Tolerance of Hybrid Perovskite Solar Cells Studied with 8 MeV Proton Irradiation Tsutomu Miyasaka[1] and Yu Miyazawa[2]; [1]Toin University of Yokohama, Japan; [2]Japan Aerospace Exploration Agency, Japan

Perovskite solar cells (PSCs) can be fabricated as lightweight, flexible, and highly efficient solar power devices at low cost. This advantage matches their applications to spacecrafts. We have evaluated the resistance of PSCs to high energy radiations, which is the biggest deterioration factor of the solar cells in the space. PSCs exhibit high radiation tolerance when the device is exposed to high fluences of 1 MeV electron and 50 keV proton beams, and perovskite crystals show a low minority-carrier diffusion length (DL) after irradiation of 1MeV electrons. It has been reported that the photocurrent-voltage (I-V) characteristics of InP solar cells, which have a low DL, recovers after radiation deterioration. To clarify whether or not that the perovskite crystals are introduced with substantial defects by radiation, I-V characteristics of PSC immediately after irradiation and its change over time have been evaluated. At room temperature, 8 MeV proton beam (an energy that can penetrates the PSC by causing deterioration to the all layers in PSC) was irradiated to high-efficiency PSCs with $CsMAFAPb(IBr)_3$ perovskite absorber. The energy incident on the PSC (<1 μm) after passing through the 0.3 mm thick quartz glass substrate was 4.4 MeV. We measured the remaining factor of the parameters of I-V characteristics of PSC (short-circuit current (Isc), open-circuit voltage (Voc) and fill factor (FF)) as a function of proton beam fluence. Up to a radiation dose of 1×10^{13} /cm^2, no significant degradation occurs in all parameters. With a radiation dose of 1×10^{14} /cm^2, degradation of less than 5% was observed in the Isc while FF decreased by 24% and Voc decreased by 9% immediately after irradiation. However, FF and Voc were almost recovered in 3 min after irradiation. The deterioration and recovery of I-V characteristics is considered to be due to some change of conductivity in the charge transport layers. The above investigation endorses that no defects are introduced into the perovskite crystals to deteriorate power generation performance with a radiation dose of 1×10^{14} /cm^2 and corroborate high radiation tolerance of the hybrid perovskite semiconductor.

All-Dielectric Transmissive High-Q Active Metasurfaces for Thermo-Optic Beam-Steering Morgan D. Foley, Claudio Hail, Ruzan Sokhoyan, Souvik Biswas and Harry A. Atwater; California Institute of Technology, United States

All-dielectric nanophotonics has the potential for designing active metasurfaces that exploit highly localized high-quality-factor modes, yielding new ways to individually address each element to shape the overall wavefront. We have designed an all-dielectric metasurface capable of actively steering light via thermo-optic tuning. Our metasurface consists of subwavelength high-index amorphous silicon resonators on a thin SiO_2 spacer layer and a crystalline silicon substrate. The dielectric resonators support high-quality-factor Mie modes (Q ~ 1000 - 10,000) that are optically capable of two-dimensional beam steering. Furthermore, by tailoring the SiO_2 layer thickness to specific values, we can tune the Fano asymmetry parameter of the resonance, and hence the transmittance of the modes. By adding doped amorphous silicon electrodes across one of the two principal axes of the array, metasurface elements can be actively index modulated under electrical actuation via Joule heating ($\triangle n \sim 0.01$). We have demonstrated via finite-difference-time-domain simulations that our metasurface can steer light to a range of angles by generating one-dimensional phase gradients via dynamic refractive index modulation. From three-dimensional finite element thermal simulations, we calculate a response time for our system of ~ 7μs, corresponding to a modulation frequency of ~ 140kHz. Importantly, our design operates in transmission, opening the possibility of cascading with other transmissive metasurfaces to perform multiple operations, such as optical edge detection for imaging. Our work contrasts with previous active designs, such as active plasmonic metasurfaces which primarily operate in reflection and exhibit strong loss, or liquid crystal systems which have a slower modulation time. We also report on our experimental progress towards realizing an all-dielectric active metasurface capable of performing dynamic beam steering. Thermo-optic modulation of two-dimensional dielectric metasurfaces has many potential applications for optical sensing, lensless imaging and display technologies.

9:15 AM EL16.01.03
Selective Placement of Nanocrystals in Plasmonic Arrays for Tailored Directionality and Polarization of Photoluminescence Maya Ramamurthy, Pavlos Pachidis, Bryan M. Cote and Vivian Ferry; University of Minnesota - Twin Cities, United States

Light-emitting metamaterials are promising candidates for applications where polarization and directional control of photoluminescence is desired, including security tagging, beam shaping, 3D displays, and photonic circuits. While most work to date involves uniformly coating the metasurface with light emitters, placing emitters in specific locations enables more complex and controlled effects. Here, we are interested in metamaterials comprised of Au nanobars and *patterned* light emitters that form their own, collective solids. These solids can be realized using direct-write electron beam lithographic patterning of luminescent semiconductor nanocrystals.
In this work, we use finite difference time domain (FDTD) simulations and experiments to study how the placement of luminophores in plasmonic arrays affects the circular polarization and directionality of photoluminescence. We modeled the luminophores as incoherent dipole sources with peak photoluminescence emission at 630 nm. The plasmonic array was modeled as a 23 x 23 square periodic array of Au nanobars with dimensions 160 nm x 300 nm x 70 nm and a pitch of 600 nm. To compare the effects of patterning light emitters into specific locations versus a uniform coating, the dipoles were either placed within a cylindrical disk (diameter = 140 nm, n = 1.75) adjacent to each nanobar, or uniformly distributed within a film (n = 1.59) placed on top of the nanobar array.
These luminescent metamaterial arrays were fabricated on ITO-coated glass slides using a two-step lithographic patterning process where the Au nanobars were fabricated in the first step, and CdSe/CdS core/shell nanocrystals were patterned resist-free in the second step.
We show that selective placement of luminophores in certain locations around the Au nanobar produces systems that preferentially outcouple either right or left circularly polarized light (RCP/LCP). Additionally, the angular distribution of RCP/LCP light outcoupling reflects the symmetry of the metamaterial array. Therefore, the metamaterial comprised of a uniform film of luminophores emits polarized light at certain angles, but no net polarization is observed when averaged over all angles of emission. By contrast, when luminophores are placed in locations that render the metamaterial chiral, polarized light is emitted not only at specific angles, but also when averaged over all angles.
We also find that the distinctive placement of emitters changes the direction of light outcoupling by changing the Raleigh-Wood modes of the periodic array, compared to when the emitters comprise a uniform film. Finally, we demonstrate how to create metamaterials that emit light with any desired circular polarization or direction by analyzing the near-fields around the Au nanobar and placing luminophores in regions of high circularly polarized field enhancement. This creates systems that simultaneously achieve a high degree of circular polarization (DCP) and a high photoluminescence intensity at the desired angle of emission. These studies advance understanding of light-mater interactions in nanostructured arrays and are broadly relevant in nano-optics.

9:30 AM BREAK

10:00 AM *EL16.01.04
Flat Optics for Dynamic Wavefront Manipulation Mark L. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of metasurfaces, i.e. nanostructured optical coatings, has further accelerated the development of flat optics through the realization that nanoscale antenna elements can be utilized to facilitate local and nonlocal control over the light scattering amplitude and phase. In this presentation, I will highlight recent efforts in our group to realize electrically-tunable metasurfaces employing nanomechanics, tunable transparent oxides, electrochemistry, microfluidics, phase change materials, and atomically-thin semiconductors. Such elements are capable of dynamic wavefront manipulation for optical beam steering, holography and future display technologies. The proposed optical elements can be fabricated by scalable fabrication technologies, opening the door to a wide range of commercial applications.

10:30 AM EL16.01.05
Metasurface-Enabled Full-Space Structured Light Illumination for Depth Imaging Jooyeong Yun[1], Gyeongtae Kim[1], Yeseul Kim[1], Inki Kim[2] and

Junsuk Rho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Laser-based imaging technology has shown promising potential in three-dimensional (3D) depth sensing platforms enabling variety of applications such as autonomous driving, robot vision, and face recognition in mobile devices. To image 3D objects over a wide field of view (FOV), the laser beams illuminate the objects, and the backscattered light is monitored through detectors. Structured light (SL)-based imaging system splits the light into an array of dots or a specific pattern into the object scene, enabling imaging of multiple objects simultaneously. So far, diffractive optical elements (DOEs) or spatial light modulators (SLMs) have been used to form the laser dot arrays. However, such architectures suffer from small FOVs, low efficiency, and bulkiness due to the large micron-scale pixel size. Here, we propose a metasurface-based SL imaging platform, allowing for subwavelength scale manipulation of incident light. The scattered light from the metasurface covers the full 180° FOV, with a high-density ~10K dot array. The metasurface is composed of a periodic supercell, and the properties of diffraction patterns are analyzed by convolution theorem regarding the supercell as a kernel function. As a proof-of-concept, we place face masks one on the laser beam axis and the other 50° apart from axis within distance of 1 m and estimate the depth information from the backscattered light using a stereo matching algorithm. Furthermore, we demonstrate the replication of our metasurface on a glass surface using the nanoimprinting of a nanoparticle-embedded-resin (nano-PER) for high-throughput fabrication.

10:45 AM EL16.01.06

Dislocation Study in InGaAs QW Metamorphic Lasers Nicholas Stephen[1], Praveen Kumar[1], Agnieszka Gocalinska[2], Emanuele Pelucchi[2] and Miryam Arredondo[1]; [1]Queen's University Belfast, United Kingdom; [2]Tyndall National Institute, Ireland

There has been a drive to produce novel InGaAs Quantum Wells (QW) on GaAs substrate lasers for telecommunication applications that can replace current InP based lasers. The In concentration in the InGaAs QW can be fine-tuned so that the emission is in the C-band (1330nm) or O-band (1550nm) telecommunication bands. Furthermore, compared to the current InP substrates, GaAs is less brittle, cheaper and available large wafer sizes: making them ideal for mass fabrication [1]. Difficulties can arise due to lattice mismatches between the InGaAs QW and GaAs substrate, which causes an increase in non-radiative recombination centres (whereby phonons instead of photons are produced) [2]. One proposal that has been used to overcome this problem is metamorphic growth, where a buffer layer is grown between the substrate and active region. In turn, this creates an artificial substrate with a lattice constant that can be tailored to greatly reduce the lattice mismatch between active region and substrate.

In the metamorphic buffer layer, strain is relieved via the creation of dislocations. These dislocations are confined to a certain region within the metamorphic buffer [3]. It is well known that these can be classified in many ways such as 60° or 90° (pure edge) dislocations and it is common for the burgers vectors to be identified using techniques such as weak beam dark -field transmission electron microscopy [4,5]. However, to date, few studies have provided in-depth details on the distribution of the type dislocations within an InGaAs metamorphic buffer and how this could be linked to the performance of the laser.

This work investigates a series of InGaAs QWs on GaAs substrate metamorphic lasers grown by Metal Organic Vapour Phase Epitaxy (MOVPE) using transmission electron microscopy techniques. This study identifies and characterises properties of dislocations within the metamorphic buffer. We also address the In concentration of the metamorphic buffer which these dislocations are based around.

Finally, our data elaborates further on the distribution of the dislocations. These findings lend themselves towards the understanding of laser emission behaviour and the mechanism of relaxation in the buffer. In turn, allowing novel metamorphic lasers to be manufactured with characteristics similar to current commercial semiconductor lasers.

Engineered Hydrogenated Amorphous Silicon (a-Si:H) and Nanoparticle-Embedded-Resin (nano-PER) for Low-Loss and Scalable Optical Metasurfaces Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Here, we present a printing-based highly-productive scalable nanofabrication method to manufacture dielectric metasurfaces working in the visible and near-infrared (NIR) regime. A main idea is that transferred patterns of UV-curable resin from a printing mold directly work as metasurfaces without any secondary operations such as thin film deposition and etching, but the problem is that the refractive index of the typical resin is not high enough for metasurfaces. Therefore, we develop the effective medium of nanoparticle composite (NPC) that consists of high-index dielectric nanoparticle (NP) inclusion in the matrix of UV-curable resin. This hierarchy enables to achieve the sufficiently-high refractive index for metasurfaces. By using our method, we demonstrate various metasurfaces such as metaholograms and metalenses. The fabricated metalens and metahologram based on titanium dioxide NPs exhibits a high conversion efficiency of 90.6% at the wavelength of 532 nm. Theoretically, the efficiency can be further increased up to 96.4% by optimizing the nanostructures of the metasurfaces. A 4 mm-diameter NIR metalens made of the silicon NPC is also demonstrated to verify that the metalens can be fabricated by one-step printing without any thin-film deposition nor etching processes4. The fabricated NIR metalens shows focusing efficiency of 47% at the wavelength $\lambda = 940$ nm. We also use the NIR metalens to realize a compact NIR camera and confirm its imaging capability by capturing the distribution of veins underneath human skin. Therefore, this work will pave the way for practical applications of metalenses such as night vision, thermal imaging, biometric technologies and light detection and ranging (LiDAR) devices. Considering that the proposed nanoimprinting method enables low-cost production of metasurfaces, we expect that NPC-based functional metasurfaces will be implanted on various photonic applications from infrared to visible frequencies. Also, if time allows, I will discuss the materials and fabrication progress.

SESSION EL16.02: Controlling Thermal Emission with Nanostructure and Active Control Plasmonic Devices
Session Chairs: Mark Brongersma and Wenshan Cai
Monday Afternoon, April 10, 2023
Moscone West, Level 3, Room 3016

1:30 PM *EL16.02.01
Free-Form Plasmonic Meta-Optics via Machine Learning Wenshan Cai; Georgia Institute of Technology, United States

Advanced neural networks and optimization algorithms have enabled a paradigm shift in the discovery and design of structured photonic materials and devices. In this talk we report a diverse set of inversely designed meta-optical structures, devices, and systems for wavefront control, imaging, computing, and nonlinearity.

Flat optics, represented by metamaterials and metasurfaces, foresees a promising route to ultra-compact optical devices. Conventional designs of such meta-structures start with a certain structure as the prototype, followed by extensive parametric sweeps to accommodate the requirements of phase and amplitude of the emerging light. Regardless of how computation-consuming the process is, a predefined structure can hardly realize the independent control over polarization, frequency, and spatial channels, which hinders the potential of metasurfaces to be multifunctional. Besides, achieving complicated and multiple functions calls for designing meta-systems with multiple cascading layers of metasurfaces, which introduces exponential complexity. We have developed a series of deep-learning enabled generative frameworks for the inverse design of plasmonic structures in response to on-demand optical properties, with extended case studies and experimental demonstrations. Moreover, we further present a hybrid deep learning framework for designing multilayer meta-systems with multifunctional capabilities, as well as nonlinear metasurfaces for the generation of new spectral components and active control of light waves.

Metasurfaces composed of meta-molecules with spatially variant building blocks, such as gradient metasurfaces, are drawing substantial attention due to their unconventional controllability of the amplitude, phase, and frequency of light. However, the intricate mechanisms and the large degrees of freedom of the multi-element systems impede an effective strategy for the design and optimization of meta-molecules. We propose a hybrid artificial intelligence-based framework consolidating compositional pattern-producing networks and cooperative coevolution to resolve the inverse design of meta-molecules in metasurfaces. The efficacy and reliability of the design strategy are confirmed through experimental validations. This framework reveals a promising candidate approach to expedite the design of free-form, large-scale metasurfaces in a systematic manner.

We further introduce a deep learning framework for the discovery and design of a multilayer multifunctional meta-system, which is too complicated to be accomplished through conventional design processes. As solid illustrations, we report three examples designed by our framework: a polarization-multiplexed dual-functional beam generator, a second order differentiator for all-optical computing, and a space-polarization-wavelength multiplexed hologram. These functions are barely achievable by single-layer metasurfaces, and the devices are hardly approachable by conventional design means. The designed devices are constituted of arbitrary patterns, which indicates the extremely high degrees of freedom of the structures involved.

The machine learning methods developed here is applicable to the inverse design of other photonic components and systems, including photonic crystals, chip-scale silicon devices, quantum-optical devices, and nonlinear optical materials. This design methodology is also significant to other disciplines of natural sciences, such as the design of nano materials, searching for new topological insulators, planning of chemical syntheses, prediction of protein structures, and many more.

2:00 PM EL16.02.02
Electronic Steering of Directional Thermal Emission based on Delocalized Photonic Mode Resonator Combined with Graphene-Metal Hybrid Metasurface Joel Siegel[1], Shinho Kim[2], Margaret Fortman[1], Phillip Hon[3], Luke Sweatlock[3], Min Seok Jang[2] and Victor Brar[1]; [1]University of Wisconsin-Madison, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Northrop Grumman Corporation, United States

There have been various studies to control the thermal emission of hot objects to obtain a narrowband or directional emission spectrum that is difficult to achieve by the conventional blackbody emitter. Recent studies have reported that elaborately designed metasurface/metamaterial combined with active materials enables dynamic control of the emission spectrum by external stimuli. However, previous studies have focused on emissivity modulation for the frequency spectrum, and the steering of directional thermal emission has not yet been demonstrated.

In this report, we experimentally demonstrate an electrically tunable directional thermal emission from a delocalized optical mode resonator combined with a graphene-metal hybrid metasurface. The wavelength scale thick dielectric layer is sandwiched by the metal electrode layer and the metasurface, supporting vertically oscillating Fabry-Perot mode. The delocalized Fabry-Perot mode has a sufficiently long coherence length, resulting in phase alignment of random thermal dipoles to obtain sufficient interference effect between emissions of each metasurface element.

The dynamical behavior of emissivity is estimated by calculating the absorption of the proposed structure for various incident angles of TM polarized light and Fermi levels of graphene. Due to the metasurface's non-resonant scattering, the proposed structure's resonant absorption spectrum could be completely explained by the Fabry-Perot reflection model. The phase of the reflection coefficient of the metasurface is modulated by altering the Fermi level of graphene, resulting in the resonance frequency shift of Fabry-Perot reflection. The maximum absorption of the proposed structure is achieved by nearly complete destructive interference of direct and Fabry-Perot reflections. From the constraint of wavevector for the direction of oscillation imposed by the

Fabry-Perot resonance condition, the difference of resonance frequencies for different Fermi levels is equivalent to the steering angle of thermal emission. For a fixed frequency, the angle of directional thermal emission is continuously modulated by varying the Fermi level of graphene. We measured the emissivity of the device by collecting the thermal emission of the device on the 250°C heating stage through Fourier transform infrared spectroscopy. The Fermi level of graphene is modulated by applying the voltage on the backside metal reflector and the graphene layer. The experimental measurement of the device shows maximum emissivity over 0.9 for each resonance frequency. For the change of 1.15 x 10^{13} cm^{-2} carrier density in graphene, the steering angle at 1508 cm^{-1} is larger than 10°. This work inspires new approaches to controlling thermal emission and pave the way for expanding applications of thermal emitters beyond conventional limitations

2:15 PM EL16.02.03

Exploring the Design of Mid-Infrared Thermal Emitters Using Graphene-Si Hybrid Resonances with Coupled Mode Theory Arun Nagpal[1], Ming Zhou[2], Ognjen Ilic[3], Zongfu Yu[4] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]Stanford University, United States; [3]University of Minnesota Twin Cities, United States; [4]University of Wisconsin–Madison, United States

Thermal emission is typically spontaneous, broadband, and isotropic. Modifying the emissivity and absorptivity of a nanostructure allows for the development of devices for heat management and leads to advances in beamforming metasurfaces for generally incoherent light or emissive sources. Here we discuss the use of coupled-mode theory to design metasurfaces whose working principle couples the guided mode resonance of a silicon photonic crystal to the localized surface plasmons of a graphene ribbon array. The resultant devices are predicted to have a Q factor of greater than 10,000 and can be tuned through the application of a gate voltage from a peak emissivity of more than 0.98 to nearly 0. We show that predictions made using coupled mode theory run two orders of magnitude faster than equivalent FEM simulations, allowing us to quickly define the phase space of device geometries that produce critically coupled, narrowband TM-polarized thermal emission. We will also present results of experimental measurements of tunable graphene resonators coupled to high quality factor photonic crystals. We show through the choice of realistic material parameter modelling, the resultant structures are amenable for fabrication.

Multipole Mie Resonances in Lattices of Lossy Materials Amanda Romero, Md Sakibul Islam and Viktoriia Babicheva; University of New Mexico, United States

Due to the high losses, achieving high light confinement and efficient harvesting in the nanostructures of lossy materials is challenging. We design, fabricate, and experimentally characterize resonant nanostructures to achieve efficient mode concentration and dynamic tuning of nanophotonic elements made of lossy materials, such as titanium and nickel. We have achieved the excitation of strong lattice resonances and more significant absorption in the arrays of lossy nanoparticles, which can result in a higher generation of hot electrons. We explore the optical properties of novel nanostructures, intending to use them in laser devices and for enhanced emission. We have shown that the narrowband or broadband functionality of such lossy nanostructures can be improved using a multiple-period array and can be applied to photodetectors. Arranged in the periodic array, nanoparticles facilitate a strong enhancement in the resonances and absorption profiles. We also show that these nanostructures can provide high-efficiency hot-electron generation.
This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science by Los Alamos National Laboratory (Contract 89233218CNA000001) and Sandia National Laboratories (Contract DE-NA-0003525). The work is also supported by Contract DE-2375849.

3:30 PM EL16.02.06

Tuning the Generation of Luminescent Silver Nanodots with Printed ssDNA on the Surface Junhua Yu and Sungmoon Choi; Seoul National Univ, Korea (the Republic of)

Stable luminescent silver clusters, named as silver nanodots (AgNDs), have been successfully encapsulated in several scaffolds, such as dendrimers, [1] microgels, [2] peptides, [3] and single stranded DNA (ssDNA). [4] ssDNA with varying sequences have produced the widest variety of and most robust nanodot emitters with spectrally pure emissions from the blue to near-IR wavelengths. Besides the much better brightness due to the competitive luminescent quantum yield and excellent molar extinction coefficient, silver nanodots exhibit excellent stability, at least 15-fold more photostable than organic dyes, illustrating great potential as a new generation of fluorophores. [5]

Silver nanodots are usually generated by reducing a mixture of silver ions and their protective group in solution, followed by the rearrangement of the reduced silver to form luminescent clusters. [6-8] Their characterizations are conducted thereafter or in a polyvinyl alcohol) (PVA) film. However, the generation and activity of silver nanodots on the surface has not been studied well. Surface chemistry plays an important role in determining the functionality of nanomaterials. [9] The interactions between the surface and the reactive molecules on the surface, as well as between these reactive molecules, may influence the reactivity of the surface molecules. Moreover, the stabilization of the silver cluster core in the nanodot is mainly related to coordinated covalent bonding. This indicates that the interactions between the silver cluster and the surrounding ligands are critically important, and therefore, the surface chemistry plays an even more essential role in the stabilization of silver nanodots. Herein, we have investigated the factors that determine the generation of silver nanodots and selectively controlled the spectrum of the silver nanodot.

We found that the fundamentals for the generation of silver nanodots on surfaces is different from that in solution.[10,11] Adsorbed ssDNA molecules cannot efficiently assist the generation of silver nanodots by either direct chemical reduction or photoactivation. Instead, silver nanodots can be instantly generated on the surface by silver cluster transfer, significantly faster than other methods to generate the same emitter in solution. Contrary to the most easily generated red emitter in solution, the predominant species on the surface is the near-IR emitter. This is likely due to the surface structure that stabilizes the near-IR emitter. Moreover, the kinetic trapping of ssDNA molecules on the surface also limits the reorganization of the resulting silver nanodots for other silver nanodot emitters. Adjusting the freedom of the adsorbed ssDNA on the surface can tune the generation of various silver nanodots on the surface.

Optically Tunable Wavefunctions of Plasmonic Metals Kanij Mehtanin Khabir, Leila Hesami and Mikhail A. Noginov; Norfolk State University, United States

Active plasmonics and nanophotonics are of great interest for fundamental science and applications of light.
In our recent studies, we researched (i) effects of dye-doped polymers (Rh590:PMMA) on workfunction of Au and Ag [1,2] as well as (ii) effects of metal-dielectric substrates on photopolymerization of BITh molecules [3]. At this time, we report on control of the workfunctions of Ag and Au films coated with BITs by external light.
Our samples were thin Ag and Au films deposited on glass and spin coated with BITh molecules. They were exposed to radiation of a broadband quartz lamp, which was a part of the Kevin Probe (KP) apparatus, and their workfunctions as well as the reflection spectra were studied using the Kelvin Probe and the spectrophotometer, respectively.
We have found that in BITh-coated Ag and Au films, the workfunction decreased by several hundreds electron-volts during the photoexposure and almost returned to its original value when the light was turned off. The characteristic time scale of the process was ~15 minutes and it did not correlate with the rate of photopolymerization. (In particular, we did not see any reversibility of the photopolymerization.)
As the workfunction is expected to affect the optical properties of metals and metal-based waveguides, the observed phenomenon paws the road to tunable Fabry-Perot resonators, Metal-Insulator-Metal (MIM) waveguides, and control of strong coupling of excitons with cavities and surface plasmons.

4:00 PM EL16.02.08

Active Wavefront Shaping in Transmission from Tunable Excitonic Resonances Melissa Li, Claudio Hail, Souvik Biswas and Harry A. Atwater; California Institute of Technology, United States

We demonstrate dynamic beam steering in transmission by utilizing the large tunability of the complex refractive index enabled by excitonic resonances. While reconfigurable metasurfaces have been explored using tunable materials such as transparent conducting oxides, liquid crystals, or phase change materials, these concepts rely on coupling to resonant antennas or optical cavities which are sensitive to geometric parameters. Rapid advances in understanding excitonic resonances intrinsic to materials have stimulated thinking about active metasurfaces where the excitonic material can act both as the resonant scatterer and the tunable material. However, demonstrations of active metasurfaces exploiting excitonic resonances for amplitude and phase modulation have been limited to operating in reflection. Here, we show how in excitonic materials where the quantum yield is over 70%, for example, in monolayer transition metal dichalcogenides, quantum dots, or perovskites, we can modulate the phase shift of the transmitted light by over 250°. By varying the voltages from ±5 V between adjacent electrodes, we can then dynamically steer the transmitted beam to ±39° near the exciton resonance. Our results suggest the potential of leveraging the tunability of excitonic resonances for arbitrary wavefront shaping in emerging photonic applications.

4:15 PM *EL16.02.09

Nanophotonics with Coherent and Temporally Controlled Single Photon Light Emission Harry A. Atwater; California Institute of Technology, United States

Advances in synthesis of excitonic materials and color-centers are giving rise to sources of coherent and single photon light emission that can enable new types of nanophotonic systems. Recent developments in color center-based single photon sources have demonstrated homogeneously broadened and electrically tunable single photon emission from color centers in hexagonal boron nitride. These color centers are optical frequency single photon emitters with linewidths of <100 MHz and are wavelength tunable over a >400 GHz frequency range under electrical gating, with precisely determined dipole orientation. I will discuss the implications of these results for electrical control of single photon emission, in which we can envision nanophotonic structures for tailoring the temporal and spectral characteristics of color centers and excitonic emitters to enable indistinguishability and photon correlation for applications such as emitter-emitter entanglement and quasi-noiseless amplification of weak optical signals by single photon addition to thermal light sources.

SESSION EL16.03: Nonlinear and Tunable Optics

Session Chairs: Yao-Wei Huang and Pin Chieh Wu
Tuesday Morning, April 11, 2023
Moscone West, Level 3, Room 3016

10:30 AM *EL16.03.01

High Quality Factor Meta-Atoms for Extremely Energy-Efficient Dynamic and Nonlinear Flat Optics Mark Lawrence[1], Lin Lin[1], Samuel Ameyaw[1], Bo Zhao[1], Jennifer A. Dionne[2], Sahil Dagli[2] and Jack Hu[2]; [1]Washington University in St Louis, United States; [2]Stanford University, United States

Phase gradient metasurfaces represent a new paradigm for designing diffractive optics that offer unprecedented spatial resolution combined with multifunctionality, all within an ultrathin footprint. By sculpting light waves via independent subwavelength pixels each with access to all possible phase values, a wide array of impressive wave transformations has been realized, including aberration-free high NA lenses, artifact-free holograms, and skin invisibility cloaks. An intriguing next step is the prospect of adding nonlinear, dynamic, and active functionality, to target new LiDAR sensors, AR/VR glasses, quantum and classical light sources, and all-optical analog signal processors, for example. Unfortunately, a combination of vanishingly small material coefficients and weak optical resonance (quality factors $(Q)\sim10$) has meant that nonlinear, dynamic, and active phase gradient metasurface demonstrations have suffered from exceedingly low efficiency and/or limited performance.

Here, we introduce metasurface building blocks that dramatically boost the light-matter coupling strength while maintaining the sub-wavelength continuous phase control that makes metasurfaces so powerful. Specifically, we reveal dielectric nanoantennas that support multi-polar guided mode resonances (MGMR) which, thanks to subtle symmetry breaking, exhibit huge Q-factors. Counterintuitively, these high-Q nanoantennas can be placed very close together while maintaining independent scattering signatures, making them excellent meta-atoms. We even demonstrate that by using interference to suppress residual coupling, we can build phase gradient metasurfaces with spacing $<\lambda/2$ between elements with $Q>10^4$. Beyond the strong resonant intensity enhancement that this represents, we reveal that MGMRs share the rich scattering characteristics of Mie resonators. To demonstrate the potential of this new platform within real-world applications, we realize efficient electro-optic and electro-thermal beam-steering as well as incident angle independent low-threshold Kerr switching.

11:00 AM EL16.03.02
Plasmonic Control of High Energy Ligh-Materials Interaction Pavel Shafirin, Pengli Feng and Artur Davoyan; University of California, Los Angeles, United States

Thermoplasmoncis offers an unprecedented potential for creating optically induced heat sources at the nanoscale. Importantly, by creating nanoscale structures heat transfer and related heat induced processed can be efficiently controlled. Here, we study experimentally and theoretically the effects of intense laser beams interaction with plasmonic nanostructures in the ablation regime. Specifically, at high laser beam fluences we create ablation plasmas and study their properties as a function of the underlying plasmonic nanostructure. Our work hints the possibility of controlling ablation plasmas with properly selected and structured thermoplasmonic systems, offering new opportunities for a range of applications from compact accelerators to additive and emerging manufacturing to plasma medicine.
To investigate laser driven ablation we study pulsed (5-50 ns) high energy laser (1064 nm, 10 mJ- 1J) interaction with plasmonic nanostructures. Upon focusing we observe formation of short lived plasmas, which we measure characterize with short gate time ICCD camera to produce time resolved images of the plasma plume and emission spectra with resolution down to 3 ns. With this approach we determine the temporal evolution of ablation plasma temperature, ionization state and its density. We then compare measured ablation dynamics for bulk metals (such as copper, aluminum, and steel) with micro and nanostructured metals (such as thin ~100 nm films). We show that the ablation dynamics for these systems is drastically different, which signifies that by nanostructuring heat generation and transfer are modified. To reveal the complex light materials interaction we develop a theoretical framework that couples optical absorption together with heat transfer and associated series of phase changes. Influence of fast nanosecond evolution and nanoscale interaction in structured plasmonic materials is discussed.

11:15 AM EL16.03.03
Excitation Dependent Saturation Intensity in Ultrathin Epsilon-Near-Zero Films Quynh T. Dang[1], Sudip Gurung[1], Kent Nguyen[1], Subhajit Bej[2], Aleksei Anopchenko[1], Andrea Marini[3] and Ho Wai (Howard) Lee[1]; [1]UC Irvine, United States; [2]Tampere University, Finland; [3]University of L'Aquila, Italy

Studies in epsilon near zero (ENZ) thin films have shown extreme nonlinear light-matter interactions leading to giant ultrafast nonlinearities. This corresponds to the excitation of ENZ modes and the associated electric field intensity enhancement (FIE) inside the material. Recent progress in the field mainly focuses on ENZ nonlinearity caused by electron absorption within the conduction band only, thus lacking an understanding of optical transition absorption near the ENZ regime. Therefore, an in-depth study of the nonlinearity, especially the nonlinear absorption behavior of the ENZ materials in the presence of optical transition, is crucial. With three-photon absorption, the intensity-dependent absorption coefficient can be written as: $\alpha = \alpha_{ns} + \alpha_0 / (1 + I/I_{sat}) + \gamma I^2$, where the 1st and the 2nd term are related to the saturable absorption caused by conduction band free electrons, and the 3rd term is related to the 3-photon absorption. α = total absorption coefficient, γ = 3-photon absorption coefficient, α_{ns} = nonsaturable absorption, α_0 = linear absorption coefficient, and I_{sat} = saturation intensity is defined as the intensity when nonlinear absorption becomes $\alpha_0/2$.
In this work, we demonstrated that at ENZ wavelength (1190 nm for a 300 nm thick ITO sample), where 3-photon absorption is absent, saturable absorption decreases as intensity and angle of incident of light increase. These are because of the increased absorption and enhancement field intensity caused by ENZ mode excitation at a larger angle of incidence. We also observed that near the ENZ regime (1090nm), where 3-photon absorption is possible, saturable and 3-photon absorption compete with each other. In contrast to the saturable absorption, 3-photon absorption increases with increasing intensity but decreases at larger angles of incidence. The decrease of 3-photon absorption at a large incident angle can result from increased absorption by the free electrons in the conduction band. Since ENZ mode excitation causes the free electrons to absorb more photons at larger incident angles, there are fewer photons available to contribute to multiple-photon absorption. These competing nonlinear absorption mechanisms can provide a new and significant optical-nonlinearity tuning mechanism to implement in optics/optomechanical devices (i.e., ultrafast all-optical switches/modulators).

11:30 AM *EL16.03.04
Metasurfaces from Tunable Materials Matthew D. Escarra; Tulane University, United States

Huygens metasurfaces, utilizing coupled electric and magnetic dipole resonances in nanophotonic structures, show promise for integrated photonics, flat optics, and optical modulators. Novel phase tunable materials such as antimony trisulfide (Sb_2S_3) and vanadium dioxide (VO_2) may be used directly as nanoresonators to take advantage of the high sensitivity of this type of metasurface, enabling highly tunable optics with binary (Sb_2S_3, non-volatile) or continuous (VO_2, volatile) variability. Amplitude and phase modulators, beam deflectors, varifocal lenses, and tunable holograms are possible with these materials. Here we report progress in design, nanofabrication, and characterization of tunable metasurface optics from these materials. Related advances with Huygens metasurface-based biosensing and 2D materials will be briefly mentioned.

SESSION EL16.04: Ultrafast Photonics and Quantum Emission in Metasurfaces Nanostructures
Session Chairs: Ho Wai (Howard) Lee and Pin Chieh Wu
Tuesday Afternoon, April 11, 2023

1:30 PM *EL16.04.01

Engineering Quantum Phenomena with Epsilon-Near-Zero (ENZ) Materials Jeremy N. Munday; University of California, Davis, United States

Epsilon-near-zero (ENZ) materials have given rise to a rich variety of phenomena such as electromagnetic supercoupling, resonance pinning, perfect optical absorption, and ultrafast optical switching. In addition, ENZ materials have been successfully exploited to modulate the spontaneous emission intensity, including the spectrum and directionality, of quantum emitters. Here we present two additional phenomena that can arise as a result of ENZ materials interacting with quantum vacuum fluctuations. First, we will present the concept of electromagnetic bandgaps for nanoparticles comprising an ENZ material. The suppressed radiative emission is found to be invariant with respect to particle size and is therefore an intrinsic property of the ENZ material. Even for non-ideal ENZ materials (e.g., ITO), a suppression of ~90% is achieved within the bandgap region. Second, we will show how tunable ENZ materials can be used to convert electrical bias into mechanical motion through the Casimir force, resulting from a confinement of the quantum fluctuations of vacuum. Together, these effects show the potential of engineering quantum fluctuations through novel material systems for future device applications.

2:00 PM EL16.04.02
Perovskite Phonon Polaritonics in the Terahertz Gap Rui Xu[1], Tong Lin[1], Jiaming Luo[1], Xiaotong Chen[1], Elizabeth Blackert[1], Alyssa Moon[2], Khalil Jebailey[1] and Hanyu Zhu[1]; [1]Rice University, United States; [2]Texas A&M University, United States

Photonics in the "new terahertz (THz) gap" between 5 and 15 THz have numerous applications from molecular sensing to ultrafast materials manipulations. However, there are few choices of photonic materials in this frequency range due to prevalent phonon absorption in solids. Recent progress in phonon-polariton microstructures and metamaterials demonstrated low-loss and sub-wavelength photonic devices in the mid-infrared frequencies, but many require crystalline thin films and have small bandwidths. Crystalline ternary oxides were predicted to have great potential as broadband phonon-polaritonic materials in mid- and far-infrared frequencies, but the difficulty in fabrication has impeded further development. Here we report surface phonon-polaritonics based on single-crystalline SrTiO3 that realizes planar ultrafast concentrators with a tunable resonance in 7–13 THz. Our design principle allows simple fabrication without damaging the crystalline quality of the materials. Experimentally, we achieved polarization-independent field amplification by a factor of 5 and average spectral enhancement over 30 times. We measured the resonance spectra and transient electric fields of the concentrators by THz-field induced second harmonic generation (TEFISH), showing up to 0.5 GV/m field strength in a large, optically resolvable area with a table-top source. The ability to generate strong, multicycle, variable-polarized THz fields in the new terahertz gap offers a convenient platform for studying driven phases and nonlinear phononics in quantum materials.

2:15 PM EL16.04.03
Rectifying Effect of Ratcheting Quasi-ballistic Electrons in Plasmonic Resonators Hue T. Do[1,1,2], Lin Wu[3,2] and Michel Bosman[1,2]; [1]National University of Singapore, Singapore; [2]Agency for Science, Technology and Research, Singapore; [3]Singapore University of Technology and Design, Singapore

Geometric diodes exhibit current rectification by preferential scattering of quasi-ballistic electrons in designed resonator geometries. High rectification ratios at room temperature have been shown in graphene [1] and recently also in silicon geometric diodes [2], which enables energy harvesting from radiation in the THz and GHz domains. In this work, we present rectification in plasmonic resonators operating in the near-IR frequency range. We use Particle-in-cell simulations [3][4] that solve the full-wave Maxwell equations while also considering the electron dynamics at the resonator boundaries that result in preferential scattering. Our approach reveals AC rectifying behaviour of such geometric diodes, which was not possible in earlier analytical models [1][2]. We demonstrate up to 1.7 asymmetry ratio between the current density in forward and backward direction for resonators that are locally excited by fast-moving electrons; and significant charge accumulation upon continuous-wave laser illumination. Following these theoretical predictions, we have fabricated TEM samples of our designed geometric diodes and by using nano-optical spectroscopy in the TEM, we experimentally confirm our predictions. This work will open opportunities for energy harvesting from near IR radiation and surface plasmon polariton rectification in plasmonic circuits.

Epsilon-Near-Zero Mode Excitation in TCO Thin Film Coated Optical Fibers Stuart Love; University of California Irvine, United States

Epsilon near zero (ENZ) materials have been extensively studied recently due to their unique and extreme optical properties [1]. Ultrathin transparent conducting oxide (TCO) ENZ—the real part of permittivity approaches zero—layer can support plasmon polariton mode with enhanced and highly confined optical field [2]. Furthermore, the ENZ properties of TCO can also be tuned dynamically by field effect dynamic [3-6]. However, excitation of ENZ resonances in optical waveguides, more specifically optical fibers, has been under investigated.

In this work, we demonstrate the excitation of ENZ mode in optical fiber via direct phase matching between the fundamental mode of the fiber and the ENZ mode supported by the AZO thin film. With the TCO coating near the core of a D-shaped single-mode fiber, we have shown up to 10 dB of transmission resonance in the ENZ wavelength regime. Using a supercontinuum laser (500-1750nm) we couple directly to a single mode fiber that has partially polished cladding in the center, allowing for proximity to the core. By depositing aluminum zinc oxide (AZO) film on the polished surface, this can allow for coupling to the ENZ modes of the AZO while the light is propagating through the fiber. Varying thickness of AZO coating, which changes the central ENZ wavelength, further change the coupling of the ENZ mode in the fiber by shifting the resonance peak. In comparison with uncoated fibers, there is a clear excitation of hybrid ENZ mode. By launching ultrafast high power pulse laser into the ENZ optical fiber, nonlinear ENZ mode coupling and generation of harmonic light are expected to be observed, which will be presented at this conference.

This work was supported by the Air Force Office of Scientific Research (Award number: FA9550-21-1-02204).

A Multifunctional Imaging Metalens for Arbitrary Structuring Quantum Emission Jaehyuck Jang[1], Chi Li[2], Trevon Badloe[1], Junsuk Rho[1], Igor Aharonovich[2] and Haoran Ren[3]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]University of Technology Sydney, Australia; [3]Monash University, Australia

Quantum emission is essential for realizing quantum photonic applications such as computing, communication, and cryptography. The representative example of a quantum light source at room temperature is solid-state single photon emission (SPE) observed in defects in two-dimensional (2D) hexagonal boron nitride (hBN). Recently, it is of great interest to arbitrarily modulate quantum light sources with multiple degrees of freedom, including directionality, polarization, and orbital angular momentum. However, modulating the SPE in a conventional way entails a bulky optical system such as an objective, wave plates, and diffractive optical elements, which is inappropriate in a confined on-chip quantum system. Metasurface, an array of ultra-thin subwavelength nanostructures, is capable of multiplexing multiple functionalities of bulky optical components on it. Therefore, multiplexed metasurface can dramatically reduce the volume of the optical system that engineers the quantum emission of SPE.
In this presentation, I will introduce our recent work in structuring quantum emissions using a multifunctional imaging metalens [1]. First, a beam-splitting metalens was proposed for splitting SPE from ultra-bright defect in hBN depending on its orthogonal polarization states. Next, multiplexed metalenses were designed to imprint any arbitrary wavefront onto orthogonal polarization states, manipulating directionality, polarization, and orbital angular momentum of the output quantum source. This hybrid quantum metalens could unleash the full potential of solid-state SPEs for their use as high-dimensional quantum sources for advanced quantum photonic applications.

Metamaterial Analogue of a Continuous Time Crystal Tongjun Liu[1], Bruce Ou[1], Kevin F. MacDonald[1] and Nikolay I. Zheludev[1,2]; [1]University of Southampton, United Kingdom; [2]Nanyang Technological University, Singapore

Time crystals are an eagerly sought phase of matter in which time-translation symmetry is broken. Quantum time crystals with discretely broken time-translation symmetry have been demonstrated in trapped ions, atoms and spins while continuously broken time-translation symmetry has been observed in an atomic condensate inside an optical cavity. Here we report that a classical metamaterial nanostructure, a two-dimensional array of plasmonic metamolecules supported on flexible nanowires, can be driven to a state possessing all key features of a continuous time crystal: continuous coherent illumination by light resonant with the metamolecules' plasmonic mode triggers a spontaneous phase transition to a superradiance alike state of transmissivity oscillations resulting from many-body interactions among the metamolecules, and which is characterized by long-range order in space and time. As the state can be manipulated optically, the phenomenon is of interest to topological and non-Hermitian physics and applications in frequency conversion, memory, modulation, nonreciprocity and amplification.

Twins of Ultrasmall Gold Nanoparticles (1-2 nm) by Covalently Attached DNA Oligomers Jonas Sager[1], Sebastian Kollenda[1], Kai Klein[1], Kateryna Loza[1], Marc Heggen[2] and Matthias Epple[1]; [1]University Duisburg-Essen, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Ultrasmall gold nanoparticles (1-2 nm) are smaller than most biomolecules like proteins and DNA plasmids. DNA oligomers were covalently attached by azide-alkyne click chemistry to the nanoparticle surface. A thorough control over the reaction conditions permits to limit the number of DNA strands on each nanoparticle to one or two. This allows a hybridization of two nanoparticles that each carry a complementary DNA strand. Furthermore, each nanoparticle was labelled with a fluorescent dye. Thereby, supramolecular structures with nanophotonic effects are generated: Nanoparticle twins (dumbbell-like) with an adjacent FRET pair of dyes.
The nanoparticles and their hybridization products were thoroughly characterized by transmission electron microscopy, NMR spectroscopy, and UV spectroscopy. The twins were isolated and purified by gel electrophoresis, removing aggregates that consisted of more than one pair of particles. The successful hybridization was demonstrated by Foerster resonance energy transfer (FRET) from donor/acceptor dyes at the complementary DNA strands, opening the way for a control over nanophotonic properties by variation of the length of the DNA duplex that connects both particles.

Edge States with Spin-Valley Locking Characteristics Through Staggered Photonic Crystals with Honeycomb Lattice Yeseul Kim[1], Minkyung Kim[2] and Junsuk Rho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of)

Topological photonics imitate topological condensed matter physics, which has created opportunities for efficient and reliable photon transport. In this poster presentation, we present the demonstration of spin-valley locking of edge states using staggered chiral photonic crystals with the two-dimensional honeycomb lattice[1]. With a bandgap in the spin-valley locked edge states and calculations using the coupled dipole technique, we show the bulk band dispersion. And the staggered chirality breaks the inversion symmetry, resulting in the spin-valley locking properties.

Size-Dependent Electron-Phonon Coupling in Monocrystalline Gold Nanoparticles Yannic U. Staechelin[1], Dominik Hoeing[1,2], Florian Schulz[1] and Holger Lange[1,2]; [1]Universität Hamburg, Germany; [2]CUI: Advanced Imaging of Matter, Germany

The absorption of light very effectively generates hot electrons in plasmonic nanoparticles. These hot electrons can be used to photocatalyze chemical reactions. Relaxation of the hot electrons takes place via thermalization with the lattice. In our recent study, we investigated this so-called electron-phonon coupling in gold nanoparticles (AuNPs). Size dependency of the electron-phonon coupling has been controversially discussed in literature. By comparing mono- to polycrystalline AuNPs, we could show that electron-surface scattering contributes substantially to electron-phonon coupling, giving rise to size-dependent electron-phonon coupling in monocrystalline AuNPs, while blurring the size dependency in polycrystalline AuNPs.[1] We investigated further aspects of the hot electron dynamics in plasmonic nanoparticles such as its temperature dependency or the excitation mechanism of breathing oscillations.

Robust Metasurfaces Using Versatile Encapsulation Coating Without Critical Optical Losses Junhwa Seong, Younghwan Yang and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Metasurfaces, which are comprised of 2D subwavelength artificial structures, have been extensively studied owing to their unprecedented wavefront manipulations, especially for visible range. By virtue of these capabilities, metasurfaces can serve as highly functionalized photonic systems, such as metalenses, and metaholograms, with the great pliability of electromagnetic wave control. Despite these benefits, many professionals predict that metasurfaces are challenging to be utilized realistic devices, because of their low robustness. Nowadays, dielectric metasurfaces have been devised to avoid a decrease in efficiency. These optical losses are induced by the electron oscillation of metal when light comes. Particularly, hydrogenated amorphous silicon (a-Si:H) which has a high refractive index and low extinction coefficient has been developed to implement high-efficiency dielectric metasurfaces at the visible. Here, we propose high-efficient and high-robustness encapsulated metasurfaces through bandgap engineering of hydrogenated amorphous silicon, achieving 95% in 532 nm wavelength. We vary the atomic arrangement of hydrogenated amorphous silicon by optimizing process terms of plasma-enhanced chemical vapor deposition for high-efficient dielectric metasurfaces. Moreover, encapsulation coating using atomic layer deposition and spin-on glass enables self-cleaning and high abrasion-resistant metasurfaces, while maintaining high efficiency in the visible frequencies. Unlike conventional metasurfaces, the introduced encapsulated metasurfaces can strongly resist external contaminations and abrasions. We believe that our novel method, enhancing the robustness of metasurfaces, can be applied to pragmatic outdoor applications.

5:00 PM EL16.05.07
Purcell-Enhanced Single-Photon Emission in Hexagonal Boron Nitride Integrated with Bound States in the Continuum Cavity Jihae Lee[1], Minsu Jeong[1] and Junsuk Rho[1,1,2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]POSCO-POSTECH-RIST Convergence Research Center for Flat Optics and Metaphotonics, Korea (the Republic of)

Hexagonal boron nitride (hBN) has drawn attention as a promising candidate for single-photon sources operating at room temperature.[1] Photonic cavities have been employed for single-photon emitters to enhance the spontaneous emission rate[2], which is known as the Purcell effect[3]. In this work, we demonstrate Purcell enhancement of the single-photon emission in hBN combined with the bound states in the continuum (BIC) cavity. The cavity is designed to support the BIC mode at the emission wavelength of single-photon emitters. Single-photon emitters in mechanically exfoliated hBN are activated by argon annealing, followed by the integration into the BIC cavity using a deterministic transfer. The lifetime of the single-photon emission is reduced in hBN coupled with the BIC mode.

Multilayered Metal-Dielectric Structures for Control of Magnetic Dipole Emission MD Afzalur Rab, Shamaar R. Howard, John N. Munga and Natalia Noginova; Norfolk State University, United States

Metal-dielectric multilayers with nanoscale layer thickness exhibiting hyperbolic dispersion and infinite density of photonic modes, provide opportunities for modification and control of quantum processes in or in a close vicinity to such structures. In our work, we explore multilayered metal-dielectric structures for control of spontaneous emission of $Eu3^+$ ions at the magnetic dipole transition. Using COMSOL software, we model the structure consisting of metal, dielectric and emitting layers, study its optical and plasmonic properties, and explore the possibility to selectively enhance or suppress magnetic and electric dipole emission. This possibility presents the special interest for $Eu3^+$ organic systems where the electric dipole transitions are the main competitive channels for the magnetic dipole transition. Theoretical results are compared with the experiment.

5:00 PM EL16.05.11
Monitoring Electrochemical Growth of Copper on Gold Nanoparticle Ensembles Hyunsik Hwang and Hyunjoon Song; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Metals and semiconductor materials have been of interest due to their prominent intrinsic properties on the bulk scale. Nowadays, hidden optical, catalytic, and biomedical applications with enhanced physicochemical properties that go beyond intrinsic properties have newly emerged over decades by nanostructuring. Among them, the shape of structures also has contributed to improving the characteristics. The application of designed nanoparticles has become a key factor in the fields of batteries, catalysts, and energy storage. As a bottom-up approach for controlling sophisticated morphologies, using surface-regulating agents is the most general strategy in synthetic phases. Although strong binding to specific facets has a great effect on selective deposition, there is sometimes a critical disadvantage to shielding other surface reactions in applications. As an alternative to this, various nanostructures are formed without any additives in electrodeposition. Thermodynamic or kinetic preferential structures could be formed according to the degree of diffusion layer gradient during the particle shaping process. The electrochemical reactions on nanoelectrode ensembles, uniformly or non-uniformly continuous arrays of nanoparticles on an inert working electrode, selectively react only in a limited area. Nanoelectrode ensembles have high sensitivity with a good signal-to-noise ratio to resolve chemical reactions. Interestingly, nanoparticle electrode ensembles are the unique features the distance between the nanoelectrodes directly controls the diffusion modes. Also, it was confirmed that radial diffusion layers generated near nanoparticles change the degree of overlapping by scan rate and particle distance. Selective electrodeposition on the nanoparticles dispersed at an active working electrode occurs in certain metal ions for some reasons such as surface energy difference and underpotential deposition. This system behaves like nanoparticle ensembles electrodes, so it was speculated a change in diffusion mode might occur due to the interparticle distance. If the assumption is correct, particle density during diffusion

layer formation can be a decisive factor in morphological control.
Herein, without any variables except particle density, three well-defined morphologies of single Cu nanostructures were successfully synthesized on Au nanoparticle ensembles via electrochemical deposition. As the number of Au nanoparticles on the ITO substrate, it changed to octapods, holed cubes, and cubes. A similar growth mechanism was identified in anisotropy Au rods. Interestingly, the seed asymmetry was transferred to the final structures. In order to understand the progress of growth, in-situ monitoring using dark-field microscopy was performed to obtain both electrochemical and optical signals simultaneously. The strong plasmon properties of metals such as Au and Cu enabled the in-situ reaction monitoring in the solution phase with a simple optical dark-field microscope. The discussion of the diffusion layer near the nanoparticle-modified electrode is just now becoming an important topic in nanocatalysis. By applying these ideas to electrodeposition, we expect to produce functional improvements with only a simple manipulation in the original direct electrodeposition process.

SESSION EL16.06: Plasmonic in the Visible
Session Chairs: Yao-Wei Huang and Yang Zhao
Wednesday Morning, April 12, 2023
Moscone West, Level 3, Room 3016

8:15 AM EL16.06.01
The Design Principles and the Experimental Characterization of Electrically Tunable Bifocal Metalens System in Visible Range Yeseul Kim[1], Trevon Badloe[1], Inki Kim[2], Joohoon Kim[1] and Junsuk Rho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

One of the key components for three-dimensional light focusing and imaging is multifocal lens systems. As electronic devices get smaller, there is an increasing demand for light and thin multifocal systems. Metalens, a kind of flat lens that can focus light by arranging components with subwavelength range, has attracted a lot of interest since it is possible to construct a lens that is extremely light and has a thickness measured in micrometers.
In this presentation, we present how to develop an integrated liquid crystal and electrically tunable multifocal metalens system[1]. The existence of two focal points with a 4 mm difference between them has been experimentally verified. A variety of optical devices, including variable beam control and holographic devices, focusing camera modules, AR/VR display technologies, and depth of field measurement, can use the metalens' quick, millisecond-based focal length adjusting speed.

8:30 AM EL16.06.02
Scalable Manufacturing of Visible Metalenses Toward High-efficiency Virtual Reality Applications Junhwa Seong[1], Joohoon Kim[1], Wonjoong Kim[2], Heon Lee[2] and Junsuk Rho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Metasurface-based flat optics is recently in the process of transitioning from science to technology. For instance, metalenses, that have superior light-modulating performance with sub-micrometer-scale thicknesses, have emerged as alternatives to conventional optical lenses to resolve bulky systems and aberrations. However, many experts forecast that metalenses are arduous to commercialize because of serious materials and pattering limitations such as high production costs and low throughputs. To overcome these crucial bottlenecks, we introduce the mass production of visible metalenses with cost- and throughput-effective skills using argon fluoride lithography and wafer-scale nanoimprint lithography integrated with a high-index atomic layer. Once a 12-inch wafer-scale master mold is imprinted, hundreds of 1 cm metalenses are produced with a resolution of 40 nm which is high enough to fabricate the visible metalens. To increase efficiency, we thinly coated the high-index TiO2 atomic layer on printed metalenses, making it a drastic increase of conversion efficiency from 10% to 90%. As a proof of concept, we further apply our scalable produced metalens to a virtual reality device. Furthermore, this approach can also be employed for the scalable manufacturing of various metasurfaces like holograms and biosensors. We believe that our work will enable the extension of metasurfaces to the industry.

8:45 AM EL16.06.03
Imaging NIR to Visible Upconversion Luminescence from Single $NaYF_4$:Yb^{3+},Tm^{3+} Nanoparticles on Ag Nanowire Composites Kim Yip Chiok[1], Anahita Haghizadeh[1], Aravind Baride[2], Steve Smith[1] and Robert Anderson[1]; [1]South Dakota School of Mines and Technology, United States; [2]University of South Dakota, United States

Tm-doped energy transfer upconversion (ETU) $NaYF_4$: Yb^{3+}:Tm^{3+} nanoparticles have potential applications in deep tissue imaging and energy conversion devices due to their visible (450nm) and infra-red (800nm) upconversion emission, but suffer from low quantum efficiency. We use single particle spectroscopic imaging and statistical analysis to assess the plasmonic enhancement of NIR-to-visible upconversion luminescence (UCL) from single β-$NaYF_4$:Yb^{3+}:Tm^{3+}upconverting nanoparticles (UCNPs) supported on substrates consisting of random arrangements of Ag nanowires or nanowire composites (NWCs). By examining the effects at the single particle level, and accumulating a statistical sampling of single particle emitters, both on and off the plasmonic substrates studied, we obtain a statistical description of UCL emission enhancement in the Tm-doped UCNPs and map out the statistical distribution of excitation and luminescence enhancement on the plasmonic substrates. The distributions obtained are compared to Finite Difference Time Domain (FDTD) calculations of the fields near the plasmonic substrate, assuming the variations are due to variations in UCNP coupling to the plasmonic substrate based on an exponential decay with distance. We use both wide field and confocal spectroscopic imaging of single UCNPs on and off the plasmonic substrates in combination with energy and time resolved spectroscopy and compare these results to a coupled rate equation analysis to elucidate the energy transfer upconversion enhancement mechanisms for these substrates.

Emerging Materials for Plasmonics in the Visible Region—From Discovery to Application Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Progress in understanding resonant subwavelength optical structures has fueled a worldwide explosion of interest in both fundamental processes and nanophotonic/plasmonic devices for imaging, sensing, solar energy conversion, and information processing. However, plasmonic platforms in the visible region with robust, high-performance, thermo-stable, and low-cost remains remain unexplored. In this presentation, I will particularly discuss emerging plasmonic platforms based on transition metal nitrides. I will present an overview of my research works over the past five years on the plasmon-enhanced light-matter interactions in the visible regions and their applications [1-6], including the plasmonic nanolasers [1-2], tunable plasmonic modulators [3], plasmonic phototransistors [4], plasmon-enhanced solar energy harvesting [5], and the refractory plasmonic colors for back-light free displays [6]. My group discovered several unique working mechanisms that utilize plasmonic nanostructures to improve optoelectronic device performance. By engineering the local electromagnetic field confinement, the light-matter interaction strength can be enhanced, which results in efficient energy conversion in the designed nanosystem. The detailed mechanisms and possible applications will be discussed. These results have broad implications for the use of plasmonic crystals/metasurfaces in high-performance optoelectronic devices with efficient energy conversion.

10:15 AM EL16.06.07
Building Metastructures with Unconventional Plasmonic Material—Advances in Structural Colors and Active Tuning Potential Carlota Ruiz de Galarreta[1], Fernando Chacón[1], María Eva Nieto Piñero[1], Marina Garcia-Pardo[1], Nicolas Ramos[2], Jan Siegel[1] and Rosalia Serna[1]; [1]IO-CSIC, Spain; [2]University of the Basque Country UPV/EHU, Spain

In this work we explore a novel approach for the building of metasurfaces using a non-conventional plasmonic material (bismuth) with phase change potential. [1-3] Our choice is based in the excellent plasmonic response demonstrated by Bi-based nanostructures in the ultraviolet and visible promoted by interband transitions [2-3]. In addition, Bi exhibits a relatively low melting temperature (~270 C), with its solid-to-liquid phase transition being accompanied by significant changes in its optical response. Profiting from this property in previous works we have demonstrated the optical switching of Bi-nanocomposite films by hot-plate annealing (phase light switching) or under ns-laser irradiation (ultrafast response) [4-5].
In this work, we explore and experimentally validate two different approaches to high quality bismuth plasmonics for the realization of pure, pre-designed macroscopic colors. Both approaches are based on Al/oxide/Bi structures: one relies on the use of gap-plasmon metasurfaces where the top, 20 nm-thick Bi layer is structured in the form of nanodiscs arranged in a square lattice and supporting localized dipolar resonances. The second approach relies on more conventional and practicable Fabry-Perot cavities based on continuous 10 nm-thick Bi films lying on an oxide/aluminum thin film configuration. Both types of designs have been successfully fabricated employing e-beam lithography and pulsed laser deposition techniques for the case of structured devices, and pulsed laser deposition-only for the Fabry-Perot cavities. Characterization all the devices was carried out via angularly resolved reflectance measurements, showing excellent agreement with respect to simulations. We will discuss peculiarities, pros and cons of each approach in terms of color purity, fabricability and specific advantages for different applications. Finally for the case of the nanostructured Bi metasurfaces, we will show preliminary results of the tuning potential of the reflectance spectrum upon heating and melting of embedded Bi nanodisks, exploiting the solid-to-liquid optical contrast of Bi.

10:30 AM EL16.06.08
Mapping Phonon Polaritons with Visible Light Kiernan E. Arledge[1], Michael A. Meeker[2,3], Chase Ellis[2], Nazli Rasouli Sarabi[1], Vincent R. Whiteside[1], Chul Soo Kim[2], Mijin Kim[2], Daniel Ratchford[2], Binbin Weng[1] and Joseph G. Tischler[1]; [1]University of Oklahoma, United States; [2]U.S. Naval Research Laboratory, United States; [3]The City University of New York, United States

Surface phonon polaritons (SPhPs) are surface electromagnetic modes resulting from the strong coupling of infrared light with optical phonons in polar materials. SPhPs show great promise for tailoring light-matter interactions at size-scales below the diffraction limit. Interrogating SPhP modes has mostly been pursued by measuring the far field behavior of resonant modes (i.e., eigenvalues), through which SPhPs can be investigated by looking at resonant frequencies and linewidths along with the strength of the resonances. In other instances, the study of SPhPs has been accomplished by mapping electromagnetic fields (i.e., eigenstates) solely at the surface of nanostructured resonators by atomic force microscopy assisted techniques and, in some limited cases, measuring the three-dimensional fields using electron scattering. Accurate knowledge of SPhPs has been hindered by the absence of experimental techniques to map eigenstates in three dimensions that are easy, cheap, and non-destructive.

Here, using Indium Phosphide (InP) nanopillars, we demonstrated direct three-dimensional measurements of SPhP modes. Confocal Raman microscopy is used to obtain the spatial distribution of phonon modes in the nanostructure. By comparing these maps with simulation results, we demonstrated that SPhPs couple to bulk Raman modes through the material's polarizability and, to a lesser extent, via electron-phonon coupling. These observations provide a new method for measuring SPhP modes in nanostructured materials and a novel way to investigate the physical phenomena involved in coupling bulk phonons to SPhPs.

Sodium Surface Plasmon Polaritons Ankun Yang; Oakland University, United States

Sodium (Na) is predicted to be an ideal plasmonic material with ultra-low optical loss across visible to near-infrared. However, there has been limited research on Na plasmonics due to its high reactivity. Here we develop a scalable fabrication method for Na nanostructures, by combining phase-shift photolithography and a thermo-assisted spin-coating process. Using this method, we fabricated Na nano-pit arrays with varying periodicities (300-600 nm) and with tunable surface plasmon polariton (SPP) modes spanning visible to near-infrared (NIR). We achieved SPP resonances with small linewidths as narrow as 10.2 nm. In addition, we observed linewidth narrowing of Na nanostructures from visible towards NIR, showing the prospect of high performance of Na nanostructures operating in the NIR. To address the challenges associated with the high reactivity of Na, we designed a simple encapsulation strategy and stabilized the Na nanostructures in ambient conditions for more than 2 months. As a low-cost and low-loss plasmonic material, Na offers a competitive option for nanophotonic devices and plasmon-enhanced applications.

11:00 AM *EL16.06.10
Polaritonic Metasurfaces Andrea Alu; City University of New York, United States

In this talk, I will discuss our recent progress in the area of polaritonics, and its role in advancing the field of metamaterials and metasurfaces. Tailored material resonances, based on excitons, phonons, or electronic transitions, can be strongly coupled to electromagnetic waves in engineered metasurfaces, unveiling new degrees of freedom for the control of light-matter interactions and enhancing optical nonlinearities. In particular, I will discuss how, as the degree of lattice symmetries in the involved materials and in optically engineered structures is reduced, new opportunities emerge in manipulating light and matter at the nanoscale.

SESSION EL16.07: Light Trapping and Absorber Designing with Metasurfaces and Metastructures

1:30 PM *EL16.07.01
All-Glass Metasurfaces for Durable and Large Aperture Laser Optics Eyal Feigenbaum; Lawrence Livermore National Laboratory, United States

The field of optical meta-surfaces is rapidly growing due to its great potential to enable thin optics implementation with relatively complex and flexible functions. Some of the anticipated key future optical technologies will require for its viability large optical apertures, durability to harsh environments, and robustness to laser powers and energies. These complex systems could benefit from thinner and more lightweight optics, and the improved phase-front control that metasurfaces could deliver. For example, high power and energy laser systems could benefit from optical meta-surfaces that implement beam shaping, e.g., for wave-front aberration correction, but with the advantages of smaller accumulation of nonlinearity and lighter weight. An additional benefit is the superior designs of antireflective layers that are enabled by such a technology.
We present an alternative approach, with far less limitations on scalability, and with inherent high durability. However, the main challenge for this approach is the attainable phase difference range and better understanding the underlying physics of this process. This process we recently presented and demonstrated [ACS AMI 11, 22684 (2019), Optica 7, 518 (2020), Adv. Opt. Mat. 10, 2200151 (2022)], utilizes a laser induced de-wetting of thin metal film on silica glass, followed by dry etching through the nanoparticles mask and removal of the residual metal mask, to result in an all-glass metasurface optics. In this approach the local laser induced heating, using a laser raster-scan, determines the local effective index. Alternatively, a large area and uniform antireflective layer could be generated using dewetting in a furnace. The process is relatively simple, scalable and results in an environmentally stable structure, and allows also for into-the-layer graded-index profile. However, the air-glass volumetric ratio mixing approach is limited by the depth of the layer, and so we have developed approaches to “boost” the attainable phase response and enhance the control over the nano-features shape.
In this talk we will detail the recent developments made in the controllability while preserving the scalability and durability, and the detail the recently demonstrated metasurfaces.
This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. We acknowledge LLNL LDRD support (21-ERD-002). LLNL-CONF-842487.

2:00 PM EL16.07.03
Large Photothermal Modulation of Dielectric Huygens' Metasurface Absorber Hao-Yu Cheng[1,2,2], Chi-Yin Yang[3], Min-Wen Yu[3], Wei-Ruei Chen[3], Shi-Wei Chu[1,4], Kuo-Ping Chen[3,4] and Kung-Hsuan Lin[2]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan; [3]National Yang Ming Chiao Tung University, Taiwan; [4]National Tsing Hua University, Taiwan

Mie-type resonators have been found to exhibit large nonlinearity of spectral responses under photoexcitation, which is applicable to all-optical modulation. The typical modulators, based on ring resonators are of size around 10-100 micrometers. To reduce the size of an optical modulator, one potential approach is to utilize Mie resonators. The state-of-the-art modulation depth of Mie resonators is 40-50%, which is still lower than the state-of-the-art all-optical modulator based on a silicon ring resonator. In this work, we demonstrate large modulation depth in Huygens‘ metasurface absorber. When multiple nanostructured resonators (units) are arranged periodically to form a metasurface, coupled electromagnetic interaction creates “lattice resonance” in addition to the resonances due to an individual unit itself. When the electric dipole lattice resonance (EDLR) matches with the magnetic dipole (MD) resonance and the materials possess moderate loss, each meta-atom (unit) could absorb most of the incoming electromagnetic wave due to the matched hybrid resonant modes, which is called Huygens‘ metasurface absorber. We used amorphous silicon-based Huygens’ metasurface absorber and ultrafast excitation to demonstrate two orders of magnitude enhancement of modulation depth, both theoretically and experimentally. We compared two sample structures with the EDLR matching and mismatching the MD of the single SiNB, respectively. At matched resonant condition, we found that the modulation depth was theoretically enhanced by two orders of magnitudes. Enhancement by an order of magnitudes and over 100% modulation depth were experimentally achieved at the matched resonant frequency. Since the optical spot covered tens of SiNBs in the array, our work manifested the feasibility to achieve a large modulation depth of a Mie-type all-optical modulator with size on the order of 1 micrometer. This work opens the avenue toward all-optical information processing via optimized modulation by careful spatiotemporal and spectral control over a metasurface.

3:30 PM EL16.07.06
Ultrathin Broadband Metasurface Superabsorbers from a van der Waals Semimetal Adam Alfieri[1], Michael Motala[2], Michael Snure[3], Jason Lynch[1], Pawan Kumar[1], Huiqin Zhang[1], Susanna Post[4], Christopher Muratore[4], Joshua R. Hendrickson[3], Nicholas Glavin[3] and Deep M. Jariwala[1]; [1]University of Pennsylvania, United States; [2]UES, Inc., United States; [3]Air Force Research Laboratory, United States; [4]University of Dayton, United States

Platinum diselenide ($PtSe_2$) is a novel van der Waals semimetal that exhibits extraordinarily strong interaction with light (a refractive index that exceeds 4 and an extinction coefficient over 2) over a broadband range from the visible to near infrared (NIR). We demonstrate cm-scale growth of 18 nm thick $PtSe_2$ layers with a solar-weighted absorption of 87.6% (from 400 nm – 900 nm) when transferred onto a 40 nm Al_2O_3/Ag reflector substrate[1]. By patterning the $PtSe_2$ layer into a periodic array of nanoresonators, the electric field can be localized in the $PtSe_2$, resulting in an average visible range absorption of 97.9% and a solar-weighted absorption of 97.0% (400 nm to 900 nm) in a total structure thickness of 158 nm and an active layer thickness of only 18 nm. Our $PtSe_2$ metasurfaces present a scalable approach to ultrathin broadband absorbers for photodetection and solar energy harvesting.

2:30 PM BREAK

3:45 PM EL16.07.07
Transient Color Filters and Superabsorbers Based on Magnesium Peifen Lyu, Tao Gong and Marina S. Leite; University of California, Davis, United States

Photonic devices built upon ultrathin metal films have attracted rising research interest due to their structurally simple and mechanically stable design, which is highly scalable and time-efficient compared to the nanopatterning process, without compromising the superior optical performances. The current photonic thin film research depends heavily on conventional metals (e.g., Au, Ag and Cu) with limitations of high-cost, CMOS-incompatibility and bio-incompatibility, preventing their further usages in industrial applications. Here, we present Magnesium (Mg), the eighth most abundant material on the earth's crust, as a promising candidate for its competitive low-loss optical properties with additional compatibilities in CMOS and biological devices. The first device presented is a Mg-based transient broad-band reflective color filter made from a tandem stack structure of two metal-insulator-metal (MIM) stacks, Mg/MgO/Mg and Ag/Al_2O_3/Ag, interconnecting by a thin MgO layer [1]. Our devices can successfully achieve distinctive hues across the CMY reflective color gamut and are insensitive to incident angles up to 50 degrees, which are conducive for color displays. The transient process takes place while these first vivid colors can vanish within ~40 seconds after immersing in water [2]. It is beneficial that the hue fades quickly for the security and protection of optical information. Further etching ultimately removes away the Mg-contained layers, leaving bottom Ag/Al_2O_3/Ag MIM with another reflective color which is maintained stably under ambient conditions. In contrast, the second device incorporates an ultrathin a-Si absorbing layer and exhibits a spectrally selective and tunable near-unity resonant absorption [3]. By varying the thickness of the semiconductor layers (a-Si and SiO_2), it can generate characteristic colors which cover all the primary RGB and CMY color spaces. An exposure to water can dissolve the Mg back reflection layer and the remaining bilayer transmissive color filters are ready for reconfiguration. To summarize, we propose a novel platform for transient color filters and superabsorbers with Mg-based thin films, which can attain diverse structural colors by tuning the layer thickness. Its unique feature of the single-time and irreversible transient color change process in a zero-power consumption manner, provides new opportunities for next-generation CMOS compatible, biodegradable, and low-cost photonic devices.

4:00 PM EL16.07.08
High Absorptivity Nanotextured Powders for Metal 3D Printing Ottman Tertuliano[1], Philip DePond[2], Jiho Hong[2], Andrew Lee[2], David Doan[2], Wendy Gu[2], Mark L. Brongersma[2], Manyalibo Matthews[3], Wei Cai[2] and Adrian Lew[2]; [1]University of Pennsylvania, United States; [2]Stanford University, United States; [3]Lawrence Livermore National Laboratory, United States

The widespread of application of metal additive manufacturing (AM) is limited by the ability to control the complex interactions between the energy source and the feedstock material. Here we develop a process to introduce nanoscale grooves to the surface of copper powders which increases the powder absorptivity by up to 70% during laser powder bed fusion. The absorptivity increase enables printing of pure copper structures with densities up to 92% using laser energy densities as low as 82 J/mm^3. Simulations show the enhanced powder absorptivity results from plasmonic resonances at nanoscale grooves features combined with multiple scattering events. The approach taken here demonstrates a generalized method to modifying the absorptivity and printability at low energy densities of reflective metal powders by changing the surface morphology and leveraging electric field localization in these self-evolving nanostructures.

4:15 PM EL16.07.09
Inverse Design Enables Large-Scale RGB-Achromatic Metalens and Metagrating Po-Cheng Yang[1], Lu-Yun Wang[1], Jhih-Hao Huang[1], Zhaoyi Li[2], Raphaël Pestourie[3], Steven Johnson[3], Federico Capasso[2] and Yao-Wei Huang[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Harvard University, United States; [3]Massachusetts Institute of Technology, United States

Metalenses with forward dispersion engineering promotes the correction of chromatic aberration. However, forward design of achromatic metalenses find the limitation of scale with the limited dispersion range of meta-atoms. There are many inverse design strategies of metasurface design. However, Inverse design remains very challenging for aperiodic large-scale meta-optics because of limitation of computation time and memory capacity. In this study, we utilize inverse-design framework for aperiodic large-scale complex meta-optics in three dimensions, which alleviates computational cost for both simulation and optimization via a fast-approximate solver and an adjoint method, respectively. We demonstrate an RGB-achomatic metalens with diameter up to 1 centimeter. The focusing efficiency is ~24% in simulation and ~15% in experiment. Furthermore, we demonstrate a metagrating which effectively deflects the light to the 1st order diffraction by using inverse design method. The maximum efficiency of our metagrating achieves up to 67% at large deflection angle (~70°), which is 32% higher than that with forward design in the literature [2]. Moreover, we demonstrate a future virtual-reality platforms by using our meta-eyepieces with a laser back-illuminated micro liquid crystal display. The inverse-design framework can be extended to design large-scale high efficiency multifunctionality metasurfaces.

4:30 PM EL16.07.10
SERS Chips Containing Internal Standard MoS_2 for Quantification of Analytes Seungkyun Lee, Seongdae Kwon, Kibum Kang and Yeon Sik Jung; KAIST, Korea (the Republic of)

Raman spectroscopy with Surface-enhanced Raman scattering (SERS) is one of the most selective, sensitive, and rapid methods for detecting target analytes. Recently, research for adjusting SERS to many fields such as food toxicity, biomolecules, and hazardous substances is being actively implemented. However, SERS has limitations for exact quantification, due to various factors such as spot variation, absence of standard, and reproducibility. Thus, research for integrating 'internal standard material' into the SERS chip has been conducted. It showed the possibility of calculating the ratio of 'Raman intensity of analyte' to the 'Raman intensity of internal standard material', which is supposed to be consistent within the controlled condition.
Here, we propose a 'MoS_2@Gold nanostructure SERS chip', in which the MoS_2 was used as the internal standard for the intrinsic Raman characteristic peak. Existing materials for the internal standard of SERS chips were mostly produced in form of particles or flakes, which may occur spot variation. By integrating the MoS_2 grown in film form, the uniformity and controllability of the substrate could be highly refined. Gold is located at both the top and bottom of the MoS2 in the form of film and nanogrid, which could increase the SERS effect on both MoS_2 and the analyte. This sandwiched structure resulted in a 10^{-9}M LOD of Rhodamine 6G (R6G) and a linear relationship between the Raman intensity and the concentrations of the analytes within the standard deviation of less than 4%, with the correction factors. Through the results of the linear relationship, the MoS_2@Gold nanostructure SERS chip developed in this research proposes future alternatives to the sensors on universal fields with a qualitative, quantitative, and quick method.

SESSION EL16.08: Poster Session: Nanostructure Design, Fabrication and Characterization
Session Chairs: Pin Chieh Wu and Yang Zhao
Wednesday Afternoon, April 12, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM EL16.08.01
Optical Phenomena of Si@MoS_2 Core@Shell Architecture at the Nanoscale Yea-Shine Lee[1], Tatsuki Hinamoto[2], Sina A. Dereshgi[1], Shiqiang Hao[1], Matthew Cheng[1], Hiroshi Sugimoto[2], Minoru Fujii[2], Christopher Wolverton[1], Koray Aydin[1], Roberto d. Reis[1] and Vinayak P. Dravid[1]; [1]Northwestern University, United States; [2]Kobe University, Japan

Transition metal dichalcogenides (TMDs) are attractive for next-generation photonics due to their large exciton binding energy and exciton transition dipole moment. However, because of their few-atom-layered nature, observing nanoscale light-matter interaction through absorption and emission of the electromagnetic field in TMDs has been challenging. This unfortunately makes isolated TMDs inappropriate for use in optical-to-electrical conversion applications.

Recently, TMD-encapsulated nanospheres, or core@shells, have presented a potential avenue for strong light-matter interactions by leveraging the functionality of the nanoparticle core material. In a core@shell architecture, the dielectric nanosphere core acts as an optical cavity in the Mie regime while the encapsulating 2D material shell acts as a quantum emitter. When the two constituents couple, light-matter interaction is significantly improved and optical-to-electrical conversions such as lasers and quantum information processing that had been otherwise limited in 2D materials can be realized. This geometry has potential applications in nanophotonic devices such as all-optical switches, exciton−polariton lasers, and quantum information processing, as well as various optoelectronic applications such as ultrasensitive sensors, light-emitting devices, and solar cells. However, it is challenging to grow 2D materials on curved surfaces. Moreover, there is an urgent need to develop experimental techniques to probe complex systems that cannot be easily modelled computationally. In our work, we fabricate Si@MoS_2 and use valence electron energy loss spectroscopy (VEELS) to achieve enhanced light-matter interaction and understand the principles underlying this phenomenon.

We encapsulate silicon nanospheres with multilayers of MoS_2 via chemical vapor deposition. Using transmission electron microscopy (TEM) and single-particle scattering spectroscopy, we demonstrate energy coupling in this system with the silicon magnetic dipole mode undergoing Rabi splitting at the MoS_2 A-exciton wavelength in its scattering spectrum. The coupling constant is measured to be significantly higher than that of nanoparticle-on-TMD film geometries, and is an important validation of the Si@MoS_2 system for adoption in photodetection-based nanotechnology. Photoluminescence enhancement is also demonstrated by Si@MoS_2, effectively affirming that the core acts as an antenna to excite the TMD shell emitter.

We then extract the local dielectric functions of Si@MoS_2 with high spatial resolution via VEELS, which offers information on the valence electron excitations, to understand how the electronic structure of this heterostructure evolves from its two constituents. Using a cross-sectioned Si@MoS_2, the evolution of the electronic structure from uncovered silicon to the core-shell interface is evaluated. Notably, the resulting dielectric function of Si@MoS_2 demonstrates features attributed to heterostructuring semiconductors with different band gaps. As dielectric functions embed valence electron excitation, plasmonic excitation, and intra/inter-band transitions, they directly relate to optical parameters such as absorption, reflectance, and transmissivity of the material. The presentation will explain how optical properties of core@shells can be understood and provide a platform to improve their property-performance relationship.

5:00 PM EL16.08.02
Active Modulation of Vivid Color Enabled by Functional Materials Soo-Jung Kim, Chohyeon Park and Sung-Hoon Hong; Electronics and Telecommunications Research Institute, Korea (the Republic of)

Artificial structural color possesses many advantages over pigments or dyes, such as long-term stability, low energy consumption, color diversity, and environmental friendliness. Structural colors based on Fabry-Perot (F-P) cavity do not require the complex nanofabrication and is simply a thin film stacked structure. It is an easy way to generate various colors with thickness of cavity layer in large-scale. Because of these advantages, researchers have carried out color generation using F-P cavity for many applications such as high-resolution display, color printing, anti-counterfeiting technology, and millitary application. However, there are some issues that need to be addressed: such as active modulaion, durability, and portability for practical use.
In this study, we propose a tunable vivid structural coloration based on F-P cavity by using a unique nanocrystal (NP)-based metamaterial and functional materials. Our reconstructed F-P structure consists of top porous Ag NP metamaterial layer, bottotm metallic layer, and a functional material medium layer. The Ag NP layer as an upper metal forms a porous structure with controlled NP spacing through ligand exchange of NP. Application of the porous upper metal is a key factor to detemine the vivid and marked reflective color. The functional material (phase change material, functional polymer, etc.) can control the resonant frequency by changing the index properties or structural system with an external factor (electrical force, environmental conditions).

5:00 PM EL16.08.03
Solvent Dependent Swelling of a PDMS Mold for Accurate Replication of Metasurfaces Nara Jeon, Dong Kyo Oh and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

A metasurface is composed of two-dimensionally arrayed subwavelength nanostructures, whose electromagnetic (EM) responses can be designed artificially to realize holography, optical cloaking, structural color printing, etc. Nanoimprint lithography (NIL) has overcome conventional nanofabrication limitations such as high cost and low throughput, which have been principal obstacles preventing the practical application of metasurfaces. A one-step fabrication method, however, is required to open the door to a way for the commercialization of metasurfaces. For this reason, a single-step fabrication of metasurfaces using high-refractive-index nanoparticle embedded resin (PER) has been implemented.
Methyl isobutyl ketone (MIBK) is mainly used in industrial coating solvents because resins used in paints, lacquers, inks, and other forms of surface coatings can be effectively dissolved by MIBK. In consideration of future industrialization, MIBK is chosen as an industry-compatible solvent to mix a monomer, photo-initiator, and nanoparticles for PER. However, it makes polydimethylsiloxane (PDMS), used as a soft mold, swell. Such fabrication imperfections from the swollen mold can cause undesired EM responses, or significant reduction in structures performance and Q factor of bound states in the continuum (BIC)-based metasurfaces, designed numerically to have higher resonance sharpness. Especially, since a dielectric metasurface that supported BIC used in ultrasensitive hyperspectral imaging for bio-detection requires extremely high-quality fabrication, limited fabrication tolerance has a significant impact on performance.
So far, how the swollen mold by a solvent affects the shape of replicated nanostructures is not still being considered. Here, we investigate the effects of different solvents on replicated metasurfaces to increase accuracy. By selecting appropriate solvents, the replication accuracy was increased up to 77%.

5:00 PM EL16.08.04
Direct Measurement of Ballistic and Diffusive Electron Transport in Gold Pravin Karna and Ashutosh Giri; University of Rhode Island, United States

Gold thin films are one of the most widely used thin films in plasmonic devices, where the hot electrons traverse in ballistic motion to transfer their energy to the underlying semiconductor layer used for applications in solar energy harvesting. Therefore, for efficient operation of these devices, the proper understanding of ballistic motion of electrons is of paramount necessity. However, the understanding of diffusive and ballistic electron mean-free paths in metals remains elusive, partly due to limitations of the experimental methods such as pump-probe measurements to accurately resolve the dynamics with high spatiotemporal resolution, limiting the efficient application of these thin films in plasmonic devices. For example, pump-probe measurements from prior studies have inferred the ballistic length of electrons in gold thin films to be around 100 nm, which has been accepted for over 30 years. However, a direct measurement of the ballistic (along with diffusive) mean-free paths of electrons in gold films with nanometric precision has still been lacking so far. To fill this void, in this work, we carry out an extensive experimental and first principles study to describe the characteristic scattering length scales of electron in laser heated gold thin films. Specifically, we use our homebuilt ultrafast super-resolution thermo-reflectance technique to track the evolution and scattering of electrons in gold. We find the ballistic length of these hot electrons to be in excess of 150 nm, around 50% higher than the previously accepted value of 100 nm. We also measure the diffusive length of hot electrons to be ~45 nm at peak electron temperature. Our parameter free density functional perturbation theory calculation predicts an average diffusive length scale of ~35 nm when the electrons and phonons are in thermal equilibrium. However, at elevated temperatures the reduction in electron-phonon coupling factor due to lattice stiffening arising from inter-band transition of electrons leads to a drastically enhanced mean-free paths of electrons in gold. Our results lend insights into the dynamic behavior of electrons in laser heated metals and significantly improves our understanding of warm dense matter in general.

5:00 PM EL16.08.05
Redirecting Light Propagation at the Nanoscale in Molybdenum Trioxide (MoO3) Nanobelts Mingze He[1], Levi Hoogendoorn[2,1], Saurabh Dixit[1], Zhiliang Pan[1], Deyu Li[1] and Joshua D. Caldwell[1,1]; [1]Vanderbilt University, United States; [2]Northwestern University, United States

Due to the long free-space wavelengths associated with radiation in the infrared (IR) to terahertz spectral domains, the realization of flat and subdiffractional optical components promise advances in imaging, communications, sensing, and IR sources. One approach to compress light into deeply subdiffractional length scales is to use polaritons, which are hybrid excitations in materials resulting from the interaction of light and oscillating charges. One type of particular interest is hyperbolic polaritons, which in principle allow infinitely small polaritonic wavelengths. Hyperbolic polaritons are supported in materials that are optically metallic along one crystal axis and optically dielectric along the other. Therefore, the resultant isofrequency curves indicate theoretically infinitely large wavevectors within these materials and so they have acquired an increasing interest in the past decade for applications such as super-resolution imaging and sub-diffractional on-chip waveguiding. Molybdenum trioxide (MoO3) is one of the materials that support these hyperbolic polaritons and, due to the orthorhombic crystal structure, its optical properties are different along all three crystal axes. In one frequency range (821 – 956 cm-1), only the [100] crystal direction behaves as a metal, leading to an in-plane dispersion with a hyperbolic isofrequency curve, which has allowed wavevectors in only certain directions. The fact that propagation is forbidden along the [001] within this spectral range restricts the ability to direct polariton motion, thereby limiting many applications.

In this work, we experimentally and theoretically demonstrated the topological transition of hyperbolic phonon polaritons in MoO3. This topological transition is characterized by an inversion of the polariton propagation direction in a certain subset of this frequency range and a change in behavior from type-II to type-I hyperbolic. To achieve this, we first theoretically analyzed that the topological transition can be realized in geometric confinement along the [100] direction. Due to the geometric confinement in the [100] direction, a Fabry-Perot mode can be formed. As a consequence of the in-plane hyperbolic isofrequency curve, the mode still possesses a wavevector component in the [001] direction, forming a propagating polariton in the [001] direction. This was done by controlling the nanobelt width, whereby a variation in the Fabry-Perot condition can be induced, thus forming a net wavevector along [001] direction. Next, we experimentally imaged the inverted polariton propagation using scattering-type scanning near-field optical microscopy (s-SNOM). Further, we demonstrated the criteria of this topological transition in both the frequency and geometric parameter domains. Our results open possibilities for the manipulation of hyperbolic polaritons and pave the way for promising applications in metamaterials, nanophotonics, and quantum optics based on natural vdW materials.

5:00 PM EL16.08.06
Novel Design Approach of Tri-Channel Image Display with Single-Cell and Single-Size Strategy Junhwa Seong, Joohoon Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Multi-functional meta-devices have been intensively studied owing to the great potential for highly integrated and ultra-compact meta-devices. Currently, multi-functional meta-devices have relied on layer staking and interleaving of nanostructures to increase the information encoding capacity. However, these approaches are limited to low efficiency, design complication, and fabrication complexity. Thus, a high-capacity meta-display that can contain a lot of information in a simple structure has been required for practical applications. Here, we propose a single nanostructure-based tri-channel meta-display by merging the geometric phase spin-decoupling and Malus's law intensity control. This device displays two far-field helicity-dependent holographic information and one near-field nano-printing image. To increase the efficiency, we have employed low-loss hydrogenated amorphous silicon (a-Si:H) which supports high transmission efficiency in the whole visible frequencies. Low-loss a-Si:H has also an advantage of CMOS compatible and cost-effective plasma-enhanced chemical vapor deposition process. We believe that our novel approach opens new avenues in multi-funcional meta-devices.

5:00 PM EL16.08.07
Fabrication of Plasmonic Nanohole Array-based Hybrid Plasmonic Structures by a Sacrificial Layer Combined Tip-based Lithography Jeong-Sik S. Jo and Jae-Won Jang; Dongguk University, Korea (the Republic of)

The subwavelength-scale metallic nanostructures fabricated by nano-fabrication methods are extremely important structures in subwavelength optics due to physical phenomena based on plasmonic resonance. In particular, a subwavelength hole can focus and amplify electromagnetic waves; thus metal nanohole arrays can be used in various fields including nanophotonics, highly sensitive sensing, and highly efficient energy harvesting. Here, we demonstrate tip-based lithography utilizing a sacrificial layer that can fabricate subwavelength metallic nanohole arrays in room conditions. The size of the nanoholes is controlled by changing the contact force of the tips onto the sacrificial layer, and nanoholes of a diameter of 40 nm can be obtained. The distance between nanoholes can be precisely controlled by using the piezo-based tip-based lithography system equipped with a general AFM, with which plasmonic antennas with a nanogap of the scale of several tens of nanometers can be fabricated. In addition, the hybrid plasmonic structures are also fabricated by placing metallic nanoparticles inside the nanoholes. These hybrid plasmonic structures show strong field enhancement compared to the existing plasmonic structures and have the potential for surface-enhanced Raman spectroscopy applications. The developed fabrication method will be useful for plasmonic applications and the developed hybrid plasmonic systems will provide various research opportunities related to plasmonic coupling.

5:00 PM EL16.08.08
Deep Active Learning for Metamaterials Yang Deng[1], Simiao Ren[1], Jordan M. Malof[2] and Willie J. Padilla[1]; [1]Duke University, United States; [2]University of Montana, United States

Deep learning has recently shown great potential in accelerating the forward and inverse design of metamaterials. A wide range of model architectures, inverse modeling, and hybrid algorithms was explored recently, aiming to expedite the creation of more exotic metamaterials. Without exception, all the above deep learning techniques rely on their data-driven nature, which makes the neural networks always hungry for more data. Despite deep neural networks' orders of magnitude faster inference time, applying deep neural networks demands an initial cost of data collection, posing a considerable data bottleneck that delays the rapid prototyping of next-generation metamaterials. In this work, we explore active learning techniques to advance the data efficiency of the deep learning design of AEMs compared to random sampling. We carefully compare the performance of all deep active learning algorithms and the random sampling baseline to examine the generality of active learning methods to AEM problems. It is shown that deep active learning algorithms can save as much as 40% of data compared to random sampling. However, the limited generality and additional optimization requirements pose a significant challenge to applying active learning to metamaterial design in practice.

Rare Earth Ion Crystal Growth Investigations Ashleigh K. Wilson, Violet Macauley and Natalia Noginova; Norfolk State University, United States

Rare earth ions in organic matrices are of interest for a variety of applications, including optical sources and displays. To generate luminous crystals using rare earth ions and organic ligands such as dipyridyl and phenanthroline, a solution growth approach can be used. Under UV light, the ions in the crystals may be activated and become effectively luminous. We are now investigating the best regime for the crystal development of phenanthroline-based crystals containing various Ln ions utilizing varying chemical concentrations and substrates such as flat glass, gold, nanostructured alumina membrane, and gold nanomesh systems. We also investigated the possibility of controlling crystal formation and development using a nanostructured environment and extra light stimulation.

Helical Plasmonic Meta-Arrays Sculpted by Circularly Polarized Light Ji-Young Kim, Connor McGlothin, Minjeong Cha, Zechariah Pfaffenberger, Emine Emre, Kody Whisnant, Sanghyun Lee, Wonjin Choi and Nicholas A. Kotov; University of Michigan, United States

Chiral metasurfaces from nanoscale helicoids aligned perpendicularly to substrates display unique optical, catalytic, biological and mechanical properties but are difficult to produce. Currently, subwavelength chiral geometries on substrates are created primarily by two-photon lithography followed by electroplating of metals and etching by plasma. Other top-down patterning methods include ion/electron beam induced deposition and glancing angle deposition; All of them involve time-consuming process with multi-step treatment and demand high vacuum and temperature condition. Bottom-up self-assembly of nanoparticles (NPs) could be a simpler and faster pathway to chiral metasurfaces but there are several fundamental constraints. Compared to helical molecules, the spontaneous out-of-plane alignment of nanohelices is particularly hard due to prohibitively high energy penalties. Here, we show that the unfavorable thermodynamics can be overcome for light-guided synthesis and assembly of plasmonic NPs, producing stand-up arrays of helicoids sculpted by the circularly polarized light. The handedness of the silver helicoids and their polarization spectrum are controlled solely by the ellipticity and wavelength of the incident photons. Using a programmable motorized stage, millimetre- to centimeter-scale metasurface patterns with on-the-fly control of polarization effects are printed within seconds to minutes on various substrates. Substrate versatility, high optical asymmetry, and efficiency of light-to-matter chirality transfer enable rapid printing of metasurfaces for multiple applications including but not limited to photonic, optoelectronic, and electromechanical devices, as well as enantioselective catalytic and sensing systems.

Transfer Learning For Multitasks In Large-scale Metasurface Simulations Rixi Peng, Jordan M. Malof, Simiao Ren and Willie J. Padilla; Duke University, United States

Deep learning has successfully demonstrated the capability of learning the electromagnetic response of various metamaterials with a sufficiently large dataset. A neural network can work as an accurate and fast proxy model for applications such as design optimization and dynamic control. However, each new problem requires a new dataset to train a neural network, including those with slight modifications to the original problem. In this work, we integrate the underlying physics of metamaterials into transfer learning and obtain the neural network that can be reused for variations of the original problem.

This work focuses on the scattering problem of large-area random metasurfaces. It is a well-known challenging problem due to the limitation of computational resources. Solving this scattering problem in a reasonable timeframe is highly desirable in many applications, such as disordered metamaterials and metamaterial focusing lenses. We benchmark the transfer learning scheme on various single-factor changes from the original problem, including material choices, metamaterial element shapes, substrates, and incident fields. We demonstrate that tuning the original problem's neural network using transfer learning can significantly reduce the required data size to reach a certain level of accuracy for the new problem compared to a model trained from scratch.

This study also compares the efficiency of transfer learning among different changes from the original problem and analyzes the task distance between the original problem and the target problem. The task distance provides a performance prediction on which type of changes in the problem have higher gains by using transfer learning.

Our work provides the scheme to use a neural network trained for one metamaterial problem to flexibly train another neural network for a modified problem with reduced data requirement, representing an enhanced application of deep learning in the fast-changing metamaterial area.

Fast and Rigorous Optical Simulation of Periodically Corrugated Light-Emitting Diodes Based on a Diffraction Matrix Method Chanhyung Park, Jeongmin Shin, Sanmun Kim, Juho Park and Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Organic light-emitting diodes (OLEDs) have become one of the major light sources for display applications due to their high luminosity, high color purity, and flexibility. The light emission of an OLED can be divided into two processes, which are the internal quantum efficiency and the light extraction efficiency (LEE). The internal quantum efficiency has approached almost 100%, while LEE is still limited to around 20% due to the total internal reflection. The remaining light is coupled to the bound modes such as substrate-confined modes, waveguide modes in the organic layers, and surface plasmon polaritons (SPP) modes. Adding periodic corrugation can increase LEE by extracting energies from these modes by diffraction. However, analyzing the effect of periodic corrugation quantitatively is quite challenging. To calculate the LEE of a periodically corrugated OLED, conventional electromagnetic simulation methods such as the finite-difference time-domain (FDTD) method or the finite element method (FEM) are mainly used. However, these numerical methods require huge computational power and take hours to compute. Therefore, fast calculation of corrugated OLEDs based on theoretical calculation is needed. Delbeke et al. made some progress in calculating far-field emission patterns of a periodically corrugated OLED theoretically [1]. However, a theoretical method doesn't exist that can calculate the LEE of a periodically corrugated OLED and be verified by comparison with other conventional methods.
In this work, we demonstrate how the light emission in a periodically corrugated OLED structure can be rigorously calculated. Our method, which we call the diffraction matrix method (DMM), tracks the mode conversion via diffraction matrices, which elements are calculated by rigorous coupled-wave analysis method (RCWA) [2]. We first compared DMM with the conventional FDTD method by calculating the optical properties of a periodic corrugated OLED with a single emitter. The far-field emission patterns of the model device calculated using DMM and FDTD agree well with the diffraction arcs and the emission peaks appearing at the same position in the reciprocal space. LEE and Purcell factor calculation results using DMM and FDTD agreed within error smaller than 2%, while DMM runs over 60 times faster. Also, DMM can perform optimization over 10,000 times faster than FDTD by analytical integration and reusing diffraction matrices. By DMM, we could also conduct a power dissipation analysis that helps identify the loss channel by resolving power dissipation channels into the unbound, waveguide, and SPP modes, which is impossible in FDTD. We also implemented the DMM of 2D periodically corrugated OLEDs within errors smaller than 3%.
We expect that DMM will help to find an optimal corrugated OLED structure with a higher LEE value than that of optimized planar OLED. We also expect that DMM can be applied to any photonic device that involves a wide-angle incidence within periodic geometry such as perovskite LED and QD display.

High-Yield Plasma-Dependent Fabrication of Undulated Gold Nanoplates as SERS Substrates Mary Sajini Devadas, Dariush Aligholizadeh and Wilson Turner; Towson University, United States

Anisotropic Au nanostructures have been heavily pursued in recent years due to the energetic and optical phenomena which they generate. Generally, increasing anisotropy yields greater intensities of such events, e.g. Surface-Enhanced Raman Scattering (SERS). SERS is an energetic phenomenon that enables the detection of analytes in Raman spectroscopy at pico- and nano-molar concentrations by adsorbing an analyte to the surface of a metallic nanoparticle, such a method being used in the detection of molecules that are extremely potent in low quantities, such as environmental toxins or early detection of diseases through biomarkers. It thus becomes of great value to gain the most anisotropy with minimal resources used to create practical and powerful aides in molecular spectroscopy. Herein, we propose the fabrication of highly anisotropic Au nanostructures from a simple smooth Au nanoplate through quick plasma-dependent reshaping of the Au {111} surface to create pyramidal undulations. The differences between N2 and Ar will be presented. Due to a large number of theoretical hotspots now present at the surface of the plasmonic nanostructure, the SERS enhancement must greatly increase. We further provide an in-depth SERS analysis in both liquid and solid phases with a model analyte p-NTP to determine the strength of these SERS substrates, as well as various characterizations to further elucidate the properties of these substrates.

5:00 PM EL16.08.14
Light Scattering Optical Color Filters for Enhancing the Absorption in Colorful Semitransparent Solar Cells Minji Kim[1], Jongdeok Park[2], Jun Yeong Ryu[2], Jae-Joon Lee[2] and Jerome Hyun[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Dongguk University, Korea (the Republic of)

Light scattering can be useful when applied to solar cells as it can increase the optical pathlength of light within the active medium via light trapping or multiple scattering events. Early studies demonstrated such concepts by incorporating metallic or dielectric particles inside or on top of various solar cells. The solar cells were opaque, prepared on reflective substrates, while the particles were, in many cases, placed on top to promote scattering in the forward direction. Recently, semitransparent solar cells imbued with colors have been gaining increased attention due to their applicability in colorful building integrated photovoltaics (BIPVs). By replacing the back-electrode of a semitransparent solar cell with a Fabry-Perot (FP) cavity, the transmitted colors can be tuned independent of the inherent color of the active material. In this work, we show that by preparing close-packed metal coated silica particles arrays on a metal film in place of the FP cavity, we can backscatter non-resonant light to high angles, promoting light trapping and enhancing the overall absorption while maintaining the same color rendering properties. This behavior is distinct from conventional bare scatterers, which tend to scatter light in the forward direction and a planar FP cavity which backscatters nonresonant light in the normal direction. Experimental results confirm that semitransparent solar cells with Ag coated silica particles outperform planar FP-cavity integrated solar cells in terms of the power conversion efficiency. These results suggest a simple strategy to enhance backscattering of light to high angles and further show promise in increasing the performance of semitransparent solar cells.

5:00 PM EL16.08.15
Boosting Photoelectrochemical Water Oxidation via Au Nanocluster Pattern Arrays with Amplified Localized Surface Plasmon Resonance Effect Seung Hun Roh, Jaekyum Kim and Jung Kyu Kim; Sungkyunkwan University, Korea (the Republic of)

Photoelectrochemical (PEC) water splitting is a promising method for producing renewable energy, the hydrogen fuel. The n-type metal-oxide based semiconductors have been widely researched for potential PEC photoanode due to their earth-abundant, high stability in aqueous electrolyte, and suitable band gap properties. Especially, $BiVO_4$ has been attracted the attention because of the low band gap (~2.4 eV) property that can effectively harvesting the light. However, the high recombination rates problem of $BiVO_4$, which originated by poor electrical conductance and short minority carrier diffusion length, hinders to reach high PEC performance. And the intrinsic defect causes the trade-off with light harvesting from photoanode thickness. To overcome above-mentioned bottlenecks, various strategies such as doping, morphology control, facet engineering, heterojunction, and plasmonic enhancement methods have been studied. Among them, utilizing localized surface plasmon resonance (LSPR) effect via plasmonic enhancement is regarded as effective strategy in PEC system as it has light-driven property.

LSPR phenomenon is collective charge oscillation from plasmonic metal nanoparticle which cause by incident electromagnetic wave, the light. Those charge oscillation induces the strongly localized electromagnetic field between plasmonic metal nanoparticles. From these unique properties, the device performance can be improved by two mechanisms: direct electron transfer (DET) and plasmon induced resonance energy transfer (PIRET). In DET process, the hot electrons, which are generated by LSPR, are directly injected to conduction band in neighbor semiconductor overcoming the schottky barrier. It can be preferable mechanism for enhancing light harvesting efficiency with improved the device performance from increased current. PIRET is the phenomenon of energy transfer from plasmonic metal to semiconductor which can generated electron-hole pairs without charge injection. With advantages of each mechanism, various research of enhanced device performance has been reported, and those reports are mainly focused on coupling effect between plasmonic nanoparticles, not groups. However, the LSPR phenomenon is sensitively affected by variables such as dielectric constant, shape, and size of plasmonic metal. Hence, it is reasonable that considering the configuration of plasmonic metal nanoparticles to effectively utilize LSPR phenomenon.

In this study, the highly ordered Au nanocluster (AuC) pattern arrays in Mo-doped $BiVO_4$ (BVO) is introduced to investigate the group-group coupling effect. We designed AuC hexagonal pattern structure to readily modify the configuration of Au nanoparticle. Also, the thin SnO_2 passivation layer was deposited between AuC and BVO that can induce PIRET effect rather than DET. To effectively suppress the charge recombination, DET process should be avoided. As a result, the LSPR effect was amplified by AuC configuration which is generated by particle-particle and group-group coupling effect. The photocurrent density of AuC/BVO was improved to 1.87 mA/cm^2 (~1.7 fold) at 1.23V (vs. RHE) with efficient light harvesting. Moreover, we found that the AuC pattern arrays efficiently enhanced charge transport and transfer efficiency and suppressed the overall charge recombination. From our report, we expect that the designing the configuration of plasmonic metal is essential for utilizing dense LSPR effect.

Optical Suppression of Energy Barriers in Single Molecule-Metal Binding Ivana Qianqi Lin[1,2], Shu Hu[2], Tamás Földes[3], Junyang Huang[2], Demelza Wright[2], Jack Griffiths[2], Eoin Elliott[2], Bart de Nijs[2], Edina Rosta[3] and Jeremy J. Baumberg[2]; [1]University of Twente, Netherlands; [2]University of Cambridge, United Kingdom; [3]University College London, United Kingdom

Understanding the interactions between molecules and metal surfaces is of widespread importance in electrochemistry, sensing, medical imaging/targeting, molecular electronics and spintronics. Although many techniques have characterized the molecule-metal transient bonds, **conflicting conclusions arise from their buried location and heterogeneity, while single-molecule probes are scarce**. Confinement of optical fields to picometre length-scales around adatoms (termed *picocavities* [1]) has enabled tip-enhanced and surface enhanced Raman spectroscopies (TERS and SERS) of single-molecules. However how adatoms change with molecule-metal interactions, with light (both key ingredients in photocatalysis), and how they link to picocavity formation in plasmonic nanogaps is not understood.

In this work [2], we demonstrate how the light-molecule-metal interaction influences the formation and stabilisation of adatoms yielding picocavities. Through **statistics from over a million spectra** and modelling by density functional theory (DFT), **we show how the local polarisation of molecule-metal electrons is amplified by illumination, gradually eliminating the energy barrier for adatom extraction and subsequently binding molecule-to-metal**, instead of photothermal heating at the surface. We find rates $\propto \{-U_f(I) / k_B T\}$ where intensity I suppresses the barrier, scaling as $U_f(I) \propto U_f^0 / I$.

Interactions between a polarizable molecule and metallic atom create extremely powerful optical forces (>nN) capable of rearranging the material interface. This work provides not only a vital intuition for utilising light-molecule-metal systems to **control single-atom optical switches and next generation photonic devices**, but also a strong spur to develop new theories capable of combining electromagnetism with quantum mechanics.

Deeply Subwavelength Exciton-Polariton Integrated Nanophotonics with van der Waals Materials Haonan Ling[1], Arnab Manna[2], Jialiang Shen[3], Siyuan Dai[3], Arka Majumdar[2] and Artur Davoyan[1]; [1]UCLA, United States; [2]University of Washington, United States; [3]Auburn University, United States

One of the challenges in today's integrated nanophotonics technology is that the size of optical elements has always been limited by the diffraction limit, $\lambda/2n$ [1]. This has set constraints on the individual device footprint, leading to relatively low photonic device integration density. Compared with conventional 3D covalent semiconductors at the backbone of today's integrated photonics industry such as Si and InP, bulk transition metal dichalcogenide materials (TMDCs), an emerging type of layered van der Waals materials, offer ~25% higher refractive index in the telecom frequency band. Due to their unique material properties, the high permittivity resulting from sharp exciton-polariton resonance in the visible range is preserved in the TMDC sub-bandgap (i.e., low-loss) regime [1], thus making them an ideal and promising material platform for deeply subwavelength integrated nanophotonic systems [2].

Here, for the first time to our knowledge, we demonstrate deeply subwavelength (thickness < λ/10) integrated nano-waveguiding devices made of bulk TMDCs and characterize their performances in the near-infrared bands, where loss is small. We first discuss the fabrication process of waveguides with grating couplers at both sides on exfoliated MoS_2 flakes with pre-selected thickness. Then we perform optical transmission measurement with wavelength ranging from 750 nm to 1000 nm. We find that despite the strong optical absorption close to material exciton resonance (~ 680 nm), light can be efficiently transmitted through over 20 μm long structures while operating at 910 nm and above. Moreover, we also perform polarization dependent study to show that only TE fundamental waveguide mode can be sustained in such deeply subwavelength devices.

Next we also study more complex waveguiding structures such as Y-splitters made of bulk MoS_2. By shining the light onto input coupler, the light can be coupled into and propagate along the structure get split into two arms. We can clearly observe two distinct emission spots during the measurement. By reading the transmission spectrum at each emission spot, we find a close to 50:50 power splitting is achieved. These results add the promise of using such material platform for creating deeply subwavelength integrated nanophotonic systems.

9:00 AM EL16.09.04
Plasmonic Lattice Resonances in Highly Asymmetric Dielectric Environments Brandon K. Durant[1], Igor Vurgaftman[2], Joseph A. Christodoulides[2], Marc Christophersen[2], Nicholas Proscia[1], Paul D. Cunningham[2], Adam E. Colbert[2], Janice E. Boercker[2], Chase Ellis[2] and Stanislav D. Tsoi[2]; [1]NRC Postdoc residing at the US Naval Research Laboratory, United States; [2]U.S. Naval Research Laboratory, United States

Metal-based Surface Plasmon Polariton resonances have garnered attention for their ability to confine light to sub-diffraction dimensions and enhance light-matter interactions at the nm scale across the visible and infrared (IR) spectra regime. However, these enhancements are limited by optical losses that arise from radiative coupling and absorption, which limits the quality factor (Q = λ/Δλ) of resonances. Here, we report on the narrowing of the plasmonic resonances observed experimentally in reflectance measurements of Au nanodisc lattices fabricated on a GaAs substrate when the lattice periodicity matches the wavelength for the Rayleigh anomaly in the substrate. We attribute this narrowing to the diffractive coupling of the resonators, which results in surface lattice resonances (SLRs). While SLRs are typically observed for systems with homogeneous optical environments (closely matched indices of refraction for the substrate and superstrate), our system is highly inhomogeneous ($n_{air} = \sim 1$, $n_{GaAs} = \sim 3.4$) and still supports lattice resonances. The experimental reflectivity spectra are accurately reproduced in numerical simulations. Furthermore, we couple lead chalcogenide quantum dot emitters to the nanodisc lattices and demonstrate a 3-fold increase in their photoluminescence intensity and a significant alteration of the emission line shape, in correlation with the narrow SLR. Our findings highlight the optical properties of Au nanodisc resonator arrays within a heterogeneous environment, opening new possibilities in sensing and enhanced light emission applications.

9:15 AM EL16.09.05
Introducing Coupling between Surface Plasmon Resonance and Nanophotonic Modes Wen-Hui (Sophia) Cheng; National Cheng Kung University, Taiwan

Localized surface plasmon resonances (LSPR) can harvest sunlight and generate non-equivalent hot carriers, paving a new approach for photocatalysis. However, the inefficient light matter interaction limits the efficiency. We propose strategies to realize strong coupling condition between plasmonic and other nanophotonic modes. With proper design of Si nanodisk and Au antenna, Rabi splitting greater than the average of dephasing is demonstrated through coupling between the magnetic dipole and LSPR. We found that a low index spacer is critical in the hybrid structure. In addition, coupling between Au antenna and Si cavity mode can also be achieved. For a device made of an Au-NP/p-NiO/Au film, we theoretically examine the effect of nanoparticle size and surface coverage to the coupling condition between the plasmon and Fabry-Pérot (FP) cavity mode. Greater particle sizes result in higher splitting energies at the same surface coverage, while increased surface coverage results in higher splitting energy at the same particle size. The above results as an outlook show the possibility and design principle to incorporate strong light matter interaction in the field of plasmonic photocatalysis.

9:30 AM BREAK

10:00 AM *EL16.09.06
Meta-optic Accelerators for Image Processing and Object Classification Jason G. Valentine[1], Hanyu Zheng[1], Quan Liu[1], Ivan I. Kravchenko[2] and Yuankai Huo[1]; [1]Vanderbilt University, United States; [2]Oak Ridge National Laboratory, United States

We demonstrate meta-optic based accelerators that can off-load computationally expensive operations into high-speed and low-power optics. The key to these architectures are the new freedoms afforded by metasurfaces such as optical edge isolation, polarization discrimination, and the ability to spatially multiplex, and demultiplex, information channels. I will discuss how these freedoms can be utilized for accelerating optical segmentation networks and objection classifiers, both based on incoherent illumination. This approach could enable compact, high-speed, and low-power image and information processing systems for a wide range of applications in machine-vision and artificial intelligence.

10:30 AM EL16.09.07
Surface Energy-Modified and SERS-Based Plasmonic Sensing of Urine for the Diagnosis of High-Mortality Rate Illnesses Minjoon Kim, Sejoon Huh, Sungho Jo and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

High mortality-rate illnesses such as lung cancer and prostate cancer with survival rates of less than 20% and 10%, respectively, require rapid diagnosis to significantly decrease the number of deaths. However, conventional medical imaging diagnosis methods such as endoscopic ultrasound and computed tomography have limited practicability for early detection as the test process may not only be inconvenient for the patient but also be incapable of detecting fine changes in metabolism. Then, the analysis of metabolites can be suggested as a facile method for detecting biomarker changes in patients. Metabolites are promising early-stage cancer biomarkers because they are produced in different types or concentrations in normal and cancer cells and are excreted in body fluids including blood and urine. Urine is a suitable medium for metabolite analysis because it is easy to collect, and surface-enhanced Raman spectroscopy (SERS) is an outstanding option for the detection of low-concentration metabolites by rapidly collecting molecular-specific signals with high sensitivity. However, urine analytes do not adsorb well on hydrophobic nanostructured surfaces, creating thick buildups of urine components that are not delivered to Raman “hot spot” regions and cause Raman signal damping issues. Moreover, there are signal variation issues due to overlapping of numerous peak sources as well as urine composition differences by samples within the same patient group.

Here, we propose a surface energy-modified SERS sensing platform for enhanced adherence of urine analytes on the measuring substrate and for rapid Raman spectra collection of multiple samples that are analyzed with the aid of deep learning. Via a thermally-assisted nanotransfer printing (T-nTP) technique, a large-area superhydrophobic Ag nanowire substrate is fabricated, on which superhydrophilic data collection point arrays are marked for easy location of SERS measurement points. An efficient fabrication method is applied as the T-nTP technique allows uniform printing of nanowires over large areas whose surface energy is lowered via hydrophobic self-assembled monolayer functionalization, while multiple circular superhydrophilic areas are simultaneously formed on selected areas via roughness control and SiO_2 evaporation through a shadow mask. When urine is dropped on a data collection point, the large difference in surface energy guides the droplet to be spread and dried within the selected surface energy boundary while the high surface energy of the data collection point allows strong adhesion of analytes for clear and intensified Raman signals. In contrast to previous research on utilizing SERS for urine analysis that often require tedious nanoparticle size and concentration control, compactly located regular nanogaps are formed over large areas via T-nTP for enhanced plasmonic effects and regular signal intensification. Moreover, multiple samples of different patient groups are dried simultaneously on separate hydrophilic points for a high-throughput data collection system with reduced measurement preparation time. Signals of multiple samples are detected rapidly for deep learning-based analysis to detect and classify minor differences between normal and cancer patient groups. Overall, a plasmonic sensing platform is proposed for cancer diagnosis via rapid collection of enhanced Raman signals and classification of complex signals, which can be extended to rapid diagnosis of other diseases by analyzing water-based biological samples.

10:45 AM EL16.09.09

A Multifunctional Plasmonic Sensor for Excellent UV Photodetection and NO_2 Gas Sensing by an Array of Al Nanocaps on GaN Truncated Nanocones YuPing Kuang, Abhishek Dubey and Ta-Jen Yen; National Tsing Hua University, Taiwan

Plasmonic resonance has unique subwavelength properties, strong local field enhancement, and ultrafast decay time of carriers. Based on these advantages mentioned above, plasmons have recently attracted great attention in electromagnetic, optoelectronic, and photovoltaic applications such as photodetection, gas sensing, surface-enhanced Raman scattering, water splitting, solar cells, nonlinear optics, plasmonics lasing, metalens, etc. To support plasmonic resonance, the most commonly used metals are gold (Au) and silver (Ag), mainly because of their low intrinsic losses. However, Au and Ag suffer from low plasmonic frequencies and interband transitions at 500 nm and 300 nm, respectively, so these two noble metals can be used in the infrared (IR) and visible regions, but hardly in the ultraviolet region. There are increasing demands for UV applications such as UV light detection, advanced communications, environmental and biological monitoring, air purification, high-temperature flame detection, missile tracking, and more. Therefore, there is an urgent need to obtain a high-quality plasmonic metal to facilitate electromagnetic and optoelectronic applications under UV conditions.
Among metals with higher plasma frequencies for UV applications, aluminum (Al) offers several advantages such as low cost, low intrinsic losses in the UV region, native oxide protection, and Complementary Metal Oxide Semiconductor (CMOS) compatibility and other advantages. In this work, we design a heterogeneous Al nanocap (Al-NC) array on a wide-bandgap semiconductor of GaN truncated nanocones (GaN-TNCs), and then demonstrate a versatile plasmonic sensor that enables excellent UV photodetection and air quality index (AQI) gas sensing. Therefore, for UV detection, we exhibit an ultra-high responsivity (1.8 × 108 AW^{-1}), which, to our knowledge, is the highest detection rate (1.2 × 1018 cm $Hz^{1/2}W^{-1}$) for GaN-based UV detection device. In addition, this UV photodetector also exhibits ultrafast rise time (78.3 ms) and fall time (303.5 ms) responses, respectively. For gas detection, we measure NO_2, a key AQI gas used as an indicator for the larger group of nitrogen oxides (AQI). Our results showed an excellent response of 28% and a detection limit of 500 ppb.

11:00 AM EL16.09.10

Metal Oxides Metasurfaces with Controlled Refractive Index from 1.2 to 2.7, Elaboration by Direct High Throughput NIL and Applications in Optics, Photonic and Gas Sensing Victor Malgras[1], David Grosso[1], Magali Putero[1], Marco Abbarchi[1], Martin O'Byrne[1], Badre Kerzabi[2] and Zeinab Chehadi[1]; [1]IM2NP, CNRS AMU, France; [2]SOLNIL, France

Metal oxide (MO_X) nanopatterns have been prepared from Soft-Nano-Imprint-Lithography (soft-NIL) combined with sol-gel formulations. A careful adjustment of the chemical parameters and processing conditions are used to obtain faithful replicas with high vertical aspect ratios up to 3 and refractive index up to for instance 2.7@520 nm with TiO_2, on glass, silicon wafers, fused silica. This method is CMOS-compatible, cost-effective and easy to scale-up. [2,13]

As-deposited sol-gel layers are rather difficult to imprint as a result of the fast evaporation-induced stiffening of the precursors that prevents efficient mass transfer within the cavities of the soft mould. Nonetheless, by adjusting the processing conditions to the pure inorganic sol-gel chemistry we demonstrate that the process can be highly simplified while improving the quality of the replicas and avoiding the use of sacrificial, stabilising, organic agents that is always accompanied by a high shrinkage. A compromise can be found for all sol-gel materials to reduce the xerogel viscosity necessary for capillary filling, while limiting the shrinkage upon final thermal curing. Metasurfaces bearing arrays of high aspect-ratio 3D features of different shapes and composed of hard ceramics with controlled functionalities are directly available with such a one-step process. Besides, this method is compatible with high-throughput on 200 mm glass and silicon wafers (limited only by the machine in use) and conventional production constraints. It also benefits from the countless chemical compositions available from sol-gel chemistry and has been demonstrated with many metal oxides.

In this presentation, we will focus on Silica (SiO_2), Titania (TiO_2), Alumina (Al_2O_3), and Europium-doped Zirconia (ZrO_2:Eu^{3+}) as pristine, hybrid, or mesoporous materials. They have been patterned with different designs and bearing different motif dimension (down to 100 nm) and aspect ratio (up to 3), to address different functionalities such as controlled-wetting surfaces, light harvesting coatings, diffraction gratings for light extraction, multispectral filters, enhanced spectrally and spatially controlled emitting surfaces, wave guides, structural color coatings, anti-reflection coatings, photonic VOC sensors, or flow cells for DNA sequencing. [3-15]

High-Performance and Cost-Effective Liquid Metal Nanophotonic (LIMEN) Sensors Based on Surface-Enhanced Spectroscopy Peter Qiang Liu; State University of New York at Buffalo, United States

Gallium and several gallium-rich alloys are metals in the liquid phase near room temperature and possess unique and appealing material properties for various device applications, including nanophotonic sensors. Nanoscale photonic cavities supporting high field confinement and enhancement can be conveniently formed by utilizing these liquid metals. Employing such liquid-metal-based nanophotonic structures for sensor applications allows the efficient delivery of analytes into the desired hot spot locations to be completed before cost-effectively forming the nanophotonic cavities, hence resolving the fundamental dilemma of trading off analyte delivery efficiency against field confinement/enhancement which limits the performance of conventional nanophotonic sensors based on solid metals. Here, we present our recent developments of high-performance liquid metal nanophotonic (LIMEN) sensors for both surface-enhanced infrared absorption (SEIRA) and surface-enhanced Raman scattering (SERS) sensing applications.

SESSION EL16.10: Advanced Nanostructure Design with Machine Learning I
Session Chairs: Jason Valentine and Yang Zhao
Thursday Afternoon, April 13, 2023
Moscone West, Level 3, Room 3016

1:30 PM *EL16.10.01
Physics-Informed Reinforcement Learning for Nanophotonic Device Design Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The increasing demand on a high-performance metasurface requires a freeform design method that can handle a huge design space. Accordingly, various nanophotonic device design schemes have been investigated including the ones based on machine learning. In this presentation, I discuss design approaches based on deep reinforcement learning, which have achieved great success in many different fields spanning video games, the game of Go, protein folding problems, to matrix multiplication algorithms. Reinforcement learning has not yet been actively explored in the field of nanophotonics compared to other machine learning methods such as generative or discriminative models. I will introduce how to apply deep reinforcement learning to design a metasurface beam deflector with large degrees of freedom, and discuss how to increase the sample efficiency by informing the agent of the reinforcement learning using physical constraints that govern the electromagnetic system.

2:00 PM EL16.10.02
Phonon Polaritons in Hexagonal Boron Nitride Heterostructures Mingyuan Chen[1], Yuhan Zhong[2], Eli Harris[3], Jiahan Li[4], Zhiren Zheng[5], Hongsheng Chen[2], Jhih-sheng Wu[6], Pablo Jarillo-Herrero[5], Qiong Ma[3], James H. Edgar[4], Xiao Lin[2] and Siyuan Dai[1]; [1]Auburn University, United States; [2]Zhejiang University, China; [3]Boston college, United States; [4]Kansas State University, United States; [5]Massachusetts Institute of Technology, United States; [6]National Chiao Tung University, Taiwan

Using scanning probe infrared nano-imaging, we investigated phonon polaritons in hBN heterostructures assembled from monoisotopic crystals. Our combined experimental and theoretical study reveals multiple branches of hyperbolic phonon polaritons in hBN heterostructures. We also show that wave dispersions for hyperbolic phonon polaritons can be delicately altered by engineering the heterostructures. These phonon polaritons can be interpreted by the geometric optics model of the hyperbolic rays in the heterostructures and are promising for nanophotonic and thermal applications. The method of building new forms of van der Waals heterostructures may be extended toward a range of materials and properties.

2:15 PM EL16.10.03
Pushing the Limits of Functionality Multiplexing Capability in Metasurface Design Based on Statistical Machine Learning Yihao Xu[1], Wei Ma[2], Bo Xiong[2], Lin Deng[1], Ruwen Peng[3] and Yongmin Liu[1]; [1]Northeastern University, United States; [2]Zhejiang University, China; [3]Nanjing University, China

Enabled by cleverly designed nanostructures, metasurfaces offer an unprecedented way to manipulate light on a completely planar platform. The versatility and unique optical responses of metasurfaces under different illumination conditions are beneficial to encode independent information. Typically, a top-down, two-step design process for multifunctional metasurfaces proceeds as follows: First, the design goals are decoupled to obtain the phase requirements for each illumination condition. Then, the metasurfaces are built by multiplexing single-responsive meta-atoms or assembling multiple phase-tuning techniques such as the geometric phase and resonant phase. However, with an ever increasing number of design channels, this empirical design intervention becomes infeasible.

In this study, we propose utilizing machine learning techniques to capture the statistical features in the high-dimensional joint distribution of meta-atoms in the unit cell and the corresponding optical responses, thereby supporting a quantitative evaluation of the severity of function crosstalk and an on-demand inverse design. We enhance the design capabilities for various meta-atom design frameworks with the assistance of such framework. To provide an automated end-to-end design loop for multifunctional metasurfaces, the developed machine learning model can be seamlessly integrated with the gradient-based and non-gradient optimization processes. We have successfully constructed metasurface focusing lenses and holograms operating in eight customizable channels in the near-infrared range utilizing a single metasurface, where each channel is a combination of different incident frequencies and polarizations. We have also researched free-form meta-atoms represented by binary images, which support more resonance modes and enhance the independence of each information channel.

Our results suggest that the data-driven optical design technique outperforms conventional physical-guided methods, which will expedite the development of novel optical display, communication, and computing devices and systems.

3:30 PM *EL16.11.01
Artificially Structured Electromagnetic Media Based on Freeform Metamaterials Jonathan Fan; Stanford University, United States

In this talk, I will discuss new concepts in wavefront engineering based on freeform metasurface and metamaterial systems. First, I will discuss how broadband arbitrary birefringence responses can be realized and tuned using sets of freeform metagratings, which utilize microscale motions to enable birefringence control. Second, I will discuss how volumetric freeform metamaterials can utilize strong multi-scattering and non-local interactions to enable arbitrary and multi-functional wavefront responses. Third, I will discuss how the design of artificial freeform electromagnetic media can be accelerated by three orders of magnitude using neural network-based surrogate solvers and optimizers.

4:00 PM EL16.11.02
Facile Quantification of Nanosized Bioparticles in Bright-field Micrograph via Deep Learning Jiwon Kang, Jin-Hwi Park, Young Jin Yoo, Joo Hwan Ko, Hae-Gon Jeon and Young Min Song; Gwangju Institute of Science and Technology, Korea (the Republic of)

The pathogen is considered a critical threat to public health, especially immunocompromised people such as babies, and the elderly. Initiating the apt therapy to the defected patients before turning into the peak viral load is significant to prevent their fatal damage. However, most point-of-care diagnostics are unsuitable for counting the concentration of the virus. Accordingly, various bioimaging techniques are suggested to visualize and/or count biological samples like histopathology. Despite their superb resolution and precise quantitation, the need for sophisticated equipment or professional manpower stunts the broad interest.
Explosive interest in artificial intelligence (AI) induces profuse interdisciplinary studies, especially in biomedical engineering and clinical medicine recently. Due to the property of pure convolution and superior object categorization skills, convolutional neural networks (CNNs) that model human vision has been demonstrated in comprehensive clinical data to predict patient diagnoses. Even though CNNs produce high capabilities for the assigned task, plenty of pre-processing and the requirement of expert interpretation are still mandated.
Tri-layer resonator is adopted as the optical solution to break through weak light-matter interaction in far-field optics. By harnessing thin-film interference, the modulated light produces a strong resonance in the bioparticles of low refractive index and nanoscale size and leads to the perception of targeted analytes. Additionally, the aggregation of biofunctionalized nanoparticles in drop-casted solution due to hydrodynamics of an evaporating droplet (e.g., the Marangoni flow) synergizes with the slow-light effect so that the invisible analytes can be discovered with definite chromatic information even through the usual optical microscope (OM). During the nanofabrication and surface-functionalizing, however, the residues and defects randomly exist on the surface of the designed biosensor. Hence, we introduce the CNN that establishes a correlation between the chromatic information of optical micrographs and the ground-truth of corresponding scanning electron microscope (SEM) images.
Here, we showcase the chromatic immunoassay system consisting of the biosensor that is optically optimized for general zoonotic virus and deep learning that is robustly constructed with 1596 pairs of OM images and matching SEM images. The hard negative samples of the fabrication fluctuation including the impurities and the defects are trained to identify the desired particles automatically, thus averting the false-positive and enabling accurate quantitative analysis. The image-driven biosensing system validates the limit of viral detection of 104 copies/mL which is lower than the rapid antigen test using lateral flow immunoassay (LFIA) and achieves high sensitivity and specificity for the diverse bioparticles modeling Zika virus, Monkeypox virus, and Mumps virus. The presented immunoassay platform may also be amenable to microscopic hazardous fragments such as metal oxide nanoparticles and microplastics.
In this study, we have shown that CNN-based bright-field micrograph analysis allows not only intuitive immunoassay but also quantification of minuscule subjects. Nanosized bioparticles are detected with a straightforward antibody-antigen reaction, which does not require either labeling or amplification. A single drop of the solution enables visceral recognition through the vision. Owing to the purity of the CNN, the various analytes whose diameters are below the diffraction limit can be estimated with the little training set. We also have confirmed that the presented immunoassay quantifies the concentration accurately within the average viral load from SARS-CoV-2-infected patients. We believe that the streamlined quantitative system is applicable to numerous nanoscale dicey particles.

4:15 PM EL16.11.03
Prediction of Light Extraction Efficiency Using a Transfer Learning Model Jeongmin Shin, Sanmun Kim, Wonwoo Lee, Chanhyung Park and Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Calculation of optical efficiency in an organic light emitting diode works as a bottleneck for the device geometry optimization process. However, almost all commercial simulation tools obtain solutions based on physical rules. Therefore, the calculation speed of the simulation tools is governed by the simulation space. However, prediction based on artificial neural networks is independent of the simulation space size, hence the calculation speed can be boosted while maintaining the complexity of structure which requires a large number of equations under the physical rules. [1] Despite its advantage, replacing the numerical simulation with an artificial neural network is not always efficient due to the computational load required for the generation of training data. Transfer learning is a useful method for reducing the required number of training data. There are few papers that used transfer learning to calculate the optical properties [2, 3]. However, these studies have been conducted on a case where a plane wave, which is a relatively simple case, is incident from the outside. Furthermore, the previous papers do not consider training models with data that contains errors.
This paper focuses on the OLED system and presents a method to design a network even when there is not enough trainable data. In this paper, we will explain network structure design techniques in cases where experimental or theoretical data are insufficient. To apply the transfer learning, we pre-trained a 15-layers deep learning model to calculate the light extraction efficiency spectrum of a 6-parameter OLED structure with 200,000 trainable data sets.
First, we demonstrate a transfer learning method by predicting the light extraction efficiency of a six-layer OLED system (7-parameter model) based on a neural network trained for predicting the light extraction efficiency of a five-layer OLED device (6-parameter model). We reuse some layers from the five-layer OLED prediction network and re-train the network for a six-layer OLED device with only 4,000 data. Generating speed for the whole model is 100 times faster than the non-transfer case. Root mean squared error (RMSE) is used to mark the accuracy of each model. The RMSE of the 6-parameter model is 0.0029 and the RMSE of the 7-parameter model reaches 0.0085 with only 2,000 data. For the 8-parameter model system, the RMSE is 0.0098 when applying the part of the 6-parameter network
Second, this paper also generates the deep learning model that predicts the light extraction efficiency from the measured dataset which contains both functional error and random error. Measured data not only contains random errors but also functional errors. Deep learning models cannot predict random error intrinsically, but functional error can be predicted by the deep learning model. We apply both Gaussian random error and functional error at input data that represent the structural parameter and transfer the deep learning model that is trained with error-free data. With only 8,000 training data, the model can predict the functional error with an RMSE error of 0.005.

This paper suggests a method for generating the deep neural network with a small amount of additional training data.

4:30 PM *EL16.11.04
Meta-Optics—Multifunctionality and Neural Computing Nanfang Yu; Columbia University, United States

In this invited talk, I would like to share with you two pieces of recent work from my lab on meta-optics. In the first part of the talk, I will show you passive multifunctional metasurface devices based on quasi-bound states in the continuum that can produce distinct wavefront shapes at different wavelengths, and active multifunctional metasurface devices made of conventional dielectric materials that can produce distinct wavefronts under different heating conditions. The second part of the talk is about a new class of optical neural networks based on metasurfaces that can transform complex binary and gray-scale images, such as handwritten digits and human facial photos, into “optical barcodes” to enable their identification.

SESSION EL16.12: Poster Session: Active Control Metasurfaces and Metamaterials
Session Chairs: Yao-Wei Huang and Yang Zhao

5:00 PM EL16.12.01
Diffraction Fields Optimization for Proximity-Field Nanopatterning—Toward High Contrast 3D Chihun Lee[1], Gunho Chang[2], Seokwoo Jeon[2] and Junsuk Rho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The design and manufacturing of a three-dimensional (3D) nanostructure with high resolution and uniform patterns are crucial in nanoengineering. The proximity-field nanopatterning (PnP) is one of the promising candidates for high spatial resolution and large area fabrication. The proper phase mask design is required to modulate the coherent light for high contrast 3D design. currently, optimal designs are limited to intuitive methods focusing on reducing the 0th order diffraction efficiency by changing the height of mask. In this research, with the particle swarm optimization, we concurrently optimize the phase mask with the new figure of merit for controlling the electric field intensity. We inversely designed the specific 3D electric field intensity distribution and got the required phase mask design. The optimal phase mask can fabricate uniform 3D hexagonal nanoarray structures compared to 0th suppress design which cannot modify the field distribution owing to the direct electric field intensity control. Our concurrent optimization method using global optimization can improve both the degree of freedom and nanopattern quality. Furthermore, this concurrent optimization method demonstrated versatility by varying the pattern periods and materials. We expect that the inverse design method can tune the nanostructure to improve its properties, which can benefit each application field.

5:00 PM EL16.12.02
Facile Fabrication of Titanium Nitride Nanoring Broadband Absorbers in the Visible to Near-Infrared over a Large-Area via Shadow Sphere Lithography Myeongcheol Go[1], Dasol Lee[2], Junsuk Rho[1] and Jinkon Kim[1]; [1]POSTECH, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

Plasmonic broadband absorbers have potential applications such as thermophotovoltaics, solar energy harvesting, and thermal emitters. However, poor thermal durability and fabrication in a limited area remain as a challenges. Refractory materials such as titanium nitride (TiN), chromium, and tungsten have been suggested for plasmonic absorbers because of their thermal stability, chemical resistance, and relatively low price. Colloidal lithography (CL) has been widely applied to prepare periodic two-dimensional nano-sized patterns such as nanoholes, nanodisks, and nanocones on various substrates in a large area. Further complicated hierarchical nanostructures such as nanorings and nanotowers were fabricated by using multiple patterning CL, which uses nanospheres twice as a mask for etching and mask for the deposition. In addition, Because CL uses spherical beads as a mask, it can give a shadowing effect to the pattern, unlike photolithography and electron-beam (E-beam) lithography. Thus, shadow sphere lithography (SSL), which combines glancing angle deposition (GLAD) that controls incident angle, azimuthal angle, and substrate rotation during the deposition with CL, more diverse and complex nanostructures such as nanocrescent and nanorings are easily fabricated. Herein, we fabricated TiN nanorings using SSL in a much simpler way than the conventional multiple patterning CL over a large area (inch^2) and demonstrated characteristics as a broadband absorber in the visible and near-infrared region. The nanoring absorber showed a high absorption of over 95% in a broad wavelength range (400-900 nm). The nanoring absorber verified the high potential as a broadband absorber by comparison with other absorbers having nanoholes and nanodisks prepared by CL. The nanoring absorber also showed over 2.3 times higher temperature increases than flat film without nanoring structures under the irradiation of light. This TiN nanoring absorber can be used for various photothermal applications such as thermoelectric and steam generation using solar energy.

5:00 PM EL16.12.03
Raman Identification of Single Bacterial Cells Patterned Using Capillary Assembly on Reflective Topographical Templates Joong Bum Lee[1], Minjoon Kim[1], Stefan A. Maier[2,3,4], Emiliano Cortés[4], Yeon Sik Jung[1] and Yoon Sung Nam[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Monash University, Australia; [3]Imperial College London, United Kingdom; [4]Ludwig-Maximilians-Universität München, Germany

The development of early diagnostic tools based on rapid and reliable detection of pathogenic bacteria is an actively ongoing process. Among several existing techniques, Raman spectroscopy has received growing interest due to its fast and direct output of molecular fingerprint information. However, an open challenge remains in establishing a platform with high signal reproducibility when detecting single cells. Here, we utilize a highly reflective Ag/SiO_2 film that enhances the intrinsically weak Raman signals by reflecting the laser for re-excitation of the bacteria and the downward scattered photons back into the detector. The given configuration is simple and effectively provides reproducible signals for different bacteria namely *Escherichia coli*, *Staphylococcus aureus*, *Salmonella gallinarum*, and *Corynebacterium glutamicum*. Provided that Raman intensities can vary depending on the position of the excitation laser on the cell, we employ capillary-assisted particle assembly (CAPA) to pattern single bacterial cells into a topographical template to allow the their most Raman active regions to be regularly aligned according to the trap site geometry. Moreover, the capability of CAPA to selectively trap single bacteria is utilized to directly separate cells from a suspension of artificial urine, which helps eradicate any additional steps previously required to isolate bacteria from biological samples. The simple and reliable detection method provided in this work has positive implications for clinically relevant settings.

5:00 PM EL16.12.04
Approaching to a Nanolaser via Hyperbolic Metasurface Supporting Whispering Gallery Modes TsungYu Huang and Jia Hsin Bai; Ming Chi University of Technology, Taiwan

We employed coordination transformation and designed a hyperbolic metasurface composed of metallic stripes and air trenches that revealed hyperbolic dispersion curves in the cylindrical coordination. Due to the mismatch of k_q between hyperbolic metasurface and surface plasma polaritons, such metasurfaces could function as a good resonance cavity for surface waves. To validate this idea, we employed finite element method to simulate the designed metasurface composed of a quantum well on top of a GaAs substrate, functioning as an active material, a 100-nm-thick MgF_2 spacer (permittivity of 1.8) and a 100-nm-thick silver (permittivity of -42.495+i×Í0.52152). The calculated mode showed the nature of a whispering gallery mode of $TM_{9,2}$ with a quality factor of 66.33, a modal volume of 4×10^{-22}, the normalized mode volume of 5×10^{-3} $(\lambda/ 2n)^3$, and the Purcell factor of 4726. Then, to test the lasing ability of the calculated whispering gallery mode, we used finite difference time domain simulation to demonstrate indeed such a cavity could be lasing at a frequency of 326 THz when optically pumped. Finally, such metasurface could be realized by focus ion beam and we believe that this proposed hyperbolic metasurface could facilitate the development of integrated photonics.

5:00 PM EL16.12.05
Stealthy Hyperuniform Disordered Light Trapping Designs for Solar Applications Alexander Lambertz[1], Nasim Tavakoli[2], Richard Spalding[3], Stefan Tabernig[2], Marian Florescu[3], Jorik Van de Groep[4] and Esther Alarcon-Llado[2]; [1]NWO-i AMOLF / UvA Amsterdam, Netherlands; [2]AMOLF, Netherlands; [3]University of Surrey, United Kingdom; [4]University of Amsterdam, Netherlands

Ultra-thin crystalline silicon solar cells could, in contrast to their thick counterparts, simultaneously reduce levelized cost of electricity by a large factor and be deployed on curved or non-static surfaces, windows, as well as facilitate building integration. Silicon at micron-scale thickness, however, suffers from poor light absorption and conventional light trapping approaches such as random KOH texturing fails due to the feature sizes produced.
We present hyperuniform disordered (HUD) light-trapping structures applied to ultra-thin solar cells via substrate-conformal imprint lithography. This approach enables rapid patterning of large areas (m2) at the nanoscale and can be performed on virtually any substrate and for any type of functional layer, such as the absorber, back-reflector, anti-reflection coating or carrier transporting layers. Correlated-disorder structures were shown to outperform periodic as well as random light trapping approaches [1] and the hyperuniform platform in addition offers tailored scattering to engineer light coupling to guided modes of ultra-thin absorbing layers [2]. To this end, we developed a coupled-mode theory (CMT) approach for estimating absorption with HUD patterns of arbitrary power spectral density distributions, which affords optimizations at low computational effort. CMT predictions are validated by determining the in-coupling rates per guided mods for different HUD designs, which we achieve through FDTD simulations. Furthermore, we show experimentally measured absorption in ultra-thin, free-standing, hyperuniform-patterned silicon slabs of thicknesses ranging from 1-30µm and compare with simulations. Finally, we show the performance of ultra-thin Si solar cells before and after the application of HUD light trapping structures.
In conclusion, our work exploits stealthy hyperuniformity for exceptional light trapping and aims to further expand the success of earth-abundant silicon to ultra-thin, flexible and semi-transparent PV devices, which can be produced with kerfless bottom-up technologies at significantly reduced capex and accompanying CO2 emissions while maintaining high power conversion efficiencies – A type of device that could literally pave all roads, roofs, walls, and windows by 2050!

5:00 PM EL16.12.06
3D Micro Architectures Using Intrinsic Stress in SU-8 Photoresist Zihao Lin, Shehua Thor and Jeong-Hyun Cho; University of Minnesota, Twin Cities, United States

It is commonly acknowledged that for SU-8 photoresist, a thermal stress is generated during a post bake induced cross-linking process. For decades, numerous of literature considered it as a side effect and tried to diminish or even overcome this problem. Here, conversely, we use this heat induced intrinsic stress to make 3D micro architectures. SU-8 photoresist is patterned on a pre-deposited sacrificial layer on Si wafers. Then most of the sacrificial layer is etched away, with only a tiny part holding down the structure. The structure is subsequently immersed in water with heat energy. Then, the thermal-induced stress causes the SU-8 to curve from 2D patterns to 3D architectures, such as tubes, rings, books, springs, and out of plane structures with different patterns on them. By intentionally controlling the exposure energy at different positions on the SU-8 surface, more complicated 3D structures can be made. Taking advantage of photolithography techniques, thousands of 3D microstructures can be integrated on a wafer with a self-assembly process that takes less than 30 seconds. Moreover, this assembly process allows the integration of 2D materials into the 3D structures, which enables the realization of 2D material-based 3D microstructures. This fabrication technique may promote further development of complex micro robotics, 3D sensors, and 3D passive elements.

5:00 PM EL16.12.07
Design of Ring-Patch Pattern Based Microwave Frequency Selective and Infrared Camouflage Surface Juyeong Nam, Injoong Chang, Joon-Soo Lim and Hyung Hee Cho; Yonsei University, Korea (the Republic of)

The aircraft requiring microwave communication has a frequency-selective surface (FSS) that selectively transmits the electromagnetic waves of a specific frequency. However, an infrared (IR) signature is generated on the fuselage surface for reasons such as aerodynamic heating, and this infrared signature is directly related to the survivability of the aircraft. In addition, if the location where microwave transmission is required and the infrared signature reduction is required coincide, such as the radome (nose) and leading edges of an aircraft, the previously developed FSS pattern of infrared camouflage surface including metallic mirror can not be used. Therefore, we think that the coatings capable of selectively transmitting microwaves and controlling the infrared signature is needed. In general, a thin metal film cannot transmit microwaves because it acts as an electromagnetic mirror. For this reason, many researchers designed various FSS patterns so that only desired frequency can pass through, but the FSS surface they designed did not consider those infrared signature characteristics. Similarly, many researchers studying infrared emissivity control did not consider the selective transmission performance of microwave bands. For this reason, we first fabricated the aluminum (Al) thin films by thickness using sputter equipment (LSP-06, pressure 1mTorr, sputtering rate 3.4 nm/sec) to control the infrared emissivity. The thickness of the thin film we made was 5-500 nm, and we measured the infrared spectral emissivity in long-wavelength infrared (LWIR) band using FT-IR (Fourier Transform Infrared spectroscopy) and the infrared signature images using IR camera (FLIR a655sc). In addition, we designed an FSS pattern that includes the metal thin film and allows selective transmission in the X-band (8-12 GHz), which is mainly used for aerial vehicles communication. To this end, we designed the ring-patch patten based microwave FSS to have transmittance of 90% or more at a frequency of 10 GHz using numerical analysis (COMSOL Multiphysics, RF module). The ring-patch pattern FSS derived through numerical simulation was fabricated and the FSS performance in the X-band was experimentally verified using a lens horn antenna (X-band) and a vector network analyzer (Anritsu) device.

5:00 PM EL16.12.08
Effect of Fractal Nanostructure on Multispectral Optical Properties in Visible–IR Waveband Injoong Chang[1], Juyeong Nam[1], Joon-Soo Lim[1], Namkyu Lee[2] and Hyung Hee Cho[1]; [1]Yonsei University, Korea (the Republic of); [2]Forschungszentrum Jülich GmbH, Germany

Fractal is a type of mathematical concept that the shape has a detailed or complex structure regardless of the view scale. While this concept satisfies the exact definition when the shape shows an infinitely detailed structure, in reality, there are finite-fractal structures in which a finite level of morphological repetition occurs, and they also have inherent fractality. Recently, the random fractal patterns of nanoscale structures have been reported, and the fractality has a relationship with the optical properties. These fractal-like structures make the strong and broad resonance effect in the visible spectra range owing to the extraordinary light trapping effect. However, these structures are rarely studied in the multispectral range. First, the fractal nanostructures (FNS) are formed using the wet-etching method so that the structural characteristics can control the only variable: etching time. Also, the studies on submicron-scale structures fabricated by the wet-etching method prominently show the antireflective characteristics with a similar scale waveband. Herein, a relationship between the structural and optical properties of silicon-based fractal nanostructures (Si-FNSs) is demonstrated. The six types of Si-FNSs are fabricated by Metal-assisted Chemical Etching (MaCE) method by varying the etching time from 10 to 240 min. The fractal properties (i.e., Fractal dimension and Lacunarity), calculated by capturing the scanning electron microscope (SEM) image with different magnification levels (x10k, x50k), vary by aggregation phenomenon along the etching process. Depending on the structure variation, Optical properties in visible and infrared (8-12 μm), measured by UV-vis-NIR spectrophotometer (Cary 5000, Agilent) and Fourier Transform Infrared spectroscopy (FT-IR; Vertex 70, Bruker), are dramatically change, especially the emissivity in the infrared range. The measured data are compared with the numerical simulation (COMSOL Multiphysics software) result made by an effective medium model of nanostructures. Therefore, we confirm that the fractal nanostructure fabricated by only varying the etching time can also control the multispectral properties, and it was possible to design and manipulate the visible reflective color and infrared emissive color simultaneously by controlling the etching time.

5:00 PM EL16.12.09
Hyperbolic Phonon Polaritons in Suspended α-phase Molybdenum Trioxide Jialiang Shen[1], Zhiren Zheng[2], Thao Dinh[2], Chuanyu Wang[1], Mingyuan Chen[1], Pengyu Chen[1], Qiong Ma[3], Pablo Jarillo-Herrero[2], Lixing Kang[4] and Siyuan Dai[1]; [1]Auburn University, United States; [2]Massachusetts Institute of Technology, United States; [3]Boston college, United States; [4]Chinese Academy of Sciences, China

Sample suspension is a important method to improve the mechanical, thermal, electronic, and optical properties of 2D materials. Polariton - confined half-light-half-matter wave - can be elongated its wavelength in the Type II of Reststrahlen band by the sample suspension. Previous work reported a wavelength elongation of about 10% for hyperbolic phonon polaritons (HPPs) in hexagonal boron nitride. In this work, we imaged the alteration of HPPs in a suspended α-phase molybdenum trioxide (α-MoO_3) by scattering-type Scanning Near-field Optical Microscopy (s-SNOM). This infrared nano-imaging technique combining with electromagnetic theory reveal a wavelength elongation over 60% and a propagation length increase more than 140%, because of the simultaneous wavelength elongation and dissipation elimination in the suspended specimen. We have also examined HPPs in Type I of the α-MoO_3 Reststrahlen band. The HPP wavelength is shortened and the dissipation is simultaneously reduced due to the sample suspension. The HPPs with improved quality factor in the suspended specimen may be used in the fields of nano-polaritonic circuits, biochemical sensing, emission engineering, and energy transfer.

5:00 PM EL16.12.11
Birefringence Of Chiral Hedgehog Particles Prashant Kumar[1], Emanuele marino[2], Alexander Simon[1], Daniel Katz[1], Christopher B. Murray[2] and Nicholas A. Kotov[1]; [1]University of Michigan, United States; [2]University of Pennsylvania, United States

Spiky hedgehogs can be self-assembled from twisted ribbons formed by gold-copper-cysteine complexes.[1] Furthermore, chirality of these twisted ribbons can be controlled by the cysteine amino acid and their arrangement into supraparticles is dictated by the ratio of L- vs D-form during the initial stages of self-assembly. Here we report that the seemingly spherically symmetric arrangement of twisted ribbons displays a maltese cross pattern typical of spherulites and liquid crystals under cross-polarizers.[2] This optical effect is observed at the single particle level[3] with tunable diameters of 1-10 um. We investigate the optical effects in chiral hedgehogs using single particle methodology and find that the emergence of Maltese cross pattern is dependent on the sphericity of the supraparticle and the spacing between individual spikes. We understand the interaction of light with hierarchically self-assembled structures through finite-element based electromagnetic simulations and reconstruct the distribution of electromagnetic fields around the hedgehogs in three dimensions. These hedgehogs are omnidispersible in a variety of solvents and offset the limitations of commonly observed organic molecule based spherulitic arrangement for biomolecular sensing under harsh environments.[4]

Nanostructured Photonic Hydrogels for Continuous Glucose Monitoring Israr Ahmed, Haider Butt and Amal AlGhaferi; Khalifa University, United Arab Emirates

Diabetes has become one of the top 10 causes worldwide, with ~6.7 million deaths recorded in 2021. The development of low-cost, simple, and reusable sensors can provide a potential platform for reducing diabetic complications, which can be fatal. Phenylboronic acid (PBA) based hydrogel sensors with imprinted Aztec nanostructures were demonstrated for rapid, real-time, and continuous glucose monitoring. A simple and rapid fabrication was carried out to imprint nanostructures. Aztecs are comprised of hexagonally packed ring shape pyramids with nano steps. Two sensor geometries were demonstrated: stand-alone (SA) and optical fiber (OF). The optical response of sensors was observed for the glucose concentration range of 0 – 50 mM in both transmission and reflection modes. Upon exposure to the glucose concentrations, the hydrogel matrix undergoes swelling. The swelling occurs due to cis-diol (present in glucose) binding with phenylboronic acid. A sensitivity of 3 and 1.5 μW/mM was documented for SA and OF sensors along with a fast response time of 20 s. The sensor response was also measured in the physiological glucose range for healthy and diabetic people. A smartphone readout was employed for practical use. The optical response of the sensor in different glucose concentrations was measured using a smartphone photodiode. The developed sensors may find their application for real-time, remote, and continuous glucose monitoring systems.

SESSION EL16.13: Active Control Metasurfaces and Metamaterials

Bottom-up Fabricated Tunable Metamaterials Exhibiting Broadband Enhanced Chirality Ufuk Kilic[1], Matthew Hilfiker[1], Shawn Wimer[1], Alexander Ruder[1], Eva Schubert[1], Mathias Schubert[1] and Christos Argyropoulos[1,2]; [1]University of Nebraska-Lincoln, United States; [2]The Pennsylvania State University, United States

Circular dichroism and optical activity are fundamental chiral processes to understand handedness in molecules and control the spin angular momentum of photons. However, chiral light-matter interactions have an extremely weak nature, are difficult to be controlled and enhanced, and cannot be made tunable or broadband. In addition, planar ultrathin nanophotonic structures to achieve extremely strong, broadband, and tunable chiral light-matter interactions at visible and ultraviolet (UV) frequencies are still difficult to be fabricated. In our presentation, we will demonstrate that we tackled these important problems by experimentally realizing and theoretically verifying spectrally tunable, extremely large, and broadband circular dichroism by designing new nanohelical metamaterial configurations operating at the technologically important visible to UV spectrum (U. Kilic et. al., Advanced Functional Materials 31(20), 2010329, 2021). Moreover, all-dielectric silicon-based L-shaped metamaterials will be presented that achieve tunable and strong broadband chirality with simplistic variations in their geometry. The reported novel designs of ultrathin bottom-up fabricated all-dielectric and dielectric-metallic (hybrid) plasmonic metamaterials permit wide tunability with one of the largest and broadest ever measured chiroptical response achieved by a large-scale nanophotonic structure. The demonstrated ultrathin optical metamaterials are expected to provide a substantial boost to the broad fields of classical and quantum optics leading to significantly enhanced chiral light-matter interactions at the nanoscale with applications in biosensing, topological photonics, quantum communications, and photonic circuits.

The presented new large-scale metamaterials are fabricated by using an emerging bottom-up nanofabrication approach, named glancing-angle deposition (GLAD), that is free of masks or templates and permits fast, simple, cost-effective, and scalable mass-production of nanoscale 3D structures. In addition, comprehensive and accurate experimental optical characterization and theoretical simulations are performed by using the generalized Mueller matrix spectroscopic ellipsometry in transmission and reflection mode and finite element modeling, respectively. The currently presented work sets new benchmarks in the assembly of ultrathin broadband chiral metamaterials which are poised to efficiently control and enhance the chiral light-matter interactions at the nanoscale. It provides a comprehensive road map for designing chiral metamaterials with unprecedentedly high and broadband chiroptical properties that can be used in a plethora of diverse emerging classical and quantum optical applications, such as in the design of ultrathin polarization filters, chiral sensors, circular polarized single- or multi-photon radiation sources, and directional spin-dependent nanophotonic waveguides.

Broadly Tunable Unidirectional Hyperbolic Metasurfaces of Ultrathin Periodically Aligned Carbon Nanotubes Igor Bondarev, Chandra Adhikari and Michael Pugh; North Carolina Central University, United States

Self-assembled quasiperiodic finite-thickness single-wall carbon nanotube (SWCN) films have been recently shown experimentally to exhibit extraordinary optoplasmonic properties [1-3], which is why they are getting more and more attention of experimental communities. Here, we study theoretically the intrinsic collective quasiparticle excitations responsible for the in-plane electro-magnetic (EM) response of ultrathin plane-parallel periodic SWCN arrays and weakly inhomogeneous SWCN films [4,5]. Using the low-energy plasmon response calculation technique along with the many-particle Green's function formalism in the Matsubara formulation, we derive the in-plane dynamical EM response tensor of the system in the broad spectral domain of IR to visible. We show that the EM response can be controlled by the volume fraction of constituent SWCNs, the active component of the film, and that this can be done not only by varying the parameters of the SWCN content (CN diameter and/or intertube distance) but also by merely varying the thickness of the CN embedding dielectric layer. For homogeneous single-type periodic SWCN arrays and weakly inhomogeneous multi-type quasi-periodic SWCN films, the real part of the EM response function in the CN alignment direction is negative for a sufficiently wide domain in the neighborhood of a quantum interband
transition of the constituent SWCN, to form a relatively broad negative refraction (NR) band. The system behaves as a unidirectional hyperbolic metamaterial at higher frequencies than those (typically in the IR) the classical intraband plasma oscillations have to offer. By decreasing the CN diameter it is quite possible to push this unidirectional NR band in the visible, and using weakly inhomogeneous multi-type SWCN films can make it even broader than the NR band of the single-type SWCN array. We also show that for a properly fabricated two-component SWCN film, by varying the relative weights of the two constituent CN array components, it is possible to tune the optical absorption profile to make the film transmit or absorb light in the neighborhood of an exciton absorption resonance on-demand [5].

Single-Gate Electrically Tunable Multi-Level Beam Switching Device with High Directivities Juho Park and Min Seok Jang; KAIST, Korea (the Republic of)

Beam switching, or beam steering devices with high directivity and electrical tunability are crucial component for realizing successful commercialization of LIDAR. Particularly, single-gate tunability is highly preferred due to robustness, stability issues involved in on-chip integration of LIDAR. Also, high directivity is fundamental figure of merit for realization of power efficient and highly-accurate LIDAR device. In this paper, we propose free-form optimized single-gate electrically tunable beam switching metasurface consisting of silicon metagrating, unpatterned graphene, silicon substrate and Au backreflector. The silicon metagrating layer is optimized using shape derivative, obtained by adjoint method. The optimized metasurface is capable of tuning incident mid-infrared plane wavefront into 80° (+1 diffraction order) and -80° (-1 diffraction order), according to different graphene Fermi levels. The both diffracted waves show over 99% directivities and near 50% diffraction efficiencies. By analyzing the relationship between metagrating height, substrate thickness and diffraction efficiency, we report that the sum of metagrating height and substrate thickness should be long enough to exceed light path length required to form Fabry-Perot resonance, and that too long metagrating height induces lower diffraction efficiency when substrate thickness is held constant. Next, we report three-level and four-level beam switching metasurfaces which show high directivity but moderate diffraction efficiencies. Finally, we analyze the beam switching performance on different graphene carrier mobilities.

9:30 AM EL16.13.04
Enhancing Forbidden Transition in Molecules by Toroidal Dipole Metasurface for Novel Photochemical Reactions Hiroaki Hasebe[1], Hiroshi Sugimoto[1,2], Taniyuki Furuyama[3] and Minoru Fujii[1]; [1]Kobe University, Japan; [2]JST PRESTO, Japan; [3]Kanazawa University, Japan

A molecular triplet excited state (T_1) with a long lifetime is beneficial for a mid-state of upconversion, photosensitizer, and various photochemical reactions. Because the excitation from the ground singlet state (S_0) to T_1 is spin forbidden transition, T_1 is usually excited via an intersystem crossing from a singlet excited state, which results in an energy loss of a few hundred meV. In this presentation, we propose an approach to excite a T_1 directly from S_0 by exploiting an optical resonance of a dielectric metasurface. For this purpose, we focus on the magnetic dipole transition in molecules that allows a spin-flip transition. By exploiting the magnetic dipole transition, direct excitation of T_1 from S_0 becomes possible. However, in typical molecular systems, the magnetic dipole transition rate that depends on the square of the magnetic field intensity is much smaller than that of the electric dipole one. In this work, by developing the metasurface platform that enhances local magnetic field intensity at a molecular position, we aim direct excitation of T_1 from S_0.
To enhance the local optical magnetic field, high-refractive dielectric (e.g. silicon (Si), gallium phosphide (GaP)) nanoantennas are promising because they exhibit magnetic Mie resonances in optical frequency. However, the enhanced magnetic field by the Mie resonance is localized inside the nanoantenna, which makes it difficult to harness the field for molecular excitations. In the previous work, we have realized the accessible and strong electric and magnetic field in the hexagonal array of thin Si nanodisks (diameter/height ratio ~10) exhibiting the coupled toroidal dipole (TD) resonance [1-3]. In this work, we demonstrate the enhanced photochemical reaction by exploiting the magnetic field enhancement in Si nanodisks. We first show the enhancement of excitation rate of the magnetic dipole transition in ruthenium (Ru(II)) complex molecules placed on the Si nanodisk array by photoluminescence excitation measurements. The magnetic dipole transition of Ru(II) complex molecules is approximately 40 times enhanced at the TD resonance wavelength (825 nm) of the Si nanodisk array.To demonstrate the application to photochemical reactions, we study the photosensitizing activity of Ru(II) complexes on the Si nanodisk arrays by monitoring the generation of singlet oxygen molecules. From the excitation wavelength dependence of the amounts of singlet oxygen, we successfully demonstrate the enhanced photosensitizing activity of Ru(II) complexes due to the large magnetic field by the TD resonance. The results demonstrate the singlet oxygen generation by efficient excitation of the Ru(II) complexes with much lower energy photons (~825 nm) than that of main absorption band of ~630 nm. In the presentation, we will further discuss the mechanism quantitatively by comparing the experimental results with simulation results.

Strong Coupling of Excitons in Monolayer WS_2 and Surface Plasmon Polaritons of a Silver Film Sylke Blumstengel[1,2], Nicolas Zorn Morales[1,2], Daniel Steffen Rühl[1,2], Sergey Sadofev[3] and Emil J. List-Kratochvil[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]IRIS Adlershof, Germany; [3]Leibniz-Institut für Kristallzüchtung, Germany

Monolayer (ML) transition metal dichalcogenides (TMDC) are currently of strong interest in nanophotonics due to their narrow-band intense excitonic transition which persist even up to room temperature. When brought into resonance with electromagnetic fields of a plasmonic nanostructure unique opportunities for studying and engineering strong light-matter coupling arise. This has motivated quite intense research efforts in the past years and indeed indications of strong coupling of TMDC excitons of ML flakes with localized surface plasmons hosted in a variety of metallic nanostructures have been found in scattering spectra. Here, we propose an alternative geometry as well as experimental method to study the exciton-plasmon coupling. We consider a most simple planar geometry comprised of a thin Ag film, an Al_2O_3 spacer layer and a ML of WS_2 and we employ total internal reflection ellipsometry which combines spectroscopic ellipsometry with the Kretschmann-Raether-type surface plasmon resonance configuration. The combined amplitude and phase response of the reflected light proves that despite the ML thinness of WS_2, the strong coupling regime between the A-excitonic resonance and the surface plasmon polariton propagating in the Ag film is achieved. We show that the presentation of the phasor r_p/r_s in the complex plane (r_p and r_s are the reflection coefficients in p- and s-polarization, respectively) provides a convenient means to verify the strong coupling regime. Furthermore, ellipsometry measurements at varying angle of incidence yield the dispersion plot. The observed anticrossing of the two polariton branches confirms that the strong coupling regime is achieved. Transfer matrix method simulations were performed to support the experimental findings. The present planar geometry can be regarded as a building block for the realization of all-optical or electro-optical plasmonic modulators. The tunability of the TMDC optical properties via external stimuli like electric fields and light, as well as the dielectric/chemical environment provides means of active control over the light matter interaction which paves the way for the construction of novel plasmonic devices.

10:30 AM EL16.13.06
Far-Field Analysis of Plasmon Temperature-Dependence in Graphene Nanoresonators Junhyung Kim, Geonwoo Lee, Sergey Menabde and Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Doped graphene behaves like a two-dimensional metallic sheet by exhibiting a robust plasmonic response from THz to mid-infrared frequencies. The extremely confined graphene plasmons (GP) that are supported by these graphene sheets have effective wavelengths that are up to two orders of magnitude shorter than the free-space wavelength. Despite the rising popularity of graphene plasmonics, the majority of GP research has been done at room temperature, and the temperature dependence of GP characteristics has not yet received much attention.
We report on the far-field analysis of the temperature-dependent mid-IR plasmonic response of graphene nanoresonators. As the temperature decreases from 300 to 100K, we see that the intensities of the resonance peak in the extinction spectra increase by 10-76%. The observation has two main factors: First, temperature-induced hole doping of graphene strengthens its oscillator properties. Second, the enhanced quality factor of the resonances provides additional evidence that reduced plasmon damping caused by the suppression of temperature-dependent scattering mechanisms lengthens the graphene plasmon lifetime.

We analyze the DC electrical characteristics of graphene while changing its temperature from 300 to 100K. The charge neutrality point (CNP) of graphene modifies from $V_{\mathrm{CNP}} = 62$V at 300K to 76.5V at 100K. The additional hole doping, $\Delta p = 1.04\times10^{12}\mathrm{cm}^{-2}$, is what causes the shift of $\Delta V_{\mathrm{CNP}} = 14.5$V. The cooling of graphene alters the doping concentration in addition to lowering the carrier scattering rate, which increases carrier mobility. Additionally, the hole mobility exhibits a monotonic rise with lower temperatures.

By analyzing the temperature-dependent normalized extinction spectra, we comprehensively study the temperature-dependent plasmonic characteristics of the graphene nanoresonators. Reduced temperature causes all extinction peaks to be more intense and causes a slight blueshift. This tendency can be attributed to the increased carrier density and mobility in graphene. Similar to the electrical measurement, the additional hole doping $\Delta p = 1.37\times10^{12}\mathrm{cm}^{-2}$ associated with cooling from 300 to 100K is present.

By calculating the intensities of GP resonance for observed extinction spectra, it was possible to examine the temperature-dependent electrodynamic response of the nanoresonators. Most of the time, peak intensities rose as temperature decreased. The increase in the peak intensities ranged from 10 to 76% as the temperature was cooled from 300 to 100K. We attribute the rising peak intensities to the increased doping due to cooling.

When the fermi energy decreases, the temperature dependence of the peak intensities gets stronger. This is most likely due to the fact that at lower carrier densities, the temperature-induced doping becomes more important than the electrostatic doping level. At the maximum gate bias, we also evaluate how the peak intensity varies with temperature for different resonator widths. The peak intensity in this regime is predicted to be mostly dependent on the plasmon scattering rate. Narrower resonators are predicted to contribute more to the temperature-independent extrinsic scattering rate. Indeed, compared to a wider one, the normalized extinction peaks in the narrower resonators are substantially less temperature sensitive.

We have studied the far-field temperature-dependent plasmonic response of graphene nanoresonators. The graphene plasmon resonance intensifies when the temperature decreases from 300 to 100K. The increased *p* doping brought on by cooling and the inhibition of the phonon-mediated scattering mechanism are both responsible for the increase in GP peak intensity. Our findings pave the way for enhanced graphene plasmonic devices that operate at cryogenic temperatures by illuminating significant but previously unrecognized temperature effects on tunable plasmons in large-area graphene-SiO_2 systems.

Magnetically Tunable 1D Plasmonic Photonic Crystals Chaolumen Wu and Yadong Yin; University of California, Riverside, United States

Structurally colored materials have been attractive for many years due to their vivid colors, long stability, and easy tunability. Within them, plasmonic and photonic nanostructures are two powerful systems that generate structure colors with easy control of the photonic colors. Although promising, the combination of plasmonic resonance and photonic bandgap within a single system is challenging. In this work, 1D plasmonic photonic crystals with angular-dependent structural colors are fabricated by assembling magneto-plasmonic colloidal nanoparticles under an external magnetic field. Different from conventional 1D photonic crystals, the assembled 1D periodic structures show angular-dependent colors from the selective activation of photonic diffraction and plasmonic scattering. Furthermore, the magneto-plasmonic nanoparticle chains can be fixed in an elastic polymer matrix to produce a photonic film with angular-dependent as well as mechanically tunable optical properties. Thanks to the easy and precise modulation of magnetic assembly, the orientation of the nanochains within the polymer matrix can be precisely controlled to produce photonic films with desired patterns, showing versatile colors from the backward photonic diffraction and forward plasmonic scattering. This work demonstrates an easy way to combine plasmonic and photonic properties within a single system, showing synergetic optical properties and the potential for the development of programmable optical functions for applications in color display, optical devices, and information encryption.

Exciton-Enhanced Light Scattering in Atomically-Thin Metasurfaces Ludovica Guarneri[1], Qitong Li[2], Jung-Hwan Song[2], Thomas Bauer[1], Jorik Van de Groep[1] and Mark L. Brongersma[2]; [1]University of Amsterdam, Netherlands; [2]Stanford University, United States

Nanophotonic metasurfaces employ dense arrays of optically-resonant nanostructures to manipulate the properties of light in ultra-compact optical coatings. By harnessing plasmonic or Mie resonances in metallic or dielectric nanoparticles, the phase and amplitude of the scattered light can be controlled at the nanoscale. Based on rapid advances in metasurface design, metasurfaces are now widely applied in flat optical elements for beam steering, lensing, and holography. However, novel applications in dynamic holography and augmented reality require metasurfaces and metadevices with actively-tunable functionality. So far, the use of plasmonic and Mie-resonances in active metasurfaces is limited as their optical resonances are difficult to tune dynamically.

Monolayer transition metal dichalcogenides, such as WS_2 , exhibit strong exciton resonances in the visible spectral range that dominate their optical response. The excitonic light-matter interaction in these 2D quantum materials is inherently very strong and highly tunable, which can be leveraged to realize mutable flat optical elements. To unleash the full potential exciton-enhanced light scattering in atomically-thin metasurface elements, it is essential to first achieve detailed understanding of the role of the exciton's quantum mechanical properties in passive nanophotonic wavefront shaping.

Here, we employ atomically-thin metasurface lenses carved out of a monolayer of WS_2 to directly study the influence of exciton decay and dephasing on the metasurface functionality and spectral line shape. We fabricate 500 µm diameter zone plate lenses using electron-beam lithography and reactive-ion etching. At resonance, excitonic light scattering strongly enhances the focal intensity. We systematically characterize the focal shape and focusing efficiency as a function of wavelength using confocal microscopy. To study the influence of exciton-phonon scattering and dephasing on the optical functionality of the lens, we then characterize the efficiency spectrum as a function of temperature.

At ambient conditions, the spectrum shows a strong asymmetric line shape revealing that the scattered light fields are directly governed by the monolayer susceptibility. This enables an almost background-free measurement of the optical properties of the monolayer, and thereby the excitonic light-matter interaction. Careful analysis of the line shape shows that the relative contribution from resonant excitonic light scattering is comparable to the non-resonant monolayer scattering. For decreasing temperatures on the other hand, the exciton energy shows a blue-shift, non-radiative decay and dephasing are suppressed, and the exciton becomes fully radiative. As a result, the asymmetric line shape not only narrows and increases in amplitude, but also transitions into a more symmetric line shape. This directly shows the increasing prevalence of the exciton resonance in the focusing efficiency. By comparing the results to numerical simulations and an analytical model, we show that the efficiency of the metasurface lens directly scales with the excitonic oscillator strength.

The results give direct insight in the role of exciton dynamics in optical wavefront shaping using atomically-thin metasurfaces. A full understanding of the role of exciton resonances in metasurfaces paves the way for dynamic components, combining tunable effects in quantum materials with classical metasurface optics.

Tunable Metasurfaces in III-V Materials—Design and Experiment Michelle Povinelli, Alok Ghanekar, Hyun Uk Chae, Bo Shrewsbury, Ragib Ahsan and Rehan Kapadia; University of Southern California, United States

We investigate the design of tunable metasurfaces using III-V materials as the insulator layer in metal-insulator-metal (MIM) designs. We first propose several designs for switchable and tuanble thermal emissivity in such structures. We consider the use of incorporated p-i-n junctions to tune the carrier concentration, and hence the refractive index, of the III-V structure. In one case, we introduce a perturbation to every other tooth of an MIM grating, doubling the effective periodicity. We show that this effect opens a photonic band gap, switching off the emissivity at the desired midwave infrared wavelength. In a second approach, we investigate index tuning in a slow light structure. Here, the slow light design magnifies the angular sensitivity with respect to index change. We further present our experimental progress toward such structures. In a first case, we demonstrate direct growth of InAs on a metallic substrate for realization of midwave infrared metamaterials. In a second case, we investigate epitaxial gransfer of GaAs on a metallic substrate for the same purpose.

SESSION EL16.14: Nanophotonics and Metasurfaces

The Importance of Surface Roughness on The Reflection from Epsilon-Near-Zero Substrates David Navajas[1,2], José M. Pérez-Escudero[1,2] and Iñigo Liberal[1,2]; [1]Public University of Navarre, Spain; [2]Institute of Smart Cities (ISC), Spain

Recent multiple applications and characteristics related to epsilon-near-zero (ENZ) media at infrared, visible and even ultraviolet frequencies have positioned them as a very active field of research. The performance of ENZ technologies is ultimately limited to material loss, which has been studied in detail, and the impact of surface roughness, which has attracted much less attention. In this work, the reflectivities of several silicon carbide (SiC) samples with different levels of artificially-induced roughness have been investigated numerically and experimentally. Samples have been treated via deep reactive ion etching (DRIE), and subsequently measured with a Fourier transform infrared spectroscopy (FTIR) microscope. The posterior characterization of the surface roughness of the samples focuses on the measurements made via atomic force microscopy (AFM).

Due to the dispersion of SiC, our samples enable a direct comparison of the impact of surface roughness on ENZ media, plasmonic-like systems and dielectric media, all within the same sample. The smoothest samples reveal near-perfect reflective behaviours, while the samples with more level of roughness shows a heavy decrease of the reflectivity, especially in the region between 10.3 µm and 12.55 µm. As a polar dielectric, its response at infrared frequencies exhibits this reflection band defined by the longitudinal and transversal optical phonons and a negative permittivity, it has been named Reststrahlen Band. Roughly, lower negative permittivities allow plasmonic-type effects, such as surface phonon polaritons. In consequence, the reflection band is strongly affected by the roughness. As long as the permittivity reaches high negative values, which are related to smaller skin-depths leading to hard interaction, this influence of the surface wave phenomena is decreased. The dielectric zone and the ENZ point ($\varepsilon=0$) are affected as well. However, it is found that the ENZ range is particularly robust against surface roughness.

We numerically validate our conclusions by using the full-wave solver Comsol Multiphysics. In a first approximation, the surface roughness was characterized by the sum of three waves and subsequently averaged with different periods in transversal electric (TE) polarization. Secondly, 15 AFM profiles were introduced manually and later their reflectivities calculated and averaged. Both calculations show a very precise approach to the measured reflectivities.

1:45 PM EL16.14.02
Negative Refraction in a Photon-Magnon Hybrid Junyoung Kim, Bosung Kim, Bojong Kim, Biswanath Bhoi, Haechan Jeon and Sang-Koog Kim; Seoul National University, Korea (the Republic of)

Artificially fabricated negative-refractive-index (NRI) metamaterials have been realized based on the negative values of both the permittivity and permeability of a given structure, the so-called double negative-material criterion. Here, we experimentally demonstrated, through the single-negative material criterion, the occurrence of the NRI in a photon-magnon hybrid composed of an Yttrium Iron Garnet (YIG) film and an inverted split-ring resonator (ISRR). The NRI signature was found by extracting S21 and S11 parameters versus the frequency of microwave ac currents and the static field strength from the sample. In order to obtain the underlying NRI mechanism from the YIG/ISRR hybrid structure, we analytically derived the permittivity and permeability along with the refractive index using series impedance (Z_{se}) and shunt admittance (Y_{sh}) based on an appropriate circuit model. The analytical model, which was in quantitative agreement with the experimental NRI values, revealed that the single-negative-material criterion is met at/near the intersection of resonance frequencies of YIG and the ISRR under specific field conditions. The advantages of NRI established in the photon-magnon hybrid are the tunability of NRI magnitude as well as the magnetic-field-controllable on-off switching in a fabricated structure. This work can provide a new paradigm for the realization of magnetic-field-controllable NRI metamaterials.

2:00 PM EL16.14.03
***In Situ* Optical Analysis of the High-Temperature Behavior of Refractory Materials** Margaret A. Duncan[1], Landin Barney[2], Tao Gong[1,1], Stuart Ness[1], Scott J. McCormack[1], Jeremy N. Munday[1], Mariama Rebello Sousa Dias[2], Marina S. Leite[1] and Peifen Lyu[1]; [1]University of California, Davis, United States; [2]University of Richmond, United States

The degree of control we have over the electromagnetic spectrum *via* tailoring of optical material properties and geometries governs our ability to advance cutting-edge photonic devices ranging from structural color pixels to thermophotovoltaic emitters to high-temperature sensors. A crucial step of improving this control is understanding how the dielectric functions of different materials change at high temperatures. Though the field has recently been of great interest to the photonics community for a variety of applications, most research in materials under extreme conditions have focused on structural properties. To address the growing need for high-temperature optical material properties, we present an *in situ* optical analysis of three refractory metals (Ru, Ta, and W) at elevated temperatures in an oxidizing environment. These samples preferentially oxidize when held at high temperatures (>500°C) in an oxidizing environment: by employing *in situ* ellipsometry measurements during a controlled heating treatment, we gain very precise control over the thickness of the oxide layers. We consider the application of these thin films to a structural color system, given their vibrant coloration: with our initial heating treatments our three structures generated vibrant pink (RuO_2/Ru/Si), yellow (Ta_2O_5/Ta/Si), and teal (WO_3/W/Si) hues. These structural color devices have the added benefit of being stable up to 1,200°C in an inert environment, showing the capability of these materials for use in high-temperature optical systems. We extend our technique to carbides, where a quantitative analysis of high temperature effects on permittivity will also be presented. These two sets of data represent a crucial advance in the development of robust materials for applications in extreme environments.

Tailoring Diffraction Characteristics of Resonant, Large Area Metagratings Employing Mask-Free UV Laser Interference Patterning Carlota Ruiz de Galarreta[1,2], Rosalia Serna[1], Joe Shields[2], Miguel Alvarez-Alegria[1], Rocio Ariza[1], Jose Ramon Deop-Ruano[1], Alejandro Manjavacas[1], C. David Wright[2] and Jan Siegel[1]; [1]CSIC, Spain; [2]University of Exeter, United Kingdom

Over the past decade, metasurfaces comprising arrays of localised ultrathin resonant subwavelength resonators ("meta-atoms") have been successfully employed to engineer the wavefront characteristics of optical beams, resulting in several recent demonstrations of ultra-compact devices for focusing, beam mode conversion or beam steering. To date, for the particular case of beam steering metasurfaces (nowadays known as phase-gradient metasurfaces), reflection or transmission of light at pre-designed angles has been realized based on the ray optics approximation (generalized Snells' law), via forcing linearly varying, discrete transverse phase increments to impinging waves [1]. This is typically carried out via the design and engineering of periodic "supercells" made of various meta-atoms having different shapes, sizes and/or orientation, thus imposing abrupt, local phase jumps for a given excitation frequency, which in turn results in constructive interferences at pre-designed angles. However, phase-gradient metasurfaces exhibit fundamental limits in terms of maximum achievable steering efficiencies, especially at large angles of incidence.

Recently, it has been pointed out that metasurfaces based on periodic 1D identical plasmonic dipoles lying on ultrathin insulator/metal substrates exhibit beam steering capabilities at oblique incidence with near unit diffraction efficiency when operating in the (0th, -1st) diffractive regime. Therefore, such an approach offers clear benefits with respect to more conventional phase-gradient metasurfaces, both in terms of optical performance and in terms of ease-of-fabrication using current lithographic techniques. Nevertheless, the physical realization of such "metagratings" today still requires e-beam lithography with several steps involving spin coating of appropriate photoresist masks combined with thin film deposition and lift-off or etching techniques.

In this work, we propose and experimentally validate a single-step, mask-free, nanopatterning technique for a virtually instantaneous realization of high performance, large area, near-infrared metagratings consisting of 1D metallic nanostripes. Our method exploits controlled pattern ablation of continuous gold films deposited on a SiO_2/Al/Si substrate. Nanostripe structures were fabricated by making two in-plane pulsed top-hat UV laser beams interfere at a specific angle onto the sample surface ($\lambda = 193$ nm, $\tau_{pulse} = 23$ ns), resulting in a large area 1D sinusoidal intensity distribution. A systematic study of the effect of the laser fluence and number of pulses on the final topography has revealed that a wide range of nanobar geometries can be achieved using this approach, ranging from low aspect ratio, wide nanostripes, to high aspect ratio, narrow nanostripes, depending on the processing conditions. Finite element analysis of the m=0 and m=-1 diffraction orders against the angle of incidence have revealed that the high diffraction efficiency characteristics of the fabricated devices in terms of bandwidth and dispersion can significantly vary depending on the resulting nanostripe geometry. Finally, diffraction measurements of as-fabricated devices employing spectroscopic scatterometry have been performed, confirming that laser-processed metagratings behave as predicted by our calculations, thus validating the versatility of our fabrication approach. Based on these results, we believe that our work paves the way for the realization of low cost, single-step and large area metagratings, with exotic and on-demand diffraction properties, which may find applications in many exciting fields including holography or free-space optical communications.

Toroidal Dipole-Induced Photocurrent Enhancement in Silicon Nanodisk Hexagonal Array beyond 1400 nm in Wavelength Keisuke Moriasa, Hiroaki Hasebe, Hiroshi Sugimoto and Minoru Fujii; Kobe University, Japan

A laser with the emission wavelength longer than 1400 nm is "eye safe", because light in the wavelength range is strongly absorbed in the cornea and lens and cannot reach more sensitive retina. The eye safe lasers have been used as a light source for LiDARs in atmospheric physics, autonomous driving, etc. For the development of low-cost LiDARs for autonomous driving, a silicon-based CMOS compatible photodetector operating beyond 1400 nm is crucial. Several methods have been proposed to extend the detection range of a silicon-based photodetector beyond the band gap wavelength. The most widely studied one is using internal photoemission at a Schottky junction between silicon and metal nanoantennas. Another approach is enhancing defect-mediated weak absorption of silicon by optical resonances.

In this work, we show that a hexagonal array of low-aspect-ratio silicon nanodisks formed on a silicon thin film has the sub-radiant high-Q toroidal dipole (TD) resonances that strongly enhance light absorption in the low material loss wavelength range, i.e., sub-band gap range. We also demonstrate that the absorption enhancement appears as a photocurrent enhancement at the resonance wavelength, and thus the metasurface can be used as a narrow-band photodetector operating in the silicon sub-band gap wavelength range [1-2]. To further boost the performance of that device, we design a structure having perfect absorption by introducing the concept of the bound states in the continuum (BICs) in the TD resonances of a silicon nanodisk hexagonal array. The idea is introducing a mirror below the metasurface via a silicon dioxide spacer. In proper spacer thicknesses, interference between a TD resonance in a nanodisk array and the image dipole in the mirror cancels the radiation perfectly and BICs emerge. Slight detuning of the BIC condition by controlling the spacer thickness makes the radiation loss finite and to be equal to the material loss. This results in perfect absorption at the TD resonance wavelengths. Since the absorption is predominantly in the silicon region, the photocurrent is expected to be strongly enhanced. In this structure, the absorption spectrum is relatively insensitive to the incident angle and is independent of the polarization direction. Furthermore, since the TD resonances are very narrow, the device can detect photons at specific wavelengths without a bandpass filter. The device is composed of silicon, silica and aluminum mirror and electrodes, and does not require narrow band gap semiconductors and noble metal nanostructures for the detection of long wavelength photons. Therefore, the device can be easily integrated in silicon-based electronic devices.

Picoelectrodynamics in Silicon Sathwik Bharadwaj, Todd Van Mechelen and Zubin Jacob; Purdue University, United States

The concept of photonic frequency (ω) - momentum (q) dispersion has been extensively studied in artificial dielectric structures such as photonic crystals and metamaterials. However, the photonic dispersion of electrodynamic waves hosted in natural materials at the atomistic level is far less explored. Here, we develop an atomistic nonlocal electrodynamic theory of matter by combining the Maxwell Hamiltonian theory of matter with a quantum theory of atomistic polarization. We apply this theory to silicon and discover the existence of atomistic electrodynamic waves. Atomistic electrodynamic waves have sub-nano-meter effective wavelengths in the picoelectrodynamics regime. Further, we show that the atomistic optical conductivity in silicon lattice is highly anisotropic along different momentum directions due to atomistic electronic correlations. Our findings demonstrate that the natural materials such as silicon host variety of yet to be discovered electromagnetic phases of matter and provide a pathway for material design and engineering to discover rich atomic scale light-matter interaction phenomena.

Near-Field Imaging and Spectroscopy of Optical Resonances in a Semiconductor Metasurface Alex M. Boehm[1], Sylvain Gennaro[1,2], Chloe Doiron[1], Thomas Beechem[3], Raktim Sarma[1] and Taisuke Ohta[1]; [1]Sandia National Labs, United States; [2]Meta Reality Labs, United States; [3]Purdue University, United States

Metasurfaces have emerged as a versatile platform to control light-matter interactions in sub-wavelength volumes, leading to "planar" optics with various potentially groundbreaking applications in bio-sensing, hyperspectral imaging, lasing, frequency mixing, and quantum information processing. Historically, metasurfaces tailored electromagnetic fields via localized surface plasmon resonances confined in metallic nanostructures. However, dielectric metasurfaces made of III-V semiconductors have recently garnered much interest owing to their low losses at optical wavelengths and the ability to support electromagnetic Mie-like resonances within individual resonator units. Recent efforts have further introduced symmetry breaking elements to individual resonator units lending access to high-Q symmetry-protected quasi bound states in the continuum (BICs) optical modes, that offer a promising avenue for enhanced light matter interactions. A technique capable of directly imaging the electromagnetic fields at nano-scale in these platforms is sought after to inform us on the origin and the spatial extent of these photonics processes and expand pathways to tailor nanostructures for chosen functionalities.

Imaging nanoscale optical phenomenon is non-trivial since light-matter interactions take place at length scales smaller than the wavelength of light, far below the resolution of traditional optical probes. Nonetheless, several techniques such as scanning probe-based near-field optical microscopy (SNOM), photo-induced force microscopy (PiFM), cathodoluminescence (CL), and electron energy loss spectroscopy (EELS) have begun to probe this space. An imaging technique that, despite broad applications in plasmonics research, has hitherto remained unexplored in the field of nanophotonics is photoemission electron microscopy (PEEM), a technique that capitalizes on a true optical excitation in a "photon in, electron out" approach to probe the near-field enhancement of the electric fields through photoelectron intensity. Here we employ PEEM to image broken-symmetry III-V semiconductor metasurfaces with high–quality factor, quasi-bound state in the continuum resonances. We find that through far-field optical excitation at normal incidence we can elicit highly selective mode excitation which enables high-resolution imaging of field profiles as a function of wavelength and polarization. These profiles are further used to corroborate finite difference time-domain (FDTD) simulations and develop a more complete understanding of the optical response of the metasurface. Additionally, the "electron out" portion of PEEM provides full-field spectroscopic imaging allowing us to collect near-field spectral responses at high spatial resolution. Through spectroscopic analysis of the field profiles, we reveal significant shifts in the excited resonances as a function of position within an individual resonator. Finally, we exhibit the ability of PEEM to image long range interactions among resonators as an entire array of structures can be excited and imaged simultaneously. This work highlights the powerful capabilities of PEEM for the investigation of semiconductor metasurfaces and sheds light on nature of the photonic processes occurring in this class of materials.

Design Parameters of Free-Form Meta-Color Routers for Sub-Micron-Pixel Image Sensors Sanmun Kim, Chanhyung Park, Shinho Kim and Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Meta color routers are emerging as a next generation color filter for complementary metal-oxide-semiconductor (CMOS) image sensors. In a classical image sensor, a micro-lens and a color filter is placed on top of a silicon photodetector. The micro-lens focuses the light into the photodiode area and the color filter absorbs or reflects the light of unwanted wavelength. Until now, the classical image sensor configuration has dominated the visible image sensor market, but the reduction in pixel size to sub-micron range is limiting its performance. The geometric-optics based configuration is no longer valid and reduction of pixel area leads to a smaller number of photons reaching the photodiode.

As most of the light incident on the image sensor is blocked by the color filter, the optical efficiency of the classical image sensor is limited to 25% for red/blue lights and 50% for green lights. The meta color routers break this limit by directing all the incident light into the corresponding subpixel area.

A typical meta color router is configured by allocating dielectrics of different refractive indices inside the design region, thus involves freeform optimization of high degrees of freedom (DoF). Due to the advantages that can be brought by the meta color router, optimization of the meta color router has been widely investigated, both theoretically [1, 2] and experimentally [3, 4]. However, those studies lack the investigation on the selection of design parameters. The design parameters of a meta color router are the parameters that define the geometry and the design space of the device, and have critical effects on final device performance.

In this work, we investigate how the optical efficiency of a meta device is affected by the choice of each design parameters. We classify the design parameter into two different types: physical parameters, and spatial resolution parameters. Design parameters such as pixel size, device thicknesses, and refractive indices are the physical parameters. Spatial resolution parameters are parameters that determine how the design area is gridded. Through parameter tuning, we report the existence of optical thickness of the device and optimal choice of dielectrics. Also, we report how the subpixel resolution parameters affect the optical efficiency.

Vacuum UV Nonlinear Meta-Devices Ming Lun Tseng[1], Michael Semmlinger[2,2], Ming Zhang[2,2,2], Catherine Arndt[2,2], Jian Yang[2,2,2], Mu Ku Chen[3], Din-Ping Tsai[3], Peter Nordlander[2,2,2] and Naomi Halas[2,2,2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Rice University, United States; [3]City University of Hong Kong, Hong Kong

Vacuum ultraviolet (VUV) light lies in the wavelength range from 100 nm to 200nm. It is of great importance to practical applications ranging from biomedical spectroscopy to material science. Due to the strong absorption of matter in this range, producing efficient and compact VUV devices is challenging. However, it is highly desired to realize miniaturized photonic devices to further advance and explore the applications of VUV light. In this talk, we will report nonlinear metasurfaces (1-3) capable of generating and controlling VUV light. By carefully choosing the nonlinear material, rotational symmetry, and resonance mode for their unit cells, the reported metasurfaces are able to efficiently convert the incident visible laser into VUV light and control the wave properties. Metasurfaces for VUV light focusing and beam steering were fabricated and experimentally characterized. Experimental results confirm the functionalities of metasurfaces. This work points out a promising route toward novel nanophotonic devices for this valuable wavelength range.

Electrically Tunable Metasurface for Light Detection and Ranging Junghyun Park, Byung Gil Jeong, Sun Il Kim, Minkyung Lee, Young Kim, Kanghee Won and Kyoungho Ha; Samsung Advanced Institute of Technology, Korea (the Republic of)

Tunable metasurfaces have facilitated novel spatial light modulation technologies with an unprecedentedly fast operation speed and an extreme shrinkage in pixel sizes. By exploring the optical response for given control stimulus from the Huygens' metasurfaces, we can establish the look-up table and achieve arbitrary wavefront shaping. Recent trends are focusing on how to harvest a large efficiency (power-in to power-out ratio) and a stark contrast between intended wavefront over undesirable background noise. To meet these goals, there have been various approaches; these include the adoption of materials with wide tunability such as phase change materials with low loss, the combination with nano-structured optical configuration with local control of liquid crystal, and the use of exciton manipulation in transition metal dichalcogenides. One may also consider utilizing highly sensitive resonance mechanism such as non-local metasurfaces, guided mode resonance, and dimerized gratings, to name a few. <div>In this presentation, we take a brief review on the recent progress and envision the future direction of the tunable metasurfaces. We also address potential applications that would become possible by use of electrically tunable metasurfaces, including light detection and ranging (LiDAR), free space optical communications, and holographic displays. We will present the experimental demonstration of the LiDAR by using the beam steering device based on the tunable metasurfaces, which features high reflectivity above 60% and the directivity (side mode suppression ratio) above 10 dB, as well as fast operation speed of 300 kHz.</div> <div> </div>

Crossing of the Branch Cut in Topological Metasurfaces Patrice Genevet; CRHEA, France

Research on topological photonics has considerably grown, transferring condensed matter concepts of topological insulators with the discovery of the integer Quantum-Hall effect into the realm of photonics. Today, nanophotonics, which is related to light manipulation with subwavelength objects, offers new opportunities to address light properties. New degrees of freedom in the design of optical components are attained by considering the response of topological nanostructures. So far, optical metasurfaces, made of subwavelength arrangements of nanostructures, have relied on resonant phase scattering occurring in Mie resonators or ultrathin pillars. Full wavefront control requires finding sets of nanostructures that can provide 2π optical phase retardation on the incoming beam. Ultimately, and despite all the efforts in understanding the physical mechanisms leading to optimal designs, including powerful optimization methods, metasurface designs often require witless numerical parameter searches. Relying on symmetry-breaking arguments and topological properties of the associated non-Hermitian matrices representing the metasurfaces, we provide new guidelines for achieving 2π phase coverage in transmission and reflection. This framework allows us to unravel the physical principles underlying Huygens metasurfaces, showing that it exploits degeneracies of transmission- or reflection-matrices Zeros, so-called exceptional points, corresponding to transmissionless and reflectionless states. Overall, symmetry-breaking leading to a displacement of a Zero-Pole pair with its branch cut crossing the real axis, provides a very intuitive design approach for achieving full resonant phase scattering. Encircling EPs and/or zeros in the nanostructure parameter space to provide full 2π-phase are considered, entrusting metasurfaces and flat optics with additional light modulation schemes. Our results explain the importance of topological defects and how they can be manipulated for achieving realistic and insightful metasurface designs.

Ultrafast Reconfigurability of Circular Dichroism Using Bound-State-in-Continuum Dielectric Metasurfaces Prasad Iyer[1,2], Luis M. Martinez[3,4,1], Chloe Doiron[1,2], Wesley Mills[1,5], Christina Boyd[1,6], Michael B. Sinclair[2], Ting S. Luk[1,2], Prashant Padmanabhan[1,4], Alex Cerjan[1,2] and Igal Brener[1,2]; [1]Center for Integrated Nanotechnologies, United States; [2]Sandia National Labs, United States; [3]The University of Texas at El Paso, United States; [4]Los Alamos National Laboratory, United States; [5]Utah State University, United States; [6]Rensselaer Polytechnic Institute, United States

Reconfigurable dielectric metasurfaces have shown tremendous potential to actively control the fundamental (amplitude, phase and polarization) properties of light with minimal losses. Here we demonstrate ultrafast tuning of circular dichroism (CD) using dual degenerate bound-state-in-continuum (BIC) resonances in a Silicon metasurface. We design and fabricate tall (1.27um) Z-shaped amorphous Silicon resonators in a hexagonal lattice (700nm period) on glass with overlapping left (LCP) and right (RCP) circularly polarized quasi-BIC resonances at 1.22um in reflection. These high Q (180) metasurface resonances results in a giant change in CD (0.85) over a small wavelength range (10nm). We use ultrafast (80fs) pump (600nm)-probe (1200nm) spectroscopy to tune the refractive index of the resonators through Drude free-carrier refraction; demonstrating dynamic modulation of the circular dichroism from the metasurface by more than the full-width half max (FWHM) of the quasi-BIC resonances. This is one of the first experimental demonstrations of dynamic reconfigurability of CD in a dielectric metasurface through continuous index tuning in the ultrafast (ps) regime. We believe the results presented here will enable large area scalable CMOS metasurfaces with reconfigurable all-optical control of the polarization of light in the ultrafast timescales.

9:45 AM *EL16.15.06
Dynamic Light-Engineering with Flat Optical Devices Antonio Ambrosio; Fondazione Istituto Italiano di Tecnologia, Italy

We realized a shapeshifting diffractive optical element with reconfigurable surface relief geometry that provides different optical functionality: a grating can turn into a different grating or into a lens, and back to the original grating when and if needed; on-demand. For our approach, we used films (on glass substrates) of azobenzene-containing polymers (or simply azopolymers) that have the ability to develop surface reliefs directly on the free surface of the film when exposed to spatially structured UV\visible light. The photo-induced surface structuration arises from a light-fuelled microscopic motion involving cyclic isomerizations of the azobenzene molecules which drive a macroscopic transport of the entire polymeric matrix under illumination. The geometry of the resulting surface reliefs depends on both the intensity and on the polarization distribution of the irradiated light across the surface. Not involving any destructive or chemically altering process, the light-induced surface structuration of azopolymers is intrinsically reversible. Complete all-optical reconfigurability of the structured surfaces were then demonstrated through the irradiation of a second light beam that, acting as pattern erasing beam, restores the initial flat state, making the surface ready to be re-shaped at will in successive writing steps. We used our reconfigurable diffraction gratings to dynamically select the light wavelength from a white light source that is diffracted in a specific direction, realizing a prototype of monochromator operating without any mechanical moving part. Similarly, efficient and reconfigurable flat diffractive lenses, with reprogrammable focal lengths and optimized diffraction efficiency were then directly inscribed on the azopolymer film and used in dynamical imaging systems able to focus on objects placed at different depths and to provide different zoom levels of large scenes, without the movement of multiple optical components necessary in standard bulky systems to accomplish same functionalities.
We also developed a structured light laser capable of producing vortex laser arrays with actively tunable topologies and non-local coupling dictated by the array's topology. The gain medium of our laser has a large transverse cross-section supporting many transverse modes that we forced to organize and form a lattice of a hundred laser beams by inserting a metasurface mask that modulates the phase and amplitude of the field. More specifically, the phase profile was designed to produce vortex beams with an annular intensity profile, useful for communication, microscopy and lithography applications. Importantly, in our new laser arrays, the coupling network is not limited to the nearest neighbours as for arrays of Gaussian lasers with no topological charge, but instead can be tailored to mix vortices that are widely separated in the lattice. Although different schemes for generating a single vortex inside a resonator have been demonstrated, we demonstrated the conditions for generating vortex laser arrays in a single cavity, realizing a platform to explore complex topological transformations and collective vortex effects at the source. Furthermore, we demonstrated the robustness of the designed complex light distribution to defects in the metasurface mask. This opens up the possibility of iteratively manipulating structured light parameters and could be used to develop photonic simulators.

Critical Coupling for Enhanced Biosensing and Energy Conversion Enabled via Bound States in the Continuum Stefan A. Maier[1,2]; [1]Monash University, Australia; [2]Imperial College London, United Kingdom

Metasurfaces based on bound states in the continuum enable careful tuning of the radiative loss channel of surface modes via small changes of the asymmetry parameter of unit cell resonators. This enables exploring the regimes of under-coupling, critical coupling, and over-coupling for a variety of applications in metasurface photonics. Here we will focus on the exploration of surface enhanced infrared absorption spectorsocpy, and energy conversion in a context of photocatalysis, and examine how their efficiency varies with the coupling regime. Strikingly, criticial coupling does not in all circumstances lead to the highest sensitiviy for sensing.

Plasmon Enhanced Quantum Properties of Single Photon Emitters in Hexagonal Boron Nitride Flakes Mohammadjavad Dowran, Suvechhya Lamichhane, Adam Erickson, Andrew Butler, Sy-Hwang Liou, Christos Argyropoulos and Abdelghani Laraoui; University of Nebraska-Lincoln, United States

Two dimensional (2D) materials such as hexagonal born nitride (hBN) have emerged as promising hosts of single photon sources (SPEs) which exhibits promising optical properties (high brightness, optically accessible spin states, high quantum efficiency, *etc*.), making them highly desirable elements for integrated quantum photonics [1]. In this study, we create SPEs in thin (thickness ≤ 10 nm) hBN flakes deposited on a Si/SiO2 substrate by using a high-temperature (1100 °C) annealing method under O_2 flow and characterize their quantum properties using a home-built confocal fluorescence microscope. We demonstrate plasmonic enhancement of SPE properties by spin-coating of 100 nm Ag nanotubes on top of the hBN flake: a decrease of emission linewidth by 30% and quantum emitter lifetime decrease by 60% [2]. We expect > 2 order of magnitude enhancement of SPE fluorescence when integrating them to optical nanocavities. Such enhancement is supported using COMSOL numerical simulations where hBN flakes are integrated into a composite nanophotonic structure entailing plasmonic effects from silver nanocubes and the optical frequency resonance from the fabricated metallic nanocavity. Light Trapping and Directional Scattering in Hybrid Metasurfaces Dominic Bosomtwi and Viktoriia Babicheva; University of New Mexico, United States

We design and analyze the optical response of subwavelength layered disk nanoresonators. The hybrid plasmonic / high-index dielectric nanoresonators allow for efficient light trapping and directional scattering. We investigate the scattering response of the layered nanoresonators array, and we show that varying the nanoresonator height leads to the realization of strong electromagnetic mode confinement resulting in a high-quality (Q) factor. We then demonstrate that strongly coupled electromagnetic modes in the nanostructure can interfere destructively in the surrounding medium of the nanostructure, inducing bound states in the continuum (BIC) for the modes excited in the nanostructure. Finally, we report on the observation of overlapping of electric and magnetic dipole moments giving rise to the suppression of electromagnetic waves either in the forward or backward directions.

Multipole Coupling in Nanoparticle Lattices with Quasi-Bound States Md Sakibul Islam and Viktoriia Babicheva; University of New Mexico, United States

Metasurfaces and periodic lattices have become promising candidates for numerous photonic applications due to their unique ability to manipulate, control, and confine electromagnetic waves at the nanoscale dimensions. Collective resonances are excited in the periodic lattices of nanoparticles at the wavelength close to the Rayleigh anomaly. Effectively, it occurs at the wavelength equal to the array period or the latter divided by the refractive index of the surrounding medium. In this work, we demonstrate the coupling of multipole modes and quasi-bound states in the continuum with the modes trapped and localized in the nanoparticle array. This behavior is observed due to the suppression of radiative losses and increase in quality factor due to the disappearance of the mode scattering. We show that the combination of different materials in the nanoparticle allows the tuning of electric and magnetic resonances of the nanoparticles and achieving broadband overlap.
This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science by Los Alamos National Laboratory (Contract 89233218CNA000001) and Sandia National Laboratories (Contract DE-NA-0003525). 11:45 AM *EL16.16.06
Non-Local, Non-Linear and Non-Hermitian Nanophotonics Guru V. Naik and Ciril Samuel Prasad; Rice University, United States

Miniaturing optical resonators into meta-atoms and packing them together in meta-devices have revolutionized nanophotonics. Building various meta-atoms have been extensively studied in the past. However, packing them together into meta-devices remains less explored. Quantum many-body effects offer a novel direction in this regard. Here, we discuss two approaches – emulating and integrating quantum many-body systems – to deliver meta-devices exhibiting quantum many-body effects.

Emulating quantum many-body effects in nanophotonics is difficult because nanophotonic resonators only weakly confine light in them. Radiative and often non-radiative losses are not negligible in nanophotonics necessitating non-Hermitian physics. We demonstrated a non-Hermitian metasurface based on passive parity-time symmetry. We coupled a lossy plasmonic resonator with a lossless dielectric resonator to achieve the best of plasmonics and photonics, i.e., enhanced absorption as in plasmonics and high Q-factor as in dielectric photonics. Further, we demonstrated non-trivial topology in this system resulting in robust directional thermal emission. Here, we will discuss the directionality of thermal emission from such metasurfaces. We show that a highly asymmetric thermal emission is possible from a transparent metasurface held at 900 K. Such directional, bright, and spectrally selective thermal light sources could be revolutionary for thermal imaging and efficient thermophotovoltaic energy conversion.

In another approach, we combine quantum materials with nanophotonics to leverage powerful design tools. We study the optical properties of a layered charge-density-wave (CDW) material, 1T-TaS_2 under illumination and electrical bias. We observed a unity-order index change in 1T-TaS_2 under both stimuli. Our investigation showed that charge density wave (CDW) domains reorganize into a different stacking order under a stimulus. As a result, the optical response of this quantum material is not only non-linear but also non-local. We build a non-local model to capture the light-matter interaction in 1T-TaS_2 and other quantum materials and understand the energy landscape of strong correlations in this material. Measuring non-locality could be a non-invasive probe of the quality of a quantum material and thus could catalyze the discovery of functional quantum materials. Further, we demonstrate a tunable 1T-TaS_2-based metasurface with 100% modulation depth, MHz bandwidth, and ultralow-power operation. Such tunable optical devices could be disruptive for emerging imaging and display applications.

In summary, we demonstrate that quantum many-body effects in meta-devices lead to non-local, nonlinear, and non-Hermitian light-matter interaction. Understanding this unique regime of light-matter interaction would unlock novel nanophotonic phenomena leading to meta-devices with unprecedented functionalities.

Intrinsic and Extrinsic Nonlinearities in Epsilon-Near-Zero Adam Ball[1], Dhruv Fomra[1], Samprity Saha[1], Jingwei Wu[1], Ray Secondo[1,2,3] and Nathaniel Kinsey[1]; [1]Virginia Commonwealth University, United States; [2]Azimuth Corporation, United States; [3]Air Force Research Laboratory, United States

Optical materials with a refractive index, and permittivity, that tend towards zero provide quite fascinating optical responses. From emission tailoring and perfect absorption to 'DC-light' and optical tunneling, epsilon-near-zero (ENZ) and near-zero-index (NZI) materials have provided new and interesting methods of manipulating light in a linear fashion. Perhaps to no surprise, the nonlinear properties of these materials are also quite intriguing, having recently been utilized to realize unity-order refractive index tuning, enhanced harmonic generation, and spatio-temporal control over light flow in sub-micron layers. In this talk, we will summarize the origins of the nonlinearities in homogeneous ENZ and NZI materials, focusing on the intrinsic and extrinsic factors on the response. Through this lens we will highlight avenues where such materials are less suited, where they provide unique advantages, and discuss techniques to push these advantages. We will overview our recent experimental works combining high-Q metastructures with ENZ materials as well as dual-pump tailoring of the index and loss profiles. Through this will aim to illustrate the unique benefits of ENZ materials for numerous nonlinear optical applications.

SESSION EL17.01: Hybrid Perovskite Materials, Stability and Devices I
Session Chairs: Lina Quan and Barry Rand
Tuesday Morning, April 11, 2023
Moscone West, Level 3, Room 3006

10:30 AM *EL17.01.01
Heterointerface Materials Science for Perovskite Tandems and Triple-Junctions Edward H. Sargent; University of Toronto, Canada

I will discuss issues at the materials interface (e.g. between active layer, ETL/HBL and HTL/EBL) especially as these relate to constructing perovskite tandem and triple-junction solar cells.

11:00 AM EL17.01.03
Towards Injection Lasing: Intense Electrical & Optical Co-Pumping of Perovskite Light-Emitting Diode Structures Karim Elkhouly[1,2], Iakov Goldberg[1,2], Nirav Annavarapu[1,2], Robert Gehlhaar[1], Weiming Qiu[1], Jan Genoe[1,2] and Paul Heremans[1,2]; [1]imec, Belgium; [2]KU Leuven, Belgium

Metal halide perovskites are a promising candidate as gain medium for a thin-film electrically-pumped laser. This is owing to their excellent optoelectronic properties combining high carrier mobilities and near unity photoluminescence quantum yield. Furthermore, their high optical gain values lead to low amplified spontaneous emission (ASE) thresholds. Encouragingly, optically-pumped lasing has been routinely observed from perovskite-based active layers in different resonator structures, while continuous-wave lasing has been realized not only under cryogenic conditions, but also at room temperature. Moreover, perovskite light-emitting diodes (PeLEDs) show external quantum efficiencies (EQE) values above 1% at high current densities above 1 kA/cm^2. Despite this progress, an electrically-pumped perovskite laser has not been demonstrated so far.

In this work, we demonstrate a novel PeLED architecture that yields low ASE thresholds. At the same time, the device maintains excellent electrical injection properties up to kA/cm^2 current densities. Furthermore, we study the device performance under cryogenic conditions, where we show a 3-fold increase in EQE and more than an order of magnitude lower ASE threshold compared to room temperature operation. These interesting device features allow us to study the response of the PeLED to electrical and optical excitations at different temperatures. Moreover, we study the effect of simultaneous electrical and optical excitation on device performance. Finally, by comparing the device response to optical and electrical excitations, we estimate the threshold current density needed to achieve ASE in our structure. These results pave the way toward a proof-of-concept demonstration of an electrically-pumped perovskite laser.

SESSION EL17.02: Hybrid Perovskite Materials, Stability and Devices

2:15 PM EL17.02.02
The Trade-Off Between Efficiency and Electrical Stability in Green Mn^{2+} Doped Perovskite Light-Emitting Diodes Sebastian Fernandez[1], William Michaels[1], Manchen Hu[1], Pournima Narayanan[1], Natalia Murrietta[1], Arynn Gallegos[1], Ghada Ahmed[1], Mahesh Gangishetty[2] and Daniel Congreve[1]; [1]Stanford University, United States; [2]Mississippi State University, United States

While light-emitting diodes (LEDs) made from lead halide perovskites have demonstrated external quantum efficiencies (EQEs) well over 20%, their electrical stability must be addressed before they are seriously considered for commercial applications. In an effort to improve the optoelectronic properties of lead halide perovskites for light emission, many researchers have investigated introducing both alkaline-earth metal ions (e.g., Ba^{2+} and Sr^{2+}) and transition metal ions (e.g., Mn^{2+}, Zn^{2+}, Cd^{2+}, and Ni^{2+}) into the B-site of the perovskite's ABX_3 structure. Additionally, the factors that limit the electrical stability of perovskite LEDs remain under investigation. In this work, we dope Mn^{2+} ions into an organic-inorganic hybrid quasi-bulk 3D perovskite resulting into $(PEABr)_{0.2}Cs_{0.4}MA_{0.6}Pb_{0.7}Mn_{0.3}Br_3$ thin films with the addition of tris(4-fluorophenyl)phosphine oxide (TFPPO) dissolved in a chloroform antisolvent to achieve an EQE of 13.4% and a peak luminance of 95,400 cd/m^2. While the inclusion of TFPPO into the chloroform antisolvent dramatically increases the EQE of perovskite LEDs, the electrical stability is severely compromised. At an electrical bias of 5 mA/cm^2, our perovskite LED fabricated with a pure chloroform antisolvent (2.5% EQE) decays to half of its initial luminance in 90.68 minutes. Alternatively, our perovskite LED fabricated with TFPPO (13.4% EQE) decays to half of its initial luminance in 2.07 min. In order to investigate this trade-off in EQE and electrical stability, we study both photophysical and electronic characteristics before and after electrical degradation of the perovskite LEDs. We find that given identical electrical degradation conditions, the TFPPO-based device's turn on voltage and overall electrical resistance increases in a much larger fashion as compared to the pure chloroform-based device. While the EQE characteristics of this Mn^{2+} doped perovskite LED show promise for B-site engineered perovskites, there is still large concern to simultaneously achieve both energy-efficient and electrically stable perovskite-enabled lighting. Uncovering the effects from the TFPPO additive on perovskite LEDs will reveal pathways on how to mitigate their negative consequences on electrical stability while retaining their energy-efficiency boosting properties.

2:30 PM *EL17.02.03

Comprehensive Strategies to Increase Electroluminescence Efficiency in Colloidal Metal-Halide Perovskite Nanocrystals Young-Hoon Kim[1], Sungjin Kim[2], Jinwoo Park[2] and Tae-Woo Lee[2]; [1]Hanyang University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

As the technology has advanced and the amount of information grows in an information society, display technology needs to show information more vividly and efficiently. In this sense of line, display technology has found a high color purity light emitter, metal halide perovskite, and tried to demonstrate high efficiency light-emitting diodes (LEDs). However, device efficiency of perovskite LEDs is limited by lack of comprehensive materials design strategies both to suppress formation of defects and to enhance charge carrier confinement inside perovskite nanocrystals (PNCs). Here, we report comprehensive strategies that generate smaller, monodisperse colloidal particles (confining electrons and holes and boosting radiative recombination) with fewer surface defects (reducing nonradiative recombination) to demonstrate high efficiency perovskite LEDs.

Firstly, we performed ligand engineerings during the PNC synthesis. We synthesized methylammonium lead bromide ($MAPbBr_3$) and formamidinium lead bromide ($FAPbBr_3$) PNCs with a dimension larger than exciton Bohr diameter (regime beyond quantum size), which have emitting light with size-insensitively high color-purity and constant wavelength, by controlling ligand concentration and ligand length, respectively. Ligand-engineered PNCs can increase photoluminescence quantum efficiency (PLQE) upto 70% by preventing non-radiative recombination of charge carriers and also improve the charge injection/transport capability in PNC films, resulting in external quantum efficiency (EQE) of 5.5% in PNC-LEDs.

Secondly, we conducted crystal engineering on the PNCs. We used substitutional doping of guanidinium (GA) into $FAPbBr_3$ PNCs to incorporate an optimal proportion of GA cations into the structure. The GA cations can reside in the bulk of the PNC in low concentrations (~10%). The surplus GA then accumulates on the surface of the PNC. Guanidinium incorporation provides bulk entropy stabilization, surface stabilization (by additional hydrogen bonding contributed by their extra amino group), and better electron–hole confinement, which results in high PLQE over 90%. A GA to FA ratio of 0.1 was shown to maximize the electroluminescence efficiency. Moreover, a 1,3,5-tris(bromomethyl)-2,4,6-triethylbenzene (TBTB) overcoat was introduced to heal the residual halide vacancy defects in $FA_{1-x}GA_xPbBr_3$ PNCs and to improve the charge balance in PeLEDs. The result is highly efficient PNC-based LEDs that have current efficiency of 108 cd/A (EQE of 23.4%), which rises to 205 cd/A (EQE of 45.5%) with a hemispherical lens.

Furthermore, we report that highly efficient large-area perovskite LEDs with high uniformity can be realized through the use of colloidal PNCs which decouple the crystallization of perovskites from film formation. PNCs are precrystallized and surrounded by organic ligands, and thus they are not affected by the film formation process, in which a simple modified bar-coating method facilitates the evaporation of residual solvent to provide uniform large-area films. PeLEDs incorporating the uniform bar-coated PNC films achieve an external quantum efficiency (EQE) of 23.26% for a pixel size of 4mm^2 and EQE of 22.5% for a large pixel area of 102mm^2 with high reproducibility and EQE of 21.46% in 900mm^2.

Enhancing the Performances of Blue Perovskite Light-Emitting Diodes by Controlling the Carrier Injection, Transfer and Confinement Wallace C. Choy; The University of Hong Kong, China

Recently, substantial efforts have been made in enhancing the performances of blue perovskite light-emitting diodes (PeLEDs), and efficiencies over 10% have been achieved. However, the performances still lag far behind with the efficient green, red, and near-infrared PeLED analogs. It is highly desirable to develop highly-performed and stable blue PeLEDs.

In this work, we will improve the performance from quasi-two dimensional (quasi-2D) blue PeLEDs by enhancing the carrier injection, transfer and confinement. To improve the carrier injection, we will suppress the trap states and improve the band alignment of device structure[1]. Then, we will modify introduce mixed quasi-2D perovskite structure to enhance the carrier transfer and narrow the n-phase of quasi-2D perovskites for improving the emission efficiency [2,3]. To further optimize the performance of quasi-2D blue PeLEDs, we systematically study the effects of organic passivating agents with different carbon chain lengths. Our results show that the appropriate carbon chain length of the organic agent simultaneously offer good carrier confinement for the massive radiative recombination within the perovskites, and efficient carrier transfer in quasi-2D perovskites for high emission efficiency. Benefitting from the good optical and electrical properties of TBPO incorporated perovskites, we achieve high-efficient blue PeLEDs with an EQE of 11.5 % and prolonged operational stability of 41.1 min [4]. Consequently, this work contributes the effective approaches to design high-quality perovskite films and efficient blue PeLEDs.

Binary Phase Separation of Quasi-2D Perovskite Light-Emitting Diodes in Mixed-Halide System Seok Joo Yang and Letian Dou; Purdue university, United States

Quasi-two-dimensional (2D) perovskite material has been recently receiving a lot of attention as a light emitter due to its unique quantum-well properties. However, forming undesired multi-quantum-well, called as phase separation, spontaneously occurs in quasi-2D perovskite films since ions can be migrated during the crystallization process. The phase separation produces unexpected emission wavelength, decreases external quantum efficiency (EQE) and stability in light-emitting diode (LED) devices. Therefore, many research groups try to overcome the phase separation using a new design of organic ligands or crystallization kinetics.

In the LED fields, mixing halide ions such as iodide and bromide has widely been used since it can control energy bandgap of the perovskite films. However, mixing halide ions in quasi-2D perovskite films induces phase separation much more than pure halide ions because smaller halide ions in the mixed-halide system have faster ion migration than larger halide ions. In addition, halide segregation also appears in the quasi-2D perovskite film when mixing halide ions. In this work, we define the phase separation and halide segregation as binary phase separation. And our newly designed ligands can suppress the binary phase separations effectively compared to conventional ligands.

Heterogeneity and the phase separation of the mixed-halide quasi-2D perovskite films can be spatially demonstrated using a confocal-photoluminescence (PL) measurement with different ranges of PL wavelengths. The quasi-2D perovskite films using the conventional ligands are suffered from phase separation having small *n* phase and high *n* phase even to three-dimensional phase. Moreover, the halide distribution in mixed-halide quasi-2D perovskite LED devices is analyzed by *in-situ* X-ray fluorescence (XRF). In the *in-situ* XRF mapping, the halide ions in the quasi-2D perovskite film using the conventional ligand are observed to be migrated in operating LED devices, and already segregated before applying bias. On the other hand, well-suppressed the binary phase separation using our ligands can manufacture the quasi-2D perovskite LED have controllable emission wavelength by mixing halide ions and high EQE of over 26% and higher operational stability compared to other quasi-2D perovskite LED devices.

4:00 PM EL17.02.06

Wide-Bandgap Perovskite Quantum Dots in Perovskite Matrix for Sky-Blue Light-Emitting Diodes Ziliang Li[1], Yuan Liu[1], Jian Xu[1], Yitong Dong[1], Bin Chen[1], So Min Park[1], Dongxin Ma[1], Seungjin Lee[1], Jianan Erick Huang[1], Sam Teale[1] and Oleksandr Voznyy[2]; [1]University of Toronto, Canada; [2]University of Toronto, Scarborough, Canada

The emergence of perovskite quantum dots (QDs) has enabled light-emitting diodes (LEDs) with narrowband emission and high external quantum efficiencies (EQEs). Epitaxially growing a perovskite matrix onto perovskite QDs provides robust QD surface passivation and efficient charge transport, thus further boosting luminescence efficiency and operation stability.

Efficient and stable red LEDs have been developed based on $CsPbI_3$ QD-in-perovskite matrix solids[1]. However, the synthesis of this heterostructure has so far remained elusive for wide-bandgap (E_g) perovskite emitters relevant to blue photon sources. The chemical challenge has resided in the paucity of wide-E_g QD:matrix combinations: the identification of the rare pairings that implement type-I band alignment and lattice matching between QDs and matrix.

Here, we report a wide-E_g (>2.6 eV) $CsPbBr_3$ QD-in-perovskite matrix solid that enables efficient sky-blue LEDs[2]. We initiated a wide screen of prospective A-site and B-site alloying candidates and found promising for $CsPb_{1-x}Sr_xBr_3$ as a matrix: it was the sole candidate that minimized lattice mismatch with the blue-emitting perovskite QDs while allowing an E_g of the perovskite matrix larger than that of the QDs.

In light of the hygroscopic nature of Sr^{2+}, we then developed an approach to passivate the surface of the $CsPb_{1-x}Sr_xBr_3$ matrix. By uniting molecular dynamics simulations with experimental efforts, we found that bis(4-fluorophenyl)phenylphosphine oxide (DPPO) strongly coordinates with Sr^{2+} located on the matrix surface and offers sufficient steric hindrance to block H_2O from the atmosphere. As a result, the QD-in-matrix solids exhibit efficient charge transport with enhanced stability. Sky-blue LEDs using this material as the active layer exhibit an EQE of 13.8% and a brightness exceeding 6000 cd m^{-2}.

4:15 PM EL17.02.07

Enhanced Operational Stability of Perovskite Light-Emitting Devices Through Differentiated Ion Motion Jason D. Slinker; The University of Texas at Dallas, United States

Hybrid perovskites are emerging as highly efficient materials for optoelectronic applications. However, their operational lifetime has remained a limiting factor for their continued progress. In thin-film perovskite light-emitting devices, ionic redistribution may distort the perovskite crystal structure, lowering conductivity and light emission due to the formation of vacancies and other traps. Our strategy for enhanced lifetimes involves producing differentiated ion motion within a device with a rational materials blend. The materials selectively move additive ions while restricting the transport of perovskite ions. To accomplish differentiated ion transport with optimal thin-film morphology, we combine a perovskite, a polyelectrolyte such as poly(ethylene oxide), and a salt additive such as $LiPF_6$. The added mobile Li^+ and PF_6^- ions redistribute more favorably than the intrinsic ionic species and largely preserve the inherent structure of the perovskite film. At 0.5 wt% $LiPF_6$, $CsPbBr_3$ devices exhibit 100 h operation at more than 800 cd/m^2 under constant current driving, achieving a maximum luminance of 3260 cd/m^2. Incorporating zero-dimensional perovskite nanocrystals into these devices enhances the lifetime further to a luminance half-life of 129 h at 1530 cd/m^2. We rationalize these findings through optical spectroscopy, impedance spectroscopy, X-ray photoelectron spectroscopy, scanning electron microscopy, and X-ray diffraction.

4:30 PM EL17.02.09

Highly Luminescent Lead-free Cesium Copper Halide Perovskite Nanoplatelets for Luminescent Solar Concentrator Application Junyu Wang[1], Tong Cai[2] and Ou Chen[1]; [1]Brown University, United States; [2]Northwestern University, United States

Luminescent solar concentrators (LSCs) are light-managing devices capable of absorbing and concentrating solar energy to a specific wavelength range and the target region. By coupling with photovoltaic (PV) cells, a PV-LSC system can significantly reduce the total material consumption for solar panel fabrication and simplify the design of large-scale solar harvesting devices for practical utilization. In particular, halide perovskite nanocrystals have shown promising potential for LSC applications due to their excellent optical properties, such as high photoluminescent quantum yield (PLQY), large Stoke's shift, and tunable optical bandgaps. Here, we report the fabrication of high-performance luminescent solar concentrator devices using copper halide perovskite nanoplatelets (NPLs). The $Cs_3Cu_2Cl_5$ perovskite NPLs with high photoluminescence quantum yield (PLQY) and large stock shift are synthesized through a hot-injection method. The NPLs are then deposited onto a polydimethylsiloxane (PDMS) substrate through our recently reported ultrasonic nebulization spray method with a low scattering effect and high average visible transmittance. The obtained LSC devices show a high optical efficiency performance and high-power conversion efficiency for the photons in both UVB and UVC regions, making them an ideal LSC device for capturing and energy conversion of high-energy photons.

5:00 PM EL17.03.01
Controlling Phase Transitions in 2D Perovskites by Organic Cation Alloying Rand L. Kingsford and Connor G. Bischak; The University of Utah, United States

Two-dimensional perovskite quantum wells have emerged as promising materials for optoelectronics applications, including LEDs, nanoscale lasers, and phototransistors. Ruddlesden-Popper (RP) perovskites have monovalent cation spacers and often exhibit a solid-solid phase transition, in which the organic layer undergoes an order-to-disorder transition. This "melting" of the organic layers induces changes in the inorganic layers, impacting the emissive properties of the material. Here, we demonstrate control over the phase transition temperature of RP 2D perovskites by alloying two similar organic cations. Although halide alloying is used regularly to precisely tune electronic properties, cation alloying to control thermodynamic properties has not been explored. By blending hexylammonium (HA) and pentylammonium (PA) cations in different ratios, we can tune the phase transition temperature of 2D perovskites over a large temperature range. We demonstrate this tunability in single crystals and solution-processed thin films. By correlating temperature dependent grazing incidence wide angle X-ray scattering (GIWAXS) and photoluminescence (PL) measurements, we show that the phase transition has a direct impact on the PL intensity. We also directly image this phase transition with temperature-dependent PL imaging to show that the phase transition is highly heterogeneous at the microscale. Overall, our work provides the necessary design principles to control phase transitions in 2D perovskites with the potential to use these materials as dynamically switchable optoelectronic materials.

5:00 PM EL17.03.02
Rational Ligand Pair With Short and Long Ligands to Stable and Efficient Light-Emitting Diodes Ah-young Lee and Myoung Hoon Song; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Even if perovskite nanocrystals (PNCs) have been well known as the defect tolerance in as-synthesized conditions, the unplausible defects are easily formed during the washing procedures. It is because no deep level defect states are generated due to the formation of halide vacancies, while the loss of PbX_2 shell induces the severe degradation of PNCs. Therefore, in the colloidal solution states, only loss of PbX_2 shell visibly deteriorated the performance of PNCs. However, during light-emitting diodes (LEDs) operations, halide vacancies can provide the ion migration pathways, resulting in the rapid degradation of perovskite structures. Simultaneously, Pb^0 states, generated due to electron injection, have been reported as the deep level defect states. Therefore, the rational strategies toward all possible defects are important to enhance the optical properties of PNCs and the performance of PNCs LEDs. Recently, diverse defect passivation strategies have been reported to passivate all possible defect states. General approach toward defect passivation of PNCs might be treatment of surface ligands having suitable functional groups such as ammonium, carboxylate, sulfonate, and so on. However, there is another important consideration to apply the colloidal PNCs into thin films: the binding affinity of surface ligands. Since PNCs have ionic nature, the binding of surface ligands usually has ionic nature, leading ease detachment of surface ligands from the surface PNCs. The easier detachment of surface ligands in colloidal states may induce the surface ligands loss during thin film formation of PNCs, resulting in the severe loss of efficiency of PNCs LEDs. Therefore, there are lots of effort to understand the surface binding affinity of PNCs with DOSY. Several alternatives, such as quaternary ammonium bromide and sulfonate, to replace native ligands have been reported, having higher binding affinity than native ligands. Along with the tightly bound ligands, the optical properties of PNCs are maintained adding of PbX_2 into PNCs during washing process. The addition of PbX_2 during washing can mitigate the loss of PbX_2 shell, maintaining the original photoluminance quantum yield (PLQY).
Bodnarchuk et al. reported treatment of PbX_2 and DDAB improved the colloidal stability of PNCs. The PLQY of $PbBr_2$ and DDAB treated PNCs was maintained in 90% after polar solvent washing process, while PLQY of native ligands was reduced from 60% to 30% after washing. Moreover, perovskite has self-doping properties where the electronic band structure is tuned in the ratio control over the PbX_2 and AX. The band structure tuning is important to the charge injection of LEDs operation. Additionally, the stability of LEDs is one of the important issues in perovskite societies. One of the well-known approaches is B-site metal doping. The formation energy of B-site doped PNCs was enhanced, resulting in the stable PNCs.
In this study, the ratio control over Pb to DDA was conducted to tune the band structure of PNCs. The post-synthetic surface treatment with Pb-DDA was enhanced PLQY from 46% to near unity. Based on the ratio control, highest occupied molecular orbital (HOMO) became shallow with increasing DDA ratio. Further, the charge injection of PNCs with different ratio was measured in hole only devices. The charge injection was best at Pb-DDA2, implying trade-off between energy level and ligand density in charge injection ability. Consequently, the ratio control over Pb to DDA was resulted in highly efficient LEDs, optimizing charge injection. To further enhance the stability of PNCs, additional $NiBr_2$ was treated in PNCs, called Ni-DDA. There was no significant different in PLQY. Finally, LED devices were fabricated to compared Pb-DDA and Ni-DDA. Even if the device efficiencies were similar with each other, the device stability of Ni-DDA was enhanced compared to Pb-DDA.

5:00 PM EL17.03.03
Exploring the Design Rules for Efficient Metal Halide Perovskite Light Emitting Diodes Jiajun Qin, Jia Zhang and Feng Gao; Linkoping University, Sweden

Defect passivation, through decreasing nonradiative recombination rate, has long been considered as the key to efficient perovskite light emitting diodes (LEDs). Here, by revisiting the two commonly used defect passivation strategies, stochiometric ratio tuning and additive engineering, in various perovskite systems, we found its limitations in explaining the superior high performance in light emitting. Surprisingly, a different mechanism other than defect passivation is proved to be responsible for efficient perovskite LEDs. Our low-temperature photoluminescence and ultraviolet photoelectron spectroscopy (UPS) results indicate that these strategies lead to increment of shallow traps and thus p-dope the perovskites. Such p-doping largely enhances the photoluminescence quantum efficiency especially at low carrier density region and can even go beyond 90%. Through carrier dynamics analysis, we point out that the dominant factor responsible for high efficiency in perovskites is the enhancement of radiative recombination via doping rather than defect passivation. Furthermore, this p-doping effect is verified by special device design where poor hole injection results in high external quantum efficiency of perovskite light emitting diodes (PeLEDs). Our discoveries provide design rules to fabricate high-efficiency PeLEDs.

5:00 PM EL17.03.04
Photopatterning of Perovskite Nanocrystals with Photo-Crosslinkable Ligands Evon Ong and Zhi Kuang Tan; National University of Singapore, Singapore

Perovskite nanocrystals (NCs) have emerged as promising luminescent materials for full-colour display applications due to their strong optical properties, widely tunable emission, and narrow full-width half maximum. By precise tuning of their emission spectra, high-resolution full-colour light-emitting diode (LED) arrays can be achieved by micro-patterning red, green, and blue sub-pixels with perovskite NCs as emitters. Currently, photolithography is the most widely used patterning technique in the industry due to its capabilities to achieve high resolution, large area production, and low cost. However, due to the ionic nature of perovskite NCs, conventional photolithography techniques are incompatible as the use of polar solvents can damage underlying perovskite NC patterns, resulting in defect formation and luminescence quenching. Herein, we report a series of novel photo-crosslinkable ligands for the microscale patterning of perovskite NCs. We incorporated photosensitive acrylate groups in the ligands, which upon exposure to ultraviolet light, undergo polymerization and changes the solubility of the NC films. This enables the direct photo-patterning of perovskite NCs without the need for additional photoresist. Through a facile solution-phase ligand exchange process, we functionalized cesium lead halide ($CsPbX_3$) NCs with our photo-crosslinkable ligands. We also demonstrate the photopatterning of 10 µm features on the $CsPbX_3$ NC films via direct laser writing with a 405 nm laser. Our approach offers a versatile strategy for the patterning of perovskite NC films in a simple and cost-effective manner, thus enabling the integration of perovskite NCs in various display applications.

5:00 PM EL17.03.05

External Distributed Feedback Halide Perovskite Lasers Fabricated by High-Throughput UV Nanoimprint Lithography Iakov Goldberg[1,2], Nirav Annavarapu[1,2], Simon Leitner[3], Robert Gehlhaar[1], Karim Elkhouly[1,2], Cedric Rolin[1], Jan Genoe[1,2] and Paul Heremans[1,2]; [1]imec, Belgium; [2]KU Leuven, Belgium; [3]University of Leoben, Austria

Metal-halide perovskites have emerged as promising gain media for lasing applications. In the state-of-the-art, perovskite gain media can be deposited atop a pre-patterned substrate. Alternatively, a negative mould pattern can be directly embedded into the perovskite to form desirable photonic nanostructures. However, conventional thin-film deposition techniques such as spin-coating, vacuum evaporation, etc., exhibit poor conformality and are only marginally compatible with the deposition on textured substrates or above high-aspect-ratio features.

In this work, we present an all-solution fabrication approach of external second-order one-dimensional distributed feedback (1D DFB) gratings by means of soft UV-nanoimprint lithography (UV-NIL). This high-throughput fabrication method can be carried out in the ambient environment, and it requires mild temperatures as low as 70 °C, gentle imprint pressure, and the use of compatible UV-NIL resin that does not attack the chemically fragile methylammonium lead iodide ($MAPbI_3$) perovskite film used in this work. The UV-NIL gratings are isolated from the perovskite layer and are limited to the UV-NIL resin deposited above the perovskite, thus preserving perovskite morphology and low roughness. We show that commercially available UV-NIL products are suitable for a high-fidelity pattern transfer to perovskite-based optical lasers without affecting perovskite optoelectronic properties.

As a result, we reproducibly achieve a single-mode, low-threshold (below 100 $\mu J/cm^2$), narrow linewidth (below 0.2 nm), and strongly polarized (extinction ratio above 50) optically pumped lasing. In addition, we explore characteristic lasing far-field and mode patterns of these 1D DFB gratings. We believe that the proposed resonator integration approach can be extended towards the complete electrically active devices, enabling an alternative integration route towards perovskite injection-lasing.

5:00 PM EL17.03.07

Surface Metallic Lead Passivation of 2D Ruddlesden-Popper Perovskite via Molecular Acceptor Deposition Kitae Kim[1,2], Donghee Kang[1], Sylke Blumstengel[3], Nicolas Zorn Morales[3], Emil J. List-Kratochvil[3,4], Soohyung Park[2], Hyunbok Lee[5] and Yeonjin Yi[1]; [1]Yonsei University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Humboldt-Universität zu Berlin, Germany; [4]Helmholtz-Zentrum für Materialien und Energie GmbH, Germany; [5]Kangwon National University, Korea (the Republic of)

Two-dimensional Ruddlesden-Popper (2D RP) perovskites have emerged as promising materials in optoelectronics. The 2D RP perovskites possess significantly improved stability against oxygen, moisture, heat, and ion migration while they still have novel properties such as large exciton binding energies and tunable band gaps. However, 2D RP perovskites suffer significantly from photostability. Photodegradation induces various defects in 2D RP perovskites, such as undercoordinated halide or metal ions like 3D perovskites. The photodegradation of 2D RP eventually leads to the metallic lead (Pb^0), a critical defect for all kinds of lead-based perovskite. The Pb^0 not only plays a role as a deep trap for carrier and exciton transport but also accelerates the degradation process. We employed a strong organic molecular acceptor 2,2′-(perfluoronaphthalene-2, 6-diylidene) dimalononitrile (F6-TCNNQ), to suppress such Pb^0 formed on phenylethylammonium lead iodide (PEA_2PbI_4). We systematically derived the Pb^0 with a blue laser (405 nm) irradiation on PEA_2PbI_4, then deposited the F6-TCNNQ molecules on its surface. *In-situ* X-ray and ultraviolet photoelectron spectroscopy (XPS and UPS) measurements showed the changes in Pb^0 states with F6-TCNNQ deposition. Pb^0 on the surface was completely suppressed after the deposition of F6-TCNNQ. It reduced the non-radiative recombination and consequently recovered the photoluminescence slightly. Interestingly, the recovered film showed much-improved photostability by preventing the formation of photoinduced Pb^0. UPS measurements revealed that the Pb^0 is passivated into Pb^{2+} due to the electron transfer from Pb^0 states into F6-TCNNQ, which is the only possible route. Our results provide a new efficient passivation strategy to improve the performance and stability of 2D RP perovskites, suggesting the importance of understanding the charge transfer at the interface.

High-Throughput Exploration on the Phase Growth Behaviors in Quasi-2D Formamidinium-Based Perovskites Jonghee Yang and Mahshid Ahmadi; University of Tennessee, United States

Low-dimensional quasi-two-dimensional (2D) perovskites – a mixed structure of 2D and three-dimensional (3D) perovskite lattice – are now the leading materials platform for the demonstration of functional optoelectronics. The dimensional confinements of perovskite lattice by molecular spacer cations and the resulting quantum-well structures bestow their unique functionalities including chemical robustness and strong light-emission properties. Despite its versatility, little has been known on the principle of phase control in quasi-2D perovskites. Herein, by using a robot-based high-throughput automated synthesis platform, we explore the phase formation behaviors of quasi-2D phenethylammonium-formamidinium perovskite system in a wide range of 2D (PEA_2PbI_4):3D ($FAPbI_3$) compositions. We observe that, in contrast to the stoichiometric consideration, incorporation of only 1% of the 3D component provides substantial emergence of n=2 2D phase, which is prominent up to the 3D ratio of 92%; after this composition, 3D-like phases that are more stable than the pristine 3D $FAPbI_3$ mainly emerge. Coupled with hyperspectral cathodoluminescence microscopy, we uncover that thermal annealing is necessary for thin film fabrication of quasi-2D perovskites, but concurrently involves the emergence of PbI_2. Our work provides practical insights into the fundamental principles in 2D perovskite phase control, further benefitting the functionalities of novel materials systems towards sustainable device applications.

5:00 PM EL17.03.09

Transport Layer Engineering Towards Lower Threshold for Perovskite Lasers Jia Zhang, Jiajun Qin, Xiao-Ke Liu and Feng Gao; Linköping University, Sweden

Lead halide perovskites are promising candidates for future lasers as they are proven good gain medium, low-cost solution processable, and exhibit bandgap-tunable luminescence with high color purity and photoluminescence quantum yields. Sandwiching the perovskite layer into transport layers is inevitable during the integration of electrical devices for electrically pumped perovskite lasers. However, the appearance of perovskite/transport layer interfaces is absent in most reported optically pumped perovskite lasers, and is usually considered as detrimental factors to lasing actions. This is why the electrically pumped perovskite lasers are still not realized even with the realization of high injection current densities ($> 1\ \text{kA/cm}^2$) and achievement of optically pumped continuous wave (CW) perovskite lasers at room temperature. Here we report the treatment of perovskite polycrystal thin films with different transport layers effect of transport layers, and the amplified spontaneous emission (ASE) threshold are studied to investigate the influence of perovskite/transport interfaces on lasing actions. We demonstrate largely reduced ASE threshold (22.0%) and enhanced ASE intensity (18.6%) with introducing an additional hole transport layer poly(triaryl amine) (PTAA) on top of perovskite layer. We show that the key role of PTAA layer is to accelerate the hot carrier cooling process from 488 fs to 422 fs by extracting the excess hot holes of perovskites. With suppressed hot holes, the Auger recombination loss is largely reduced, which in turn reduces the ASE threshold. Our work for the first time exemplifies how to further reduce ASE threshold with transport layer engineering. This is critical to maintain the good gain medium properties of perovskites when integrating perovskites into electrical devices and could also have a broader impact on paving the way for future electrically pumped laser fabrication.

5:00 PM EL17.03.12
High-resolution Direct Optical Patterning of Perovskite Nanocrystals Using Photo-induced Ligand Exchange Sun Jae Park, Seongkyu Maeng, Jaehwan Lee and Himchan Cho; KAIST, Korea (the Republic of)

Metal halide perovskite (MHP) nanocrystals have been recognized as a promising material class for next-generation realistic displays, owing to their excellent color purity. To adopt MHP nanocrystals to the next-generation displays (*e.g.*, augmented reality displays) with high-resolution, precise patterning method should be developed to fabricate RGB pixel arrays. However, the traditional photolithography is not suitable for patterning colloidal MHP nanocrystals since the solvent in photoresist often results in the degradation of the emissive properties of MHP nanocrystals. Direct optical patterning is a photoresist-fee method to pattern MHP nanocrystals, which uses the change in solubility due to a chemical reaction upon light source irradiation. However, the photo-induced chemical reaction often affects the passivation of MHP nanocrystals which is critical in maintaining the photoluminescence quantum yield throughout the patterning process. Herein, we propose a nondestructive photo-induced in-situ ligand exchange mechanism for direct optical patterning of colloidal MHP nanocrystals. The MHP nanocrystals became photosensitive with thiol additives; high-resolution 2-µm line patterns of MHP nanocrystals were achieved without compensating the emissive properties, which is due to the effective passivation of in-situ-exchanged thiolate ligands. The patterning mechanism was in-depth investigated by analyzing the surface properties of MHP nanocrystals at each patterning step.

5:00 PM EL17.03.13
Direct Optical Patterning of Colloidal InP-based Quantum Dots Using Photoacid Generators Jaehwan Lee and Himchan Cho; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Direct optical patterning of colloidal nanomaterials has recently received a lot of attention because of photoresist-free simple patterning procedure. The use of photoacid generator (PAG) additive has been studied as one of the promising approaches for direct optical patterning of colloidal quantum dots (QDs). With PAG, high-resolution QD patterning without complete ligand exchange is enabled. However, direct optical patterning of QDs with PAG may result in decrease in photoluminescence quantum yield (PLQY) in case of insufficient surface passivation of patterned QDs. Furthermore, such PLQY decrease could be enhanced for colloidal InP-based QD, which has high oxophilicity. Therefore, systematic and fundamental studies to achieve high-resolution InP-based QD patterns while minimizing the surface damage are required. Here, we show high-resolution direct optical patterning of InP-based core/shell QDs using a triazine-based photoacid generator. We investigate the changes in optical and structural properties of the core/shell QDs with each patterning step. Also, our study involves ligand post-treatment for the PLQY recovery of patterned InP QDs. The post-treatment passivated the surface defects and thereby increased the PLQY of InP QDs by ~90%. We believe our study suggests a facile way of patterning air-sensitive colloidal nanomaterials for various electronic and optoelectronic applications.

5:00 PM EL17.03.14
Methoxy Functionalized Conjugated Passivation Ligand for Efficient Perovskite Light Emitting Diodes Xinwen Sun[1], Kwan Ho Ngai[1], Jianbin Xu[1] and Mingzhu Long[2]; [1]The Chinese University of Hong Kong, Hong Kong; [2]South China Normal University, China

Due to the advantages such as exceptional optoelectronic properties, readily tunable emission, high photoluminescence quantum efficiency (PLQE), narrow emission bandwidth, and solution processability, metal halide perovskites are attractive for applications in light-emitting diodes (LEDs). Despite the halide perovskite LEDs (PeLEDs) have achieved high external quantum efficiency (EQE) of above 20%, there are still many issues to be further investigated in the process of promoting the industrialization of PeLEDs. Unfortunately, the solution-processed polycrystalline perovskite films suffer from severe trap-mediated non-radiative recombination and ion migration. A tremendous amount of effort has been carried out to improve the performance of PeLEDs, including blocking iodide ion migration by strengthening the space restriction on carriers, preparing high-quality crystalline perovskites, and forming interface engineering between the ETL and the perovskite light-emitting layer. Since both ion migration and non-radiative recombination are highly related to the defects in perovskites, defect passivation is essential to achieve efficient and stable PeLEDs. Although ligand-assisted mediation has proven to be a useful method for passivating the imperfections of PeLEDs, the control strategy of alkyl chain length and the electron donating ability of the ligands bring great challenge to rational passivation. Herein, by considering the electron donating ability for the defect passivation efficiency and steric hindrance for the crystallization process, we find that methoxy group can be introduced to phenethylammonium molecular served as an efficient additive, namely 4-methoxy-phenethylammonium (4-MeO-PEA) to facilitate defect passivation process in perovskite light-emitting materials. We have demonstrated that the 4-MeO-PEA agent can substantially increase the crystal orientation, enlarge the crystalline grain size and mitigate the defect centers through strong bonding between the methoxy group with Pb ions. The external quantum efficiency (EQE) value of the PeLEDs with optimized passivation reaches to a maximum of 21.57%, which is one of the best records in the near infrared PeLEDs (~790 nm emission peak) to date. In addition, a threefold increase in the T_{50} operational time of the devices is observed, compared to the control samples. The findings provide a simple and effective strategy to produce highly efficient perovskite films and to devise the high-performance optoelectronics devices.

The work is in part supported by Research Grants Council of Hong Kong, particularly, via Grant Nos. N_CUHK438/18, and CUHK Group Research Scheme.

5:00 PM EL17.03.15
Optimizing the Quasi-Equilibrium State of Hot Carriers in All-Inorganic Lead Halide Perovskite Nanocrystals Through Mn Doping—Fundamental Dynamics and Device Perspectives Jie Meng and Kaibo Zheng; Lund University, Sweden

Hot carrier (HC) cooling accounts for the significant energy loss in lead halide perovskite (LHP) solar cells. Here, we study HC relaxation dynamics in

Mn-doped LHP $CsPbI_3$ nanocrystals (NCs), combining transient absorption spectroscopy and density functional theory (DFT) calculations. We demonstrate that Mn^{2+} doping (1) enlarges the longitudinal optical (LO)–acoustic phonon bandgap, (2) enhances the electron–LO phonon coupling strength, and (3) adds HC relaxation pathways via Mn orbitals within the bands. The spectroscopic study shows that the HC cooling process is decelerated after doping under band-edge excitation due to the dominant phonon bandgap enlargement. When the excitation photon energy is larger than the optical bandgap and the Mn^{2+} transition gap, the doping accelerates the cooling rate owing to the dominant effect of enhanced carrier–phonon coupling and relaxation pathways. We demonstrate that such a phenomenon is optimal for the application of hot carrier solar cells. The enhanced electron–LO phonon coupling and accelerated cooling of high-temperature hot carriers efficiently establish a high-temperature thermal quasi-equilibrium where the excessive energy of the hot carriers is transferred to heat the cold carriers. On the other hand, the enlarged phononic band-gap prevents further cooling of such a quasi-equilibrium, which facilitates the energy conversion process. Our results manifest a straightforward methodology to optimize the HC dynamics for hot carrier solar cells by element doping.

SESSION EL17.04: Colloidal Quantum Dots, Patterning and Devices I

8:00 AM *EL17.04.01
Colloidal Quantum Dot Laser Diodes Victor I. Klimov; Los Alamos National Laboratory, United States

Electrically pumped lasers or laser diodes based on solution-processable materials have been long-desired devices for their compatibility with virtually any substrate, scalability, and ease of integration with on-chip photonics and electronics. Such devices have been pursued across a wide range of materials including polymers, small molecules, perovskites, and colloidal quantum dots (QDs). The latter materials are especially attractive for implementing laser diodes as in addition to being compatible with inexpensive and easily scalable chemical techniques, they offer multiple advantages derived from a zero-dimensional character of their electronic states. These include a size-tunable emission wavelength, a low optical-gain threshold, and high temperature stability of lasing characteristics stemming from a wide energy separation between their atomic-like discrete energy levels.

Several challenges complicate the realization of colloidal QD laser diodes (QLDs). These include extremely fast nonradiative Auger recombination of optical-gain-active multicarrier states, poor stability of QD solids under high current densities required to achieve lasing, and unfavorable balance between optical gain and optical losses in electroluminescent (EL) devices wherein a gain-active QD medium is a small fraction of the overall device stack comprising multiple optically-lossy charge-transport layers.

Here we resolve these challenges and achieve electrically driven laser action due to amplified spontaneous emission (ASE) in a colloidal-QD optical-gain medium. To demonstrate this effect, we employ compact, continuously graded QDs with strongly suppressed Auger recombination incorporated into a low-loss photonic waveguide integrated into a pulsed, high-current density light-emitting diode. These prototype QLDs exhibit strong, broad-band optical gain and demonstrate low-threshold, room-temperature laser action which leads to intense edge-emitted EL with intensity of more than 100 microwatts.

8:30 AM *EL17.04.02
Synthesis of Novel Quantum Dot Emitters in Molten Inorganic Salts Aritrajit Gupta, Wooje Cho, Ruiming Lin, Zirui Zhou, Justin Ondry and Dmitri V. Talapin; University of Chicago, United States

Many functional nanomaterials used for catalysis, healthcare, solid-state lighting, and displays are synthesized by colloidal techniques. The scope of chemical transformations accessible to colloidal chemists is determined by the stability and compatibility of solvents and surfactants used as a reaction medium. For example, very few traditional solvents can handle temperatures above 400C, while many inorganic phases require even higher temperatures to form. We are developing comprehensive understanding of a novel class of colloidal systems, colloids in molten inorganic salts. Nanoparticles of different transition metals, semiconductors, oxides, and magnetic materials can form true colloids in molten inorganic salts. The colloidal stability of nanoparticles in molten salts could not be explained by traditional electrostatic and steric stabilization mechanisms. Our experimental and computational studies point to the importance of the long-range ion correlations in the molten salt near the nanocrystal interface.
In addition to the fundamental exploration of new colloidal systems, molten salts expand the boundaries for solution synthesis of many nanomaterials that have been out of reach for colloidal chemists. We have used molten salts to synthesize colloidal GaAs, $In_xGa_{1-x}As$, $In_xGa_{1-x}P$ and GaN quantum dots, which resisted numerous synthetic attempts for over two decades. By further developing colloidal chemistry in molten salts, we hope to enable synthetic routes toward various functional nanomaterials previously considered unsynthesizable by colloidal methods.

9:00 AM DISCUSSION TIME

9:30 AM EL17.04.04
The Dynamics of Reversible Hole Trapping in InP/ZnSe/ZnS Quantum Dots Paul Cavanaugh[1], Anne Myers Kelley[1], Christian Ippen[2], Haochen Sun[1], Ilan Jen-La Plante[2], Maria Bautista[2], Ruiqing MA[2], Xudong Wang[2] and David F. Kelley[1]; [1]University of California Merced, United States; [2]Nanosys Inc, United States

The presence of impurities or defects in most quantum dots leads to irreversible carrier trapping. However, high quality InP/ZnSe/ZnS quantum dots (QDs) behave very differently. In this case, excess indium in the ZnSe shell of gives rise to hole traps that are transiently populated following photoexcitation. This leads to a slow (hundreds of picoseconds to nanoseconds) photoluminescence (PL) risetime.[1] Equilibrium between these traps, which are optically dark, and the emissive valence-band state also results in delayed emission and therefore longer PL lifetimes. The radiative lifetime can be varied from 32 to 48 ns, depending on the density of traps. Transiently trapped holes also affect the biexciton kinetics, allowing for variation of the electron versus hole Auger excitation ratios under high flux. In addition, the amplitude and time scale of the slow PL rise and the delayed emission time can be varied by different treatments of the InP cores prior to shell deposition, as indicated by resonance Raman spectroscopy. The Raman spectra are interpreted in terms of different radial distributions of the indium-based hole traps which can be related to differences in the interfacial lattice strain. Modulating the core/shell interface can also create interfacial dipoles varying the trap depth, in extreme cases leading to 10% of the photoluminescence coming from repopulation of the band edge by deep traps that occurs on the microsecond timescale.[2]
Several possible chemical and structural assignments of the traps are considered, and a substitutional indium adjacent to a zinc vacancy, In^{3+}/VZn^{2-} , is found to be the most likely.[3] This assignment is consistent with the observation that trapping occurs only when the QD has excess indium and is supported

by experiments showing that the addition of zinc oleate or acetate decreases the extent of trapping, presumably by filling some of the vacancy traps. We also show that addition of alkyl carboxylic acids causes increased trapping, presumably by creation of additional zinc vacancies.
This material is based upon work supported by the U.S. Department of Energy's Office of Energy Efficiency and Renewable Energy (EERE) under the Award Number DE-EE0009164 and NSF CHE-1506803.

Origins of Red Emission from ZnS:Cu Colloidal Nanocrystals and Potential Applications for Quantum Information Science Sarah M. Thompson[1], Cuneyt Sahin[2], Shengsong Yang[1], Michael Flatté[3], Christopher B. Murray[1], Lee Bassett[1] and Cherie R. Kagan[1]; [1]University of Pennsylvania, United States; [2]Bilkent University, Turkey; [3]The University of Iowa, United States

Colloidal ZnS:Cu nanocrystals (NCs) are prototypical colloidal nanophosphors in bio-imaging and optoelectronic applications thanks to their bio-compatibility and broadly tunable luminescence properties. Visible luminescence from ZnS:Cu colloidal NCs is typically dominated by green and blue peaks (denoted G-Cu and B-Cu), with observations of red (R-Cu) luminescence from nanocrystalline ZnS:Cu remaining extremely limited. Here, we present a synthetic method for obtaining colloidal ZnS:Cu NCs that emit primarily R-Cu. We use time- and temperature-resolved luminescence spectroscopies to study the emission mechanism, which provides advanced knowledge of the electronic structure produced by defects in ZnS:Cu that is critical for controlling the luminescence properties of this material. We also discuss the applicability of colloidal nanocrystals containing color centers to quantum information science, where electronically isolated defect states can serve as optically addressable spin qubits.

Semiconductor Nanocrystal Optoelectronics Using Colloidal Quantum Wells for Lighting and Displays Hilmi Volkan Demir[1,2]; [1]Nanyang Technological University, Singapore; [2]Bilkent University, Turkey

Lighting and displays are integral parts of human activities and economic development. Semiconductor nanocrystals, now offering a market volume exceeding 1 Billion Euros annually, have attracted great interest in quality lighting and displays in the last decade. Such colloidal semiconductors enable enriched color conversion essential to superior lighting and displays. These colloids span different types and heterostructures of semiconductors, starting in the form of colloidal quantum dots and most recently extending to the latest sub–family of nanocrystals, the colloidal quantum wells. In this talk, we will present most recent examples of photonic structures and device architectures using the colloidal quantum wells for lighting and displays. Also, we will present a powerful, large–area self–assembly technique for orienting these colloidal quantum wells either all face down or all edge up. We will demonstrate three–dimensional constructs of their oriented self–assemblies with monolayer precision. Finally, we will show record high–efficiency colloidal LEDs of these quantum wells employed as the electrically–driven emitter layer. Given their current accelerating progress, these solution–processed quantum wells hold great promise to challenge their epitaxial thin–film counterparts in semiconductor optoelectronics in the near future.

11:00 AM EL17.04.07
Tuning Phonon Energies in Nanocrystals for Enhanced Nonlinearity and Upconversion Emory Chan, Artiom Skripka and Zhuolei Zhang; Lawrence Berkeley National Laboratory, United States

Optical applications of lanthanide-doped nanoparticles require materials with low phonon energies to minimize nonradiative relaxation and promote nonlinear processes like upconversion. Heavy halide hosts offer low phonon energies but are challenging to synthesize as nanocrystals. Here, we demonstrate size-controlled synthesis of low-phonon-energy potassium lead halide nanoparticles and the ability to tune nanocrystal phonon energies. These nanoparticles are moisture resistant and can be efficiently doped with lighter lanthanides. The low phonon energies of these nanoparticles promote upconversion emission from higher lanthanide excited states and enable highly nonlinear, avalanche-like emission when doped with neodymium ions. The realization of nanoparticles with tunable, ultra-low phonon energies facilitates the discovery of nanomaterials with phonon-dependent properties, precisely engineered for applications in nanoscale imaging, sensing, luminescence thermometry and energy conversion.

11:15 AM EL17.04.08
Low Dimensional Perovskite for Wearable Optoelectronics Xiwen Gong; University of Michigan, United States

Multifunctional skin-interfaced electronics is one of the most anticipated medial Internet of Things (IoT) technologies that enables non-invasive collection of high-quality data on biological activity. This is realized thanks to their wearability and conformal coverage of our body. Building on these data and recent advances in deep learning, artificial intelligence-based bioimaging, diagnosis, and therapy will be performed with higher accuracy and speed than ever before. Furthermore, skin-like multifunctional sensors are revolutionizing the technologies and applications of soft robotics. This talk will first focus on the current knowledge gap in designing intrinsically deformable optoelectronic materials using low dimensioal perovskite. We will then discuss new material design strategies to achieve mechanical deformability in perovskite optoelectronic material and devices.

11:30 AM EL17.04.09
Room-Temperature Distributed Feedback $CsPbBr_3$ Perovskite Lasers Integrated on Silicon Nitride Waveguide Platform Federico Fabrizi[1,2], Piotr Cegielski[1], Manuel Runkel[3], Saaed Goudarzi[2], Cedric Kreusel[3], Bartos Chmielak[1], Stephan Suckow[1], Thomas Riedl[3], Surendra B. Anantharaman[1] and Max C. Lemme[2,1]; [1]AMO GmbH, Germany; [2]RWTH Aachen University, Germany; [3]Bergische Universität Wuppertal, Germany

Lead halide perovskites are solution processable semiconductors, which have shown promise for applications in solar cells and light emitting diodes. Further, the feasibility of device fabrication at low- temperature (100 °C) opens the door to explore new opportunities on integrated lasers on-chip, waveguide lasers on the silicon nitride (Si_3N_4) platform [1] and other electro-optical modulators [2]. However, perovskites have much higher refractive indices ($n = 2.3$-2.6) than that of a typical Si_3N_4 waveguide ($n = 2$). Such a contrasting refractive index at the perovskite/Si_3N_4 interface makes it challenging to extract light from the perovskite lasers. In this work, we address this challenge by using the perovskite as the emission medium and the Si_3N_4 as the cavity medium. Upon optical pumping, photons emitted from the perovskite couple to the cavity via the evanescent field for light amplification leading towards lasing on-chip ([1], [2]).

In this study, the cesium lead bromide ($CsPbBr_3$) thin film (90 nm) is used as a laser gain medium and Si_3N_4 as a distributed feedback (DFB) medium. The DFB constitutes of a 200 nm thick Si_3N_4 rib waveguide with a quarter-wavelength shifted first-order grating structure etched directly into the Si_3N_4 waveguide. Using a finite difference time domain simulation (Lumerical software), the grating dimensions and the cross-section of the Si_3N_4 waveguide was optimised to maximize the effective refractive index of the waveguide mode. The mode overlap between the perovskite film and Si_3N_4 waveguide mode was identified to be ~24%. Using the optimised configuration obtained from the simulation studies, our experiments were designed to realise the perovskite DFB lasers on a 6” Si wafer with 2.3 µm of thermally grown SiO_2. The experimental workflow to achieve a high-quality DFB system will be presented. 90 nm thick $CsPbBr_3$ film was spin coated on the DFB structure followed by a planar hot process to reduce the grain boundary defects [3]. The perovskite film was patterned as reported previously ([1], [3]) and encapsulated with a 1 µm thick PMMA protective layer. The device was optically pumped using a 300 nm pulsed excitation source with 300 ps pulse width and 1 kHz repetition rate at room temperature. At low excitation fluence, the weak photoluminescence signal showed a broad linewidth (16 nm). With increasing pump fluence, a single peak with ultranarrow linewidth (0.24 nm) was observed. An S-shaped curve for the emission intensity vs pump fluence confirming a clear sign of lasing with a threshold power density of 775 $\mu J/cm^2$ will be presented. Further, the change in the emission wavelength upon varying the grating periodicity and etch depth will be presented. Our work demonstrates a DFB $CsPbBr_3$ laser on a silicon nitride waveguide platform operating at room temperature, which opens new avenues for integrated optoelectronics.

Acknowledgments: This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 956270 and NRW project PEROVSKET funding code No EFRE-0801508.

Lasing Threshold Overestimation in Optical Pumping of Metal Halide Perovskites Jiajun Qin, Jia Zhang and Feng Gao; Linkoping University, Sweden

The threshold carrier density, conventionally evaluated from optical pumping, is a key reference parameter towards electrically pumped lasers, with the widely acknowledged assumption that optically excited charge carriers relax to the band edge through an ultrafast process. However, characteristically slow carrier cooling in perovskites challenges this assumption. Here, we investigate the optical pumping of state-of-the-art bromide- and iodine-based perovskites. We find that the threshold decreases by one order of magnitude with decreasing the excitation energy from 3.10 eV to 2.48 eV for methylammonium lead bromide perovskite ($MAPbBr_3$), indicating that the low-energy photon excitation facilitates faster cooling and hence enables efficient carrier accumulation for population inversion. Our results are then interpreted due to coupling of phonon scattering in connection to the band structure of perovskites. This effect is further verified in two-photon pumping process, where the carriers relax to the band edge with a smaller difference in phonon momentum that speeds up the carrier cooling process. Furthermore, by extrapolating the optical pumping threshold to the band edge excitation as an analog of electrical carrier injection to the perovskite, we obtain a critical threshold carrier density of $\sim 1.9 \times 10^{17}$ cm^{-3}, which is one order of magnitude lower than that estimated from the conventional approach. Our work thus highlights the feasibility of metal halide perovskites for electrically pumped lasers.

Toward Halide Perovskite Laser Diodes Noel C. Giebink; The Pennsylvania State University, United States

Metal halide perovskites have emerged as promising gain media with the potential to realize wavelength-tunable, non-epitaxial laser diodes. This talk will focus on recent progress toward this goal, including continuous-wave optically-pumped lasing from methylammonium lead iodide ($MAPbI_3$), the operation of $MAPbI_3$ LEDs at ~kA/cm^2 current densities, distributed feedback $MAPbI_3$ LEDs that lase under optical pumping, and combined electrical+optical pumping experiments that demonstrate a reduction in the optical threshold for amplified spontaneous emission when the optical pulse overlaps in time with a 3 ns electrical pulse injecting >1 kA/cm^2 at low temperature.

2:00 PM EL17.05.02
Morphology-Controlled Synthesis of Ruddlesden-Popper Nanowires of Monolayered Lead Bromide Perovskite Seokhyoung Kim; Michigan State University, United States

Layered two-dimensional organic-inorganic hybrid perovskites (OIHPs) are promising materials for light emitting purposes owing to their higher exciton binding energies compared to the three-dimensional lattices. Stacking of the 2D layers into ordered phases such as Ruddlesden-Popper phase with well-formed external morphologies is expected to create nanostructures that will bring in nano-confined optical properties while maintaining the quantum-confined electronic nature of layered perovskite sheets. Coupling band excitons with optical cavity modes, for example, has been exploited in nanowires (NWs) and nanoplatelets of 3D perovskites to enable ultra-small, low-threshold lasers. The cavity-coupled light emission is expected to experience a substantial enhancement if the nanostructures are made of layered 2D perovskite sheets. In this presentation, I will show the morphology-controlled synthesis of NWs of monolayered butylammonium lead bromide, $(C_4H_9NH_3)PbBr_4$, via chemical vapor deposition (CVD). We have systematically investigated the morphological outcomes with independent growth parameters including source temperatures, reactor pressure, and gas flow rates, which is well-summarized in a morphology phase diagram. Structural, elemental, crystallographic analyses will be presented to validate the quality of our NWs. We have observed a sharp, quantized absorption around 400 nm and strong photoluminescence at 405 nm, an indication of the presence of layered $(C_4H_9NH_3)PbBr_4$ sheets. I will present time-resolved photoluminescence and variable-temperature measurements to show stronger exciton binding characteristics in NWs of 2D $(C_4H_9NH_3)PbBr_4$ than of 3D CsPbBr3. Lastly, I will share the amplified light emission behaviors of the NWs upon pulsed excitation. Our NWs of layered OIHPs present potential to develop ultra-compact, coherent ultraviolet and visible light sources.

Spin-Exchange Carrier Multiplication in Manganese-Doped Colloidal Quantum Dots Ho Jin[1,2], Clement Livache[1], Whi Dong Kim[1] and Victor I. Klimov[1]; [1]Los Alamos National Laboratory, United States; [2]The University of New Mexico, United States

During carrier multiplication (CM) a high-energy, 'hot' electron or hole relaxes within the same band by creating new electron-hole (e-h) pairs.[1] This occurs via one or more impact ionization events whereby a pre-existing valence-band electron is excited to the conduction band after an Auger-type collision with a high-energy carrier. In principle, CM could improve the performance of a variety of optoelectronic, photovoltaic (PV) and photocatalytic devices because due to this process, the quantum efficiency of photon to e-h pair conversion (*Q*eh) becomes greater than one.[2,3] However, practically realized CM efficiencies are still not sufficiently high to achieve an appreciable boost in device performance, suffering from the high CM threshold ($h\nu_{th}$) and the high e-h pair creation energy (e_{eh}).
The use of engineered colloidal quantum dots (QDs) allows one to reduce $h\nu_{th}$ down to the energy-conservation-defined value of $2E_g$.[4] However, e_{eh} is not appreciably decreased compared to bulk solids. To reduce e_{eh}, one needs to increase the energy-gain rate associated with Coulomb collisions versus the phonon-related energy-loss rate. Here, to accomplish this objective, we exploit not 'direct' but ultrafast 'spin-exchange' Coulomb interactions in magnetically doped QDs.[5,6] For this purpose, we synthesize Mn-doped core/shell PbSe/CdSe QDs wherein the dopants exhibit strong spin-exchange coupling to both CdSe and PbSe QD components. By applying transient photoluminescence measurements, we observe a highly efficient excitation transfer from the light-harvesting CdSe shell to the Mn dopants, which is followed by a CM-like spin-exchange process which leads to generation of two core excitons. Due to spin conservation, the biexciton produced via relaxation of the excited Mn ion is a combination of a dark and a bright exciton (spins 1 and 0, respectively) in two different L-valleys of PbSe. The corresponding quantum efficiency measured at $2.5E_g$ is ~140%, almost three-fold enhancement versus undoped QDs, implying that the e-h pair creation energy is less than $1.25E_g$. This is near the fundamental one-bandgap limit and is also considerably smaller (a factor of >2.5) than for the reference undoped QDs. These results suggest that the use of spin-exchange interactions represents a viable approach for realizing highly efficient CM-enhanced solar-photoconversion schemes.

Photostable Wide Bandgap Metal Halide Perovskites Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Bandgap tuning is a crucial characteristic of metal-halide perovskite, with benchmark lead-iodide compounds having a bandgap of 1.6 eV. To increase the bandgap up to 2.0 eV a straightforward strategy is to partially substitute iodine with bromine in so-called mixed-halide lead perovskites. Such compounds are prone, however, to defect-induced halide segregation resulting in bandgap instabilities, which limits their application in tandem solar cells and a variety of optoelectronic devices. The optimization of the perovskite composition and surface passivating agents can effectively slow down, but not completely stop, such light-induced instabilities. Here we identify the defect and the intra-gap electronic state that triggers the material transformation and bandgap shift. It allows us to engineer the perovskite band edge energetics to radically deactivate the photo-activity of such defects and stabilize the perovskite bandgap over the entire spectral range above 1.6 eV. Then, I will discuss how the generation of I2 in mixed-halide perovskites under illumination has a crucial role in halide segregation. In fact, I2 reacts with bromide (Br−) in the lattice to form a trihalide ion I2Br-, which mediates a Br−/I− ion exchange reaction and the formation of an I-rich phase. Importantly, we observe that the efficiency of the process is highly dependent on the binding strength of the bromide within the crystalline structure. Based on this, we propose a general paradigm where an iodine redox based model rationalizes the initiation and growth of halide photo-segregation. Thus, we show how the design of the chemical composition of the metal-halide perovskite crystalline unit can stabilize the semiconductor bandgap, and eventually the performance of related solar cells, not only acting on the reduction of the density of native defects, but stabilizing the elemental composition of the perovskite crystalline unit. This is demonstrated by the fabrication of photo-stable purely inorganic CsPbI1.5Br1.5 solar cells.

3:30 PM *EL17.05.05
Circularly Polarized Photoluminescence with Spin Selectivity Through Rashba Band Structures and Chiral Structures in Hybrid Perovskites Bin Hu; University of Tennessee, United States

Circularly polarized photoluminescence (CPL) have been observed in organic-inorganic hybrid perovskites. In general, CPL require the orbital momentum in light-emitting states that can be circularly polarized by a photoexcitation and substantially conserved within PL lifetime. Both chiral structures and Rashba band structures can fulfill this requirement: generating circularly polarizable orbitals with sufficient conservation time constant to develop CPL. In chiral structures, our experimental studies found that light-emitting states establish chirality dynamics with ultrafast response (< picoseconds) and then conserve their circular polarization up to nanoseconds, enabling CPL. This provides a circular polarizer functionality in light emission shown in chiral structures. Furthermore, spin scattering between circularly polarized light-emitting states can shorten the conservation time constant of circularly polarized orbitals, decreasing CPL. This indicates that spin interaction between circularly polarized orbitals plays an important role in developing CPL. In Rashba band structures, we found that left-hand and right-hand circularly polarized orbitals can be optically operated between spin-up and spin-down bands to generate selective CPL by using circularly polarized photoexcitation. Moreover, we found that spin polarizations can directly interact with circularly polarized orbitals in Rashba band structures through spin-exchange coupling, generating spin-switchable phenomena in 2D-superlattice perovskites. This demonstrates switchable CPL between left-hand and right-hand circular polarizations when changing spin polarizations between positive and negative magnetic field directions. This indicates that the spin-exchange coupling functions as the key parameter towards developing CPL in Rashba band structures in hybrid perovskites.

4:00 PM EL17.05.06
Optical Properties of Binary Nanocrystal Superlattices Produced by Assemblies of Strongly and Weakly Confined $CsPbBr_3$ Perovskite Nanocrystals Grigorios Itskos[1], Modestos Athanasiou[1], Andreas Manoli[1], Marios Sergides[1], Taras Sekh[2,3], Etsuki Kobiyama[4], Rainer Mahrt[4], Maryna Bodnarchuk[2,3], Thilo Stoeferle[4], Maksym V. Kovalenko[2,3] and Andreas Othonos[1]; [1]University of Cyprus, Cyprus; [2]ETH Zürich, Switzerland; [3]Empa–Swiss

Federal Laboratories for Materials Science and Technology, Switzerland; [4]IBM Research Europe – Zurich, Switzerland

Periodicity in long range-ordered nanocrystal superlattices (NC SLs) can be exploited to alter or even tailor the properties of the individual NC building blocks while generating new collective electronic and optical phenomena as a result of the enhanced interactions between NCs. Perovskite NCs have emerged as highly attractive building blocks for SLs, based on their facile fabrication as sharp, monodisperse cubes as well as due to the observation of superfluorescence from single and multi-component perovskite NC superstructures.
Binary superlattices of the ABO$_6$ type, produced via self-assemblies of CsPbBr$_3$ NCs with sizes in the strong (~5 nm) and weak (~18 nm) confinement regime are being demonstrated for the first time. We discuss the optical properties of such binary SLs, focusing on the electronic interactions between the strongly and weakly-confined NC excitons. Transient photoluminescence and absorption measurements indicate efficient depletion of the small NC exciton population at the few to tens of ps scale; a concomitant delay of the transient absorption rise time signal of the large NC exciton bleaching is also observed. Such results are consistent with a highly efficient energy transfer process from the small to the large NCs within the binary superstructure. On-going experiments are investigating whether the fast energy funneling into the weakly confined NC excitons can compete and influence the characteristics and dynamics of the superfluorescence observed in such binary perovskite SLs.

4:15 PM EL17.05.07
Direct Optical Patterning of Colloidal Nanocrystals Jia-Ahn Pan[1,2], Emory Chan[1] and Dmitri V. Talapin[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]The University of Chicago, United States

Colloidal nanocrystals (NCs) have emerged as a diverse class of materials with tunable composition, size, shape, and surface chemistry. From their facile syntheses to their unique optoelectronic properties, these solution-processed NCs are a promising alternative to materials grown as bulk crystals or by vapor-phase methods. However, the use of NCs in real-world devices is often held back by challenges in depositing them as a patterned two-dimensional layer. Alternative approaches to patterning colloidal NCs need to be established to aid the transition from individual devices to integrated optoelectronic circuits, multi-color NC displays, and nanophotonic devices. This talk will focus on the development of photo-chemical methods that enable direct optical lithography of colloidal nanocrystals. We will discuss various light-sensitive ligands and their suitability for patterning various NCs including lead halide perovskite NCs, semiconducting quantum dots, metal oxide nanoparticles, and lanthanide-doped upconverting NCs. We will show that this patterning approach preserves many of the desirable properties of the NCs, such as high photoluminescence, good charge transport, and high refractive index. Ultimately, this work aims to expediate the implementation of colloidal NCs in a broader range of functional devices.

4:30 PM EL17.05.09
***In Situ* Core/Shell Perovskites for Ultra-Bright, Efficient and Stable Light-Emitting Diodes** Joo Sung Kim[1], Jung-Min Heo[1], Gyeong-Su park[1], Seung-Je Woo[1], Changsoon Cho[2], Hyung Joong yun[3], Dong-Hyeok Kim[1], Jinwoo Park[1], Seung-Chul lee[1], Sang-Hwan Park[1], Eojin Yoon[1], Neil Greenham[2] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]University of Cambridge, United Kingdom; [3]Korea Basic Science Institute, Korea (the Republic of)

Metal halide perovskites (MHPs) have been considered next-generation light-emitting materials due to their excellent emission property of narrowband emission. Still, even after various material types of perovskites including 3D, low-dimensional quasi-2D, and colloidal nanocrystal structures were studied, perovskite light-emitting diodes (PeLEDs) have not realized high luminance, high efficiency, and long lifetime simultaneously, because of the intrinsic limitations related to the trade-off properties between charge transport and confinement in each type of perovskite materials. Here, we report an ultra-bright, efficient, and stable PeLEDs made of core/shell perovskite nanocrystals with a size of ~10 nm obtained using a simple in situ reaction of benzylphosphonic acid (BPA) additive with 3D polycrystalline perovskite films without separate synthesis process. During the reaction, large 3D crystals are split into nanocrystals and the BPA surrounds the nanocrystals, achieving strong carrier confinement while maintaining good charge-transport properties of 3D perovskites. We demonstrate simultaneously efficient, bright, and stable PeLEDs that have maximum brightness of ~470,000 cd m^{-2}, maximum external quantum efficiency of 28.9% (maximum current efficiency of 151 cd A^{-1}), and half-lifetime of 520 h at 1,000 cd m^{-2} (estimated half-lifetime >30,000 h at 100 cd m^{-2}). These results suggest that PeLEDs are not only laboratory-level high-efficiency devices but also promising candidates for commercial self-emissive displays and lighting applications.

SESSION EL17.06: Poster Session II
Session Chairs: Lina Quan and Barry Rand
Wednesday Afternoon, April 12, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM EL17.06.01
Excited State Dynamics and Transport of Self-trapped Excitons in Lead-Free Double Perovskites Hui Fang[1,2], Yanfeng Yin[2], Yang Yang[3], Haiming Zhu[3] and Shengye Jin[2]; [1]University of Pennsylvania, United States; [2]Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China; [3]Zhejiang University, China

Understanding the excited state and transport dynamics of self-trapped excitons (STEs) in lead-free double perovskites (DPs) is essential for popularizing their optoelectronic applications. Herein, we apply a series of spectroscopies and microscopies techniques to systematically investigate the formation, transport, and relaxation dynamics of SETs in Bi-doped double perovskites (Bi-DPs). The PLQY, consistent with the STEs activation energy of Bi-DPs shows an increasing and then decreasing trend as a function of Bi^{3+} content, suggesting tiny Bi^{3+} can passive the defects and more Bi could generate more non-radiative decay channels. Moreover, we find the Bi-DPs exhibit dual white emission, originating from the intrinsic STEs (i-STE) and Bi^{3+} induced STEs (Bi-STEs), respectively. The STEs formation and relaxation timescale will be detailed discussed in as well. Finally, we will present the temperature-active transport behavior. The fundamental mechanism understanding of the doping engineering established in this work will provide helpful guidance about how to improve the performance of DPs optoelectronic devices.

5:00 PM EL17.06.02
Chiral CsPbBr$_3$ Perovskite Nanoplatelets Synthesized Using Phosphaste-based Anionic Ligands Thi Kim Tran Tran and Jing Zhao; University of Connecticut, United States

Perovskite nanocrystals functionalized with chiral molecular ligands exhibit unique optical activity, making them promising materials for optoelectronic applications. However, the ligand type has been limited to cationic chiral amines in majority of the studies. In order to expand the ligand selection, chiral anionic binaphthyl molecules with phosphate functional groups have been introduced to synthesize CsPbBr$_3$ nanocrystals. Tramission electron microscopy, X-ray diffraction, together with UV-vis spectroscopy revealed that the nanocrystals are plateletes, with a thickness of five unit cells. The nanoplates show distinct circular dichroism signal and maintain their chiral properties after purification using anti-solvent. They also exhibited linearly polarized emission in solution due to the anistropy in their geometry.

5:00 PM EL17.06.03
Amino Acid-Passivated Pure Red $CsPbI_3$ Quantum Dot LEDs Dezhang Chen and Jonathan E. Halpert; The Hong Kong University of Science and Technology, Hong Kong

$CsPbI_3$ quantum dots (QDs) are promising light-emitting materials for pure-red display applications. Several methods have been tried for perovskite to obtain the red-light emission in the range 620-650 nm, including mixed-halide perovskite $CsPbI_xBr_{3-x}$, quazi-2D perovskite, and quantum-confined $CsPbI_3$. Among those methods, quantum-confined $CsPbI_3$ is the most exciting material as it is not subject to ion migration effects or contains organic cations that lead to spectral instability. Unfortunately, small colloidal quantum dots contain excess resistive ligands, negatively affecting the efficiency and stability of the resulting light-emitting diodes (LEDs). Here we developed a facile ligand-exchange method using amino acids to reduce native long-chain ligands on $CsPbI_3$ quantum dots. As a molecule with amine and carboxylate groups, amino acids can mildly exchange the oleate ligands and oleylammonium ligands on the surface of quantum dots. We also assessed a variety of related amino acids on their side-chain effects on LED performance. We found that in cysteine-exchanged QDs, both thiol and amino acid groups passivated the surface of quantum dots and led to the best LED performance. The optimized LEDs achieved an external quantum efficiency (EQE) of 18.0% and a T_{50} of 87 minutes, comparable with many of the best-reported perovskite pure red LEDs.

5:00 PM EL17.06.04
Enhancement of Photoluminescence in Two-Dimensional Tin Perovskite by van der Waals Contact with Low Work Function Metal Jun-Ho Park, Youjin Reo, Ju-Hyun Jung, Yong-Young Noh and Cheoljoo Kim; POSTECH, Korea (the Republic of)

Halide perovskites have attracted great attentions for optoelectronic elements with excellent quantum efficiency. Recent studies have focused on lead-free, tin halide perovskites with low-toxicity, but the low oxidation barrier of tin induces substantial in-gap states, which are responsible for non-radiative recombination. Previous reports show that addition of reducing agents during the material syntheses can enhance their photoluminescence (PL) quantum efficiency, however it is still unclear if the PL intensities are simply enhanced by reducing the oxidation states or changes in the electrochemical potential of the material also play a key role. Here, we show that van der Waals (vdW) contacts of aluminum (Al) onto two-dimensional $(PEA)_2SnI_4$ (PEA = phenylethylammonium) films after the material synthesis can still enhance its PL intensity by 4 times, reaching a record high quantum yield of 10 % for $(PEA)_2SnI_4$. The PL intensities do not increase in the cases of vdW contacts of copper and gold. Ultraviolet photoelectron spectroscopy measurements show that the energy level of electronic bands for $(PEA)_2SnI_4$ are shifted by 0.6 eV with the Al contact, compared to that of the as-grown sample, indicating a significant n-type doping by Al. Our results suggest that electron doping can effectively suppress the PL quenching in tin-based perovskites, mediated by defect-states.

5:00 PM EL17.06.07
Organo-metallic Halide Perovskite Thin Film/Quantum Dot Heterostructures for Novel Applications Jorge Arteaga[1], William; Delmas[1], Melissa Guarino-Hotz[2], Jin Zhang[2] and Sayantani Ghosh[1]; [1]University of California, Merced, United States; [2]University of California, Santa Cruz, United States

Organo-metallic Halide Perovskite (OMHP) thin films have been of great interest in the field of photovoltaics due to the rate at which their power conversion efficiency (PCE) has increased while maintaining low production costs. Perovskite quantum dots (PQDs) have also garnered interest for similar applications. Despite this, both PQDs and OMHP thin films have their drawbacks. Thin films have chemical stability issues, particularly in the presence of moisture and oxygen, while PQDs have not demonstrated efficiencies as high as their thin film counterparts. Some of these issues could be addressed by combining the two to form heterostructures of PQDs layered atop OMHP thin films. We have investigated charge and energy transfer mechanisms between spin-coated methylammonium lead iodide (MAPI) thin films and PQDs, where we varied both the PQD composition and the ligand molecules used for functionalizing their surfaces. We have used organic-inorganic PQDs ($MAPbBr_3$) with insulating and conducting ligands, and inorganic PQDs ($CsPbBr_3$) with insulating ligands, for a systematic study. All the selected PQDs have band gaps larger than that of MAPI, allowing for multiple routes of energy and charge transfer, not just between the PQDs and the MAPI film but also between the quantum dots themselves. Using photoluminescence (PL) spectroscopy, we have found that the emission from both $MAPbBr_3$ and $CsPbBr_3$ dots was quenched, while the MAPI film emission intensity was increased. Further, the charge carrier recombination lifetimes of the MAPI films with PQDs were significantly longer, nearly twice as long, compared to bare films, indicating that the PQDs were passivating the surface trap states in the films. However, all these changes in the thin films' optical properties depended on the types of ligands on the PQD surfaces, the excitation energy used on the heterostructures, and even the density of PQDs on the film. In particular, we discovered that a high density of close-packed PQDs reduced both emission intensity and recombination lifetimes of the MAPI films. Our results demonstrate an approach to modulating thin film behavior that could have applications not only in the field of traditional optoelectronics but also in novel areas, such as environmental sensing and detection.

The authors acknowledge funding from NASA grant no. NNH18ZHA008CMIROG6R and NSF grant no. NSFDGE-2125510.

5:00 PM EL17.06.08
Enhancement of Optical Gain in $MAPbI_3$ Perovskite Thin Films via Surface Treatment with Organo-Ammonium Halide Additives Hoonil Yang[1,2], Chieun Choi[2] and Yoon-Kyu Song[2]; [1]Samsung Electronics, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Solution-processed organo-lead halide perovskite has emerged as a promising next-generation light-emitting devices owing to the low process cost, wavelength tunability from visible to near-infrared light, and narrow full width half maximum (FWHM) characteristics [1]. Unlike perovskite materials used in photovoltaic devices, the materials used in light-emitting devices often require small grain sizes to spatially confine excitons at nano scale, thus ensure high luminous efficiencies by inhibiting exciton dissociation and increasing the radiative recombination rate. However, it is difficult to achieve high emission intensity with small grain perovskites at a large thickness, because the large framework may aggravate defects such as pinholes and grain boundary gaps [2]. Also, a thin film with small grain perovskites may generate high density of non-radiative recombination centers at the surface defects via deformation and decomposition [3].
In this work, we propose to use 4-fluorobenzylammonium iodide (FPMAI), a bulky organo-ammonium halide additive, for surface treatment through recrystallization of methylammonium lead iodide ($MAPbI_3$) perovskite thin film, thereby decreasing the grain sizes and suppressing defects in the perovskite film at relatively large thickness. The FPMAI molecules are well attached to $MAPbI_3$ nanocrystals and has high surface coverage due to its short alkyl chain length and high binding energy to perovskite. Also, we realized it is an appropriate additive to form perovskite nanocrystals with reduced defect sites in a thin film with relatively large thickness. We have fabricated FPMAI-treated perovskite thin films and demonstrated an enhanced optical gain of the perovskite films by showing the amplified spontaneous emission (ASE) under picosecond pulse pumping. As a result, the ASE threshold are reduced

approximately $6\ \mu J/cm^2$, and the optical gain coefficient are increased from 316.3 cm^{-1} to 507.1 cm^{-1}. Furthermore, we have measured significant increases in photoluminescence (PL) intensity and PL lifetime, thus show that non-radiative recombination processes are suppressed in the perovskite films with FPMAI surface treatment. Our result shows that the optical gain is improved through the surface treatment method with organo-ammonium halide additives, and it can be applied to highly efficient light emitting devices in the future organic optoelectronic systems.

5:00 PM EL17.06.10
Enforcing Blue Light Emission of Mixed Halide Perovskite Light-Emitting Diodes Enabled by Multiple Inorganic Chloride Doping Jung Jae Do, Lakshmi P. Prabakar and Jae Woong Jung; Kyung Hee University, Korea (the Republic of)

Perovskite-based light emitting diodes (PeLEDs) are promising candidates for next-generation display technologies due to their potentials such as solution processing, excellent color purity, and color tunability. However, the blue-emitting PeLEDs lag far behind those of green or red-emitting perovskites in terms of optoelectronic properties and long-term operative stability, strongly restricting the commercialization of the display technology. In this study, we first introduced CsCl in a typical sky-blue PeLEDs ($PEA-CsFAPbBr_3$) to enlarge the optical band gap and to enforce pure blue color emitting properties. Yttrium chloride (YCl_3) is then added in the perovskite emitter as an additional inorganic chloride dopant to hamper severe phase segregation and ion migration in the perovskite emitters. As a result, the multiple inorganic chloride salts simultaneously enforce pure blue electroluminescence and phase stabilization, leading to improved quantum efficiency and long-term operative stability of the pure blue PeLEDs, achieving a stable electroluminescence device at 473 nm with a full-width half-maximum (FWHM) of 17 nm. The optimized blue-light PeLEDs exhibited a maximum external quantum efficiency (EQE) of 1.06% and excellent operational stability (LT50 > 250 min), which suggests the efficacy of the multiple inorganic chloride salts for improving optoelectronic properties of pure-blue perovskite LEDs.

5:00 PM EL17.06.11
Steric Effects in Br-Based Sky-Blue Perovskites for High Quantum Efficiency Jiweon Kim[1], Ilgeum Lee[1], Lina Quan[2], Edward H. Sargent[3], Seung Soon Jang[4] and Dong Ha Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Virginia Tech, United States; [3]University of Toronto, Canada; [4]Georgia Institute of Technology, United States

Recently, perovskite light-emitting diodes (PeLEDs) have promoted considerable research interest as a next-generation LED that can replace the existing OLED and QLED due to the attractive properties of metal halide perovskite (MLH) materials such as outstanding carrier mobility, bandgap tunablity, great chemical flexibility, and remarkable color purity. However, MLH has yet met the critical requirement for viable LED devices such as inferior moisture stability, stable blue emitter, and cost-effective large area fabrication. To remedy the disadvantage, quasi-2D perovskites, e.g. $(PEA)_2(MA)_{n-1}Pb_nBr_{3n+1}$ have been proposed that evidenced improved humid-stability and tunable optoelectronic properties. In this respect, here, we show a generalized strategy to develop Br-based blue quasi-2D perovskites with enhanced stability and spectral tunability. By controlling the ratio of cation spacers, we could establish a protocol to fine-tune the spectral range of the blue emissive perovskites which may open a pathway toward commercialized PeLEDs.

5:00 PM EL17.06.14
Manipulated Interface for Enhanced Energy Cascade in Quasi-2D Blue Perovskite Light-Emitting Diodes Yun Seop Shin and Jin Young Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Quasi-two-dimensional (2D) perovskites have recently emerged as emitters in blue perovskite light-emitting diodes (PeLEDs). The cascading energy-transfer process between different 2D phases plays an essential role in the high performance of this class of PeLEDs. Herein, we propose an interfacial engineering strategy by incorporating a zwitterionic additive, L-phenylalanine, into the hole-injection layer (HIL), enabling suppression of trap-assisted deactivation channels by virtue of the coordination interactions between the additive and Pb2+ defects in the perovskite phase. In addition, the introduction of L-phenylalanine reduces the release of metallic indium species from indium tin oxide substrates initiated by acidic HILs, resulting in the suppression of luminescence quenching in the perovskite layer. The synergetic benefits create an ideal energy landscape, blocking energy losses and boosting PeLED performance with a peak external quantum efficiency of 10.98% at 480 nm and extended device lifetimes. Our approach provides a versatile strategy to achieve high-performance blue PeLEDs.

5:00 PM EL17.06.15
Strong Photoluminescence of GaP Through ZnS/GaP Reverse Type I Quantum Dot Hongjoo Shin; KAIST, Korea (the Republic of)

GaP has an innate crystal structure of zin blende and an indirect bandgap. Although its light conversion efficiency is not high due to intrinsic limitations resulting from the energy band structure, it is a material used for solid-state light-emitting diodes (LEDs) due to economic advantages. For these reasons, several computational studies have been conducted to search conditions under which GaP can have a direct bandgap. Simulation results expected a direct bandgap of GaP can be obtained when it has i) a wurtzite structure or ii) a zinc blende structure with a radius of 1 nm or less. Direct bandgap wurtzite GaP was proven through artificially grown GaP nanowire on a (111) oriented zinc blende GaP substrate in 2013. However, unlike the typical direct bandgap material, it forms a pseudo-direct bandgap between the dark conduction band and the heavy hole band, limiting its optical properties. In addition, there has been no experimental study that confirmed direct bandgap formation of zinc blende GaP via quantum confinement because synthesis if
Here, we experimentally demonstrated the direct bandgap of zinc blende GaP based on the high photoluminescence (PL) intensity and quantum yield. This was realized through the reverse type I quantum dot, which has an opposite order of band gap size between the core and the shell of general QD. In ZnS/GaP reverse type I quantum dots, electrons and holes are confined to the GaP shell rather than the ZnS core, and PL is exhibited by the GaP shell. In addition, ZnS has the advantage of stable stacking of GaP shell because of the similar lattice parameter (ZnS: 5.40A, GaP: 5.45A). We confirmed that ZnS/GaP actually has a zinc blende structure via XRD analysis, and the radius difference of 0.48 nm between ZnS and ZnS/GaP was confirmed through STEM image. These results suggest that GaP is stacked on the ZnS core surface with a one-unit cell thickness (monolayer), achieving a direct bandgap. As a result, it showed strong PL intensity even after two times purification processes and was able to achieve a high absolute PL quantum yield of 29.6%. In addition, it was confirmed that PL quantum yield hardly decreased even after 55 days of stability test. This study demonstrates a new pathway to switch many indirect-gap semiconductors to light-emitting materials with a high efficiency and good stability.

Controlling $MAPbI_3$ Crystallization from Gamma-butyrolactone for Slot Die Coated Thin Films Using Air Knife Maimur Hossain, Jesse Starger,

Jesse Efymow, Ryan Barrett, Jacob Bolduc, Nicolas Alvarez, Richard Cairncross, Aaron Fafarman and Jason Baxter; Drexel University, United States

Solvents play a crucial role in developing high quality hybrid organic–inorganic perovskite films using roll-to-roll slot die coating methods which is an efficient process for the fabrication of large area optoelectronic devices. γ-butyrolactone (GBL) is a well explored solvent for direct growth of lead halide-based perovskite single crystals. GBL coordinates weakly with Pb^{2+} center in precursor solution compared to other solvents (N, N-dimethylformamide, dimethyl sulfoxide, etc.) due to its lower Gutmann's donor number, D_N. Thus, GBL favors the formation of Pb-I-Pb bonds necessary for the octahedral framework and subsequent rapid single crystal growth. Methylammonium lead iodide ($MAPbI_3$) in GBL follows retrograde solubility, wherein there exists a threshold temperature (~60 °C) beyond which solubility decreases as temperature increases. This behavior provides a mechanism to drive supersaturation (and subsequently nucleation and bulk crystal growth) by increasing temperature, without the need for evaporation. However, the strong tendency towards single crystal growth at elevated temperatures poses a challenge for the deposition of pin-hole free perovskite thin films from GBL-based inks because elevation of processing temperature can push the precursor solution towards supersaturation rapidly. To achieve interconnected, compact and uniform morphology, the drying rate must be carefully tuned to control the nucleation and growth rates.
In this work, we describe a facile slot die coating method using a hot air knife and preheated substrate to control the perovskite crystallization and produce better quality thin films from GBL. To mitigate the dominating impact of retrograde solubility and have better control of morphology, a low concentration $MAPbI_3$ precursor solution was utilized to delay supersaturation. The crystallization of $MAPbI_3$ in GBL as function of processing temperature and drying rate was studied by microscopy. The phase and morphology of resulting films were characterized using XRD, SEM and AFM. $MAPbI_3$ crystallization at low temperatures was found to be thermodynamically controlled, which favors solvent-perovskite adduct formation. The perovskite films deposited at temperatures below 60 °C and without any air knife had poor morphology dominated by sparse, 10-100s μm sized needle-shaped crystals with large voids between them. This crystal phase can be attributed to solvent-perovskite adducts like $(MA)_2(GBL)_2Pb_3I_8$ that do not easily decompose into the perovskite crystalline structure. Slow evaporation of a thick layer of GBL perovskite solution can trigger this kind of GBL-perovskite adduct formation. High temperature processing mitigated the adduct formation, but crystal growth kinetics of the perovskite phase produced relatively poor film coverage. In contrast, the combination of hot air knife and heated substrate produced a smooth film with better coverage due to faster drying rate and better control over crystallization kinetics. In this work, we thoroughly studied crystallization of $MAPbI_3$ during large area coating and its correlation with solvent and different drying conditions. This provides insight about the processing condition which is crucial to control morphology during fabrication of large area optoelectronic devices.

5:00 PM EL17.06.17
Detection of Circularly Polarized Light Based on Perovskites with High Chirality Hyunjeong Lee, Minju Kim, Jiweon Kim and Dong Ha Kim; Ewha Womans University, Korea (the Republic of)

Recently, chiral nanomaterials have attracted significant attention for potential applications in diverse fields such as ferroelectrics, chiro-spintronics and chiroptoelectronics. Among them, hybrid organic-inorganic chiral perovskites are considered critical candidates as alternative active layers owing to their superior optoelectronic properties such as circulary polarized light (CPL) detection and effective light absorption.[2] In addition, in the ABX_3 structure of perovskite, it is possible to easily introduce chiral properties by adjusting the A site cations. Until now, chiral perovskites using (R, S)-α-methylbenzylamine, (R, S)-phenylethylamine, (R, S)-1-(1-naphthyl)ethylamine etc. have been studied as chiral organic cations.[1, 2] However, the development of perovskite-based CPL photodetectors with appreciable function is still limited. So, it is necessary to increase the performance of the CPL photodetector by developing chiral perovskites with a high g-factor.
In this work, we suggest a new class of chiral perovskites by integrating aromatic organic cations. Record-high level g-factor value is obtained compared with the existing materials reported so far. We confirmed the outstanding optical properties of 1D and 2D chiral perovskites, respectively, through dimensional control of chiral perovskites. Further, the excellent crystallinity of chiral perovskite using new chiral organic cations increases the charge transfer, resulting in enhanced efficiency of the CPL photodetector. These new chiral perovskites are expected to open the pathway for multifunctional chiroptic applications.

SESSION EL17.07: Photophysics of Colloidal Quantum Dots and Perovskites

Nonequilibrium Lattice Dynamics in Photoexcited 0D and 2D Perovskites Richard D. Schaller[1,2]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States

Limited understanding exists as to the response of highly ionic metal halide lattices upon photoexcitation. Structural deformations such as polaron formation influence local energetics and photophysical properties, which can heavily influence utility of these materials in optoelectronics. This talk will discuss structural response of 0D and 2D lead halide perovskites from direct investigations using ultrafast transient X-ray diffraction as a function of optical excitation fluence. 0D structures show slow initial evolution of structure that recovers with a timescale that depends dramatically on cation identity. For 2D structures both powder X-ray diffraction and time-resolved photoluminescence linewidths narrow over 1 ns following optical excitation for the fluence range studied, concurrent with slight redshifting of the optical bandgaps. Observations are attributed to transient relaxation as well as ordering of distorted lead iodide octahedra stimulated chiefly by electron–hole pair creation. In the case of (BA)2PbI4, appearance of the (110) reflection in following excitation would suggest a transient crystal phase transition. However, through high energy single crystal XRD we find reflections that violate glide plane conditions in the reported Pbca structure, conveying that the literature assignment of the space group is incorrect and is instead P212121. In cases of both 0D and 2D perovskites, lattice relaxation times exceed electronic carrier lifetimes which can be understood in terms of their poor thermal dissipation, but also suggests shallow potentials wells.

9:00 AM *EL17.07.02
Coherent Exciton Transport in Perovskite Quantum Dot Superlattices Libai Huang; Purdue University, United States

The performance of quantum dot (QD) devices in optoelectronic and quantum information applications relies on not only the properties of the individual QDs but also the collective properties arising from interactions between QDs within a solid. The interactions between QDs determine whether long-range coherence and transport can be achieved. Due to their large oscillator strengths, perovskite QD superlattices (SLs) have the potential for exciton superradiance. However, the ultrafast dephasing processes can limit their coherence lengths. We provide a detailed study on the key factors that control exciton delocalization and transport in perovskite QD SLs. Through temperature-dependent and time-resolved ultrafast microscopy measurements, we demonstrate coherent exciton propagation in highly ordered SLs. We unravel the effect of disorder by comparing SLs with varying degrees of inhomogeneity. Our results point to the exciting opportunities in engineering exciton coherence in perovskite solids.

Hong-Ou-Mandel Interference in Colloidal $CsPbBr_3$ Perovskite Nanocrystals Alex E. Kaplan[1], Chantalle Krajewska[1], Andrew H. Proppe[2,1], Weiwei Sun[1], Tara Sverko[1], David B. Berkinsky[1], Hendrik Utzat[3,1] and Moungi G. Bawendi[1]; [1]MIT, United States; [2]University of Ottawa, Canada; [3]University of California, Berkeley, United States

The continued innovation of on-demand sources of non-classical light is critical to fully realizing the technological potential of quantum photonics. In particular, single, indistinguishable photons from quantum emitters are the fundamental building blocks of many quantum optical applications, such as quantum networks, linear optical quantum computing, and quantum teleportation, Hong-Ou-Mandel (HOM) interference is the cornerstone photon-photon interaction that governs these quantum light technologies. In perfect HOM interference, two indistinguishable photons incident on a beam splitter leave coalesced, due to the overlap of their identical wavefunctions. Pure-dephasing processes, interactions which collapse and obfuscate the phase information of the photon-generating exciton wavefunction in a quantum emitter, impact the indistinguishability of sequentially emitted single photons. As such, HOM interference serves not only as an integral tool to quantum computing, but also an important heuristic for the pure-dephasing rate in a quantum emitter.
In our work, we show sizeable HOM interference in colloidal cesium lead bromide perovskite nanocrystals (PNCs), a first for colloidal, solution-processed material. Unlike other quantum emitters that require Purcell enhancements and device architectures to increase the radiative rate and suppress dephasing, these PNCs have yet to undergo the optimizations seen for other emitters. By comparing correlation functions for indistinguishable and distinguishable photons, the visibility of HOM interference can be calculated. We demonstrate that PNCs exhibit HOM visibilities which are factors higher than expected from indirect measurements. Our work showcases the potential of PNCs to become the first colloidal transform-limited quantum light source.

Exciton–Phonon Interactions in Lead Halide Perovskite Nanocrystals Revealed by Single-Dot Photoluminescence Spectroscopy Takumi Yamada[1], Kenichi Cho[1], Hirokazu Tahara[1,1], Terumasa Tadano[2], Hidekatsu Suzuura[3], Ryota Sato[1], Masaki Saruyama[1], Toshiharu Teranishi[1] and Yoshihiko Kanemitsu[1]; [1]Kyoto University, Japan; [2]National Institute for Materials Science, Japan; [3]Hokkaido University, Japan

Lead halide perovskite semiconductors are recently attracting much attention as a new class of optoelectronic device materials, because of their outstanding optical and electronic properties at room temperature. It is considered that strong electron–phonon interactions play a key role in unique optical and transport responses of halide perovskites [1]. They determine the effective carrier mass, the carrier mobility, the photoluminescence (PL) linewidth, the Urbach tail of optical absorption, and so on. The efficient anti-Stokes PL and the slow hot-carrier cooling are also closely related to strong electron–phonon interactions [2–5]. Since individual nanocrystals (NCs) show extremely high PL quantum yields and narrow PL linewidths, longitudinal-optical (LO) phonon replicas reflecting electron–phonon interactions can be observed in the PL spectra at cryogenic temperatures. Therefore, single dot spectroscopy is a powerful tool to investigate the exciton–phonon interactions of perovskite NCs.
Here, we prepared $CsPbBr_3$, $FAPbBr_3$, and $MAPbBr_3$ perovskite NC samples and measured their PL spectra of single NCs [6–8]. At low temperatures, $CsPbBr_3$ NCs show very sharp PL lines including fine-structure splitting in the PL peaks of excitons, biexcitons, and the LO-phonon replicas of excitons. We discuss the exciton–phonon and trion–phonon interactions in perovskites from the PL fine structures in $CsPbBr_3$ NCs. We found that the LO-phonon energies are independent of the NC size. However, the Huang–Rhys (HR) factors of excitons, i.e., the strength of the exciton–phonon coupling, depend on the LO-phonon energy. Both HR factors for excitons and trions increase as the NC size decreases. The HR factors of trions are larger than those of excitons in larger NCs. We conclude that the size-dependent HR factors for excitons and trions are closely related to the spatial distributions of the electron and hole wavefunctions in the NC.

Sensational Sensitization—Triplet Generation at the Perovskite/Organic Interface Colette M. Sullivan and Lea Nienhaus; Florida State University, United States

Photon upconversion describes a process which effectively shortens the wavelength light emitted upon irradiation, yielding photons with a higher energy than the incident photons. To ensure compliance with energy conservation laws, this process occurs by combining the energy of two low energy photons. In the triplet-triplet annihilation upconversion process of interest here, the photon energy is combined by forming a high energy singlet state from two lower energy triplet states. However, since direct optical excitation of triplet states is 'spin-forbidden', sensitizers are used to indirectly populate the triplet state.

Successful triplet sensitizers span a broad range of material classes including metal-organic complexes, inorganic nanomaterials such as quantum dots or nanoplatelets, and bulk perovskite thin films. Understanding the fundamental energy transfer mechanism across the hybrid organic/inorganic interface is crucial for the advancement of optoelectronic devices based on this process. The exact energy transfer mechanism at the interface of inorganic and organic materials remains obscure, particularly where there is a large amount of structural inhomogeneity or high defect density within the material.

To date, rubrene has been the most investigated annihilator. However, it is not the ideal annihilator for use with lead halide perovskites. Here, I discuss the recent developments of perovskite-sensitized upconversion, including new annihilators such as 1-chloro-9,10-bis(phenylethynyl)anthracene (1-CBPEA), which enables solid-state near-infrared-to-green upconversion.

Interlayer Triplet Sensitized Luminescence in 2D Hybrid Perovskites-- Photophysics and Applications YunHui L. Lin and Justin Johnson; National

Renewable Energy Laboratory, United States

Recently, hybrid perovskites have gained attention as sensitizers for molecular triplet generation. Layered, two-dimensional (2D) perovskites are especially well-suited for this purpose because the triplet donor (inorganic framework) and triplet acceptor (organic layer) are self-assembled into adjacent sheets, so that with the appropriate energetics, triplets can be driven across the interface. By leveraging interlayer energy transfer, this emerging class of 2D perovskites has potential to impact several energy-related fields and processes, including solar photochemistry, photonics, and optoelectronics. In this talk I will discuss how several 2D perovskite design parameters affect photophysical outcomes. In particular, we will (1) examine how exciton energy offsets and frontier orbital alignments between the metal-halide and molecular layers affect the dynamics of ultrafast energy transfer and (2) discuss how organic layer morphology and composition can be engineered to generate multi-colored triplet-based molecular emission. Ultimately, 2D hybrid perovskites, with their vast compositional and structural tunability, offer an exciting platform for manipulating energy flow for light-emitting applications.

Many-Body Correlations and Bound Exciton Complexes in $CsPbX_3$ (X=Br, Br/Cl) Quantum Dots Chenglian Zhu[1,2], Tan Nguyen[3,3], Simon C. Böhme[1,2], Anastasiia Moskalenko[1,2], Dmitry Dirin[1,2], Maryna Bodnarchuk[2], Claudine Katan[3], Jacky Even[3], Gabriele Raino[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Univ Rennes, France

All-inorganic lead-halide perovskite ($CsPbX_3$, X = Cl, Br, I) quantum dots (QDs) have emerged as a competitive platform for classical light emitting devices (in the weak light-matter interaction regime, *e.g.,* LEDs and laser)[1], as well as for devices exploiting strong light-matter interaction and operated at room-temperature.[2] Many-body interactions and quantum correlations among photogenerated exciton complexes play an essential role, e.g., by determining the laser threshold, the overall brightness of LEDs, and the single-photon purity[3, 4] in quantum light sources. To date, a thorough account of many-body interactions in these newly developed soft perovskite QD compounds is still missing. Here, by combining single-QD optical spectroscopy performed at cryogenic temperatures in combination with configuration interaction (CI) calculations, we address the trion and biexciton binding energies and unveil their peculiar size dependence. We find that trion binding energies increase from 7 meV to 17 meV for QD sizes decreasing from 30 nm to 9 nm, while the biexciton binding energies increase from 15 meV to 30 meV, respectively. CI calculations quantitatively corroborate the experimental results and suggest that the effective dielectric constant for biexcitons slightly deviates (5%) from the one of the single excitons, as a result of lattice distortions in the multiexciton regime. Our findings provide a deep insight into the multiexciton properties in all-inorganic lead-halide perovskite ($CsPbX_3$) QDs, essential for classical and quantum optoelectronic devices.

Extending the Defect Tolerance of Halide Perovskite Nanocrystals to Hot Carrier Cooling Dynamics Junzhi Ye[1,2], Navendu Mondal[3], Ben Carwithen[3], Yunwei Zhang[4], Linjie Dai[1], Xiangbin Fan[1], Pratyush Ghosh[1], Clara Otero Martinez[5], Zhongzheng Yu[1], Ziming Chen[3], Neil Greenham[1], Samuel D. Stranks[1], Lakshminarayana Polavarapu[5], Akshay Rao[1], Artem Bakulin[3] and Robert Hoye[2]; [1]University of Cambridge, United Kingdom; [2]University of Oxford, United Kingdom; [3]Imperial College London, United Kingdom; [4]Sun Yat-sen University, China; [5]University of Vigos, Spain

One of the key enabling properties of low-bandgap lead-halide perovskite nanocrystals ($CsPbX_3$ NCs) for optoelectronic applications is their tolerance to point defects. Thus far, the discussion around defect tolerance has mostly focussed on recombination of charge-carriers from the band-edge. But understanding influence of these defects on hot carrier (HC) cooling will also be critical for achieving more efficient NC-based devices, but has not been thoroughly explored thus far. Here, we address this knowledge gap by elucidating the influence of intentionally-introduced traps (primarily halide vacancies) on HC relaxation above the band-edge in $CsPbX_3$ NCs with different halide compositions ($CsPbBr_3$, $CsPbBr_xI_{3-x}$, and $CsPbI_3$). The HC cooling kinetics in these different NC systems are probed by energy-dependent photoluminescence quantum yield measurements, along with pump-probe (two-pulse) and pump-push-probe (three-pulse) transient absorption measurements. We show that the presence of defect states increases the chances of HC trapping, which speeds up the cooling process. However, the change in HC cooling lifetime due to the trap densities becomes smaller as the composition moves from Br-based NCs to I-based NCs. Based on density function theory (DFT) calculation and hot carrier kinetic modelling, the cooling speed is governed by both defect densities and defect position relative to the conduction band edge. Shallower defects would allow faster trapping and de-trapping process for the carriers, which it helps to maintain the free carrier densities and allow free carriers to cool slowly with the effect of Auger reheating. This work firstly demonstrated experimental observations of the defect-tolerance nature of perovskite NCs to hot carriers, which provides insights into designing high-efficiency photovoltaic devices by managing defect densities for different bandgap perovskites.

SESSION EL17.08: Structure-Property Relationship
Session Chairs: Xiwen Gong and Farnaz Niroui
Thursday Afternoon, April 13, 2023
Moscone West, Level 3, Room 3006

1:45 PM EL17.08.05
Structure-Property Relationships for 2D Halide Perovskites with Large Cage Cations Xiaotong Li[1], Yongping Fu[1], Laurent Pedesseau[2], Shelby Cuthriell[1], Constantinos Stoumpos[3], Jacky Even[2], Claudine Katan[2], Peijun Guo[4], Richard D. Schaller[1] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]CNRS, France; [3]University of Crete, Greece; [4]Yale University, United States

In 2D perovskites, the choice of the A-site perovskitizer cations is not entirely limited by the so-called Goldschmidt tolerance factor. The stabilizing effect of the spacer cations makes it possible to tolerate larger A-site cations as perovskitizers. By solving the single-crystal structures of $(BA)_2(A)Pb_2I_7$ where BA = butylammonium, and A = methylammonium (MA), formamidinium (FA), dimethylammonium (DMA) or guanidinium (GA), we have proven that the relatively large DMA and GA can serve as the A-site cation of 2D perovskites despite the fact that they are too large to formally satisfy the Goldschmidt rule. As the size of the A-site cations increases, the Pb−I bonds are elongated, which reduces the orbital overlap of Pb s- and I p-orbitals, thus decreasing the electronic bandwidths and increasing the bandgaps, as confirmed by DFT calculations. This increases the local distortions of the PbI_6

coordination environment and leads to a decrease of PL intensity and shortening of PL lifetime. The expanded cages also result in soft and anharmonic lattices, as supported by Raman spectra. Exciton-exciton annihilation processes occur in these systems with the rates being slower in the structures with larger A cations. Similar trends are also observed in lead bromide perovskites as well as tin and germanium iodide systems. Understanding the structure-property relationships of these compounds will help illustrate how the large A-site cations may influence physical properties of both 2D and 3D perovskites and facilitate their future optoelectronic applications.

2:00 PM EL17.08.03
Heterostructure Formation Origin and Size-Dependent on Phase Segregation in Mixed Halide Perovskite Nanoparticles Donghoon Shin, Minliang Lai and Chad Mirkin; Northwestern University, United States

Mixed halide perovskites consisting of multiple ions at the same lattice site (ABX_3) are an emerging class of semiconductors, with potential as high-performance optoelectronic materials. The promise of this class of materials derives from the fact that incorporation of multiple ions is a facile means to tune material properties such as band structure, emission and absorption efficiency, exciton binding energy, and carrier lifetime. Indeed, it has been well established that mixed-cation and mixed-halide composition perovskites lead to enhanced device performance and stability. However, simply using multiple ions during synthesis does not always lead to structures with desirable properties, due to the various degrees of ionic mixing and types of nanoscale arrangements possible in the complex perovskite. In addition, the source of mixing or segregation should be experimentally studied on the scale of an individual particle, enabling ones to deconvolve the effects of ion size, grain boundary, and ion migration on the final crystal morphology. Herein, an emerging method termed evaporation-crystallization polymer pen lithography (EC-PPL) is used to synthesize and systematically study the degree of ionic mixing of $Cs_{0.5}FA_{0.5}PbX_3$ (FA = formamidinium; X = halide anion, ABX_3) crystals, as a function of size, temperature, and composition. These experiments have led to the discovery of a heterostructure morphology where the A-site cations, Cs and FA, are segregated into the core and edge layers, respectively. Simulation and experimental results indicate that the heterostructures form as a consequence of a combination of both differences in solubility of the two ions in solution and the enthalpic preference for Cs-FA ion segregation. This preference for segregation can be overcome to form a solid-solution by decreasing crystal size (< 60 nm) or increasing temperature. Finally, we utilized these tools to identify and synthesize solid-solution nanocrystals of $Cs_{0.5}FA_{0.5}Pb(Br/I)_3$ that significantly suppress photo-induced anion migration compared to their bulk counterparts, offering a route to deliberately designed photostable optoelectronic materials.

Deterministic On-Site Growth of Halide Perovskite Nanocrystals for On-Chip Optoelectronics Farnaz Niroui; Massachusetts Institute of Technology, United States

Despite notable developments in halide perovskite thin-film devices, their integration into on-chip nano-optoelectronics has been limited by a lack of control over nanoscale patterning. Prone to degradation, these materials are often not compatible with the conventional top-down fabrication processes. Bottom-up assembly, on the other hand, can avoid such damage yet current strategies often lack the versatility to accomodate deterministic spatial control at the individual nanocrystal level for integration with other functional device components. Here, we introduce two techniques to enable on-site synthesis of nanocrystals down to a quantum dot-level in a scalable manner and compatible with device integration. In one, halide perovskite nanocrystals with sub-10 nm spatial accuracy and tunable sizes down to 20 nm are synthetized on-site guided using topographical templates with chemical texturing that localize growth precursors to the nanoscale. Using this platform, we have demonstrated arrays of on-chip nanoscale light emitting diodes (nano-LEDs) utilizing single nanocrystals with applications in optical communications, lasers, augmented and virtual reality displays, and quantum technologies. We will then discuss an approach that we have developed using a scanning probe technique for on-site fabrication of deterministically positioned halide perovskites quantum dots on-chip. We have used this technique to demonstrate deterministic arrays of perovskite single-photon sources with performance that can be engineered by direct integration with photonic cavities, enabling applications in quantum technologies.

3:45 PM EL17.08.06
Halogen Loss Pathways Rationalize Light-Induced Halide Segregation and Photoluminescence Quenching at Perovskite/Organic Hole Transport Layer Interfaces Zhaojian Xu[1], Daniel Astridge[2], Ross Kerner[3], Xinjue Zhong[1], Junnan Hu[1], Jisu Hong[1], Kai Zhu[3], Joseph J. Berry[3,4,5], Antoine Kahn[1], Alan Sellinger[2] and Barry P. Rand[1,6]; [1]Princeton University, United States; [2]Colorado School of Mines, United States; [3]National Renewable Energy Laboratory, United States; [4]Renewable and Sustainable Energy Institute, University of Colorado Boulder, United States; [5]University of Colorado Boulder, United States; [6]Andlinger Center for Energy and the Environment, Princeton University, United States

Metal halide perovskites have been widely implemented in various optoelectronic devices, but their poor stability under light illumination remains a big challenge. While the intrinsic photostability of isolated perovskite samples has been widely discussed, it is important to explore how charge transport layers, which are necessary for a functional device, impact photostability. In this study, we investigate the effect of organic hole transport layers (HTLs) on the spectral stability, reflecting light-induced halide segregation, and temporal stability, reflecting light-induced PL quenching, of the perovskite photoluminescence (PL) spectrum. By employing a series of HTLs with different highest occupied molecular orbital (HOMO) levels, we observe and rationalize a nonmonotonic relation between the rate of light-induced halide segregation for mixed-halide perovskite and HOMO energy of HTLs. Then, combining PL and cross-sectional scanning transmission electron microscopy–energy dispersive X-ray spectroscopy (STEM–EDX), we assert a connection between halogen diffusion into HTLs and enhanced non-radiative recombination at perovskite/organic HTL interfaces. Finally, we conclude that both instabilities in PL spectrum are related to and affected by halogen loss from the perovskite layer into the HTL, with the HTL HOMO energy ultimately determining the PL behavior at perovskite/organic HTL interfaces under light illumination. These findings highlight the detrimental effect of halogen oxidation and diffusion within perovskite devices on stability, and also provides guidelines for the design of HTLs with suitable HOMO levels to mitigate halogen diffusion.

4:00 PM EL17.08.07
Machine Learning Assisted Synthesis of Low-Dimensional Hybrid Lead Halide White Phosphors for Solid-State Lighting Hailong Yuan[1], Luyuan Qi[2], Michael Paris[1], Florian Massuyeau[1] and Romain Gautier[1]; [1]CNRS-IMN, France; [2]Certara, France

In the past few years, phosphor converted white LEDs have been widely adopted for lighting owing to their remarkable energy efficiency. However, the low color rendering of such white illumination is the main limitation of the commercialized LEDs and, for this reason, white LEDs have limited use in different areas such as medicine. A bright white emission replicating the solar spectrum (i.e., with ultra-high color rendering and tunable color temperature) is necessary to reach such high quality lighting but discovering a single-phase white phosphor with such characteristics remains challenging as it requires to navigate in complex multidimensional spaces (composition of the host matrix/ dopants, experimental conditions…). Thus, such high quality single phase white phosphor has never been discovered.
To navigate in a complex multidimensional space with the aim of designing sun like white phosphors, we decided to substitute the human decision

component of the materials discovery process by machine learning (ML) models. [1] The Mn doped solid-solution $(TDMP)Pb(Br_xCl_{1-x})_4$:yMn ($0 \leq x \leq 1$) (TDMP = trans-2,5-dimethylpiperazine) was investigated. With the guidance of such ML tools, a series of single-phase sun-like white phosphors with ultra-high color rendering indexes (above 92) and tunable correlated color temperature (from 3000K to 7000 K) were precisely designed. This is the first report of such ultra-high color rendering and broad range of tunable color temperatures for a phosphor.

Spacer Cation Control of Auger Recombination in Ruddlesden-Popper Perovskite Light-Emitting Diodes Tomoki Furuhashi, Anil Kanwat, Sankaran Ramesh, Nripan Mathews and Tze Chien Sum; Nanyang Technological University, Singapore

Quasi-2D perovskites are important materials for perovskite light-emitting diodes (PeLEDs) as the multi-quantum well (MQW) structure of the quasi-2D perovskites enhances performance of PeLEDs by efficient carrier funnelling. However, PeLEDs suffer from efficiency roll-off which is the large efficiency drop under high current density. One of the factors which causes efficiency roll-off is Auger recombination. Auger recombination is affected by the excitonic binding energy, exciton-phonon coupling, and the density of trap states. Different organic spacer cations could change these parameters by causing different distortion of the octahedral structure. Thus, studying the effect of different spacer cations on the Auger recombination behaviour in 2D perovskite is crucial to design PeLEDs with reduced roll-off. In this talk, I will discuss the use of ultrafast spectroscopy to investigate the effect of spacer in 2D perovskite on Auger recombination. Using photoluminescence and transient absorption spectroscopy, the modulation of the Auger process by the spacer will be elucidated. We will also discuss the effect of crystal structure change induced by different spacer cations on Auger recombination process, which provide insights into optimising the performance of PeLEDs based on 2D perovskites.

SESSION EL17.09: Novel Optical Property of Light Emitting Materials
Session Chairs: Himchan Cho and Tae-Hee Han

8:30 AM *EL17.09.01
Metal Organochalcogenolates—An Emerging Family of Low-Dimensional Light Emitters William Tisdale; Massachusetts Institute of Technology, United States

Metal organochalcogenolates (MOCs) are an emerging class of low-dimensional hybrid organic-inorganic semiconductors. Silver phenylselenolate (AgSePh), a prototypical 2D MOC, is a natural quantum well structure exhibiting narrow blue emission, large exciton binding energy, and in-plane anisotropy. Like transition metal dichalcogenides and 2D lead halide perovskites, MOCs can be synthesized in the form of three-dimensional crystals consisting of 2D layers held together by van der Waals forces. However, MOCs are distinguished from perovskites and other vdW crystals by the presence of organic ligands covalently bound to each 2D inorganic layer, which imparts chemical robustness and a unique handle for tuning the electronic properties.

In this talk, I will discuss efforts from my lab to synthesize new AgSePh derivatives with varying dimensionality, and characterize the excitonic nature of light emission and electron-phonon interactions in this new hybrid organic-inorganic materials family.

9:00 AM *EL17.09.02
Organic Semiconductor-Incorporated Perovskite (OSiP) Light-Emitting Materials and Devices Letian Dou; Purdue University, United States

Organic-inorganic hybrid halide perovskites are exciting new semiconductors that show great promising in low cost and high-performance optoelectronics devices including solar cells, LEDs, photodetectors, *etc*. However, the poor stability is limiting their practical use. In this talk, I will present a molecular approach to the synthesis of a new family of organic-inorganic hybrid material - Organic Semiconductor-incorporated Perovskite (OSiP). Energy transfer and charge transfer between adjacent organic and inorganic layers are extremely fast and efficient, owing to the atomically-flat interface and ultra-small interlayer distance. In addition, I will show that the energy alignment between organic and inorganic components and the assocaited optical properties can be modulated via “chemical tuning” or “pressure-gating”, opening up many new opportunities for next-generation light-emitting applications. Using these novel hybrid materials, I will demonstrate the fabrication of high quality polycrystalline thin films and highly stable and efficient LED devices with suppressed ion migration and improved external quantum efficiency, color purity, and operational lifetime.

9:30 AM EL17.09.03
Synthesis and Properties of Novel PL-Active 2D Lead-Free Double Perovskites Based on Alloys of $(PA)_4AgBiBr_8$ Andrew B. Wong; National University of Singapore, Singapore

In this work, novel two-dimensional lead-free double perovskites ($(R)_4M_aM_bM_cX_8$, a+b+c=2) were synthesized to achieve novel compositional and dimensional tunability. Herein, $(PA)_4AgBiBr_8$ was alloyed with combinations of Na/In as well as Ag/In with the goal of forming PL active materials. Moreover, the samples were tuned to be PL-emissive under room temperature via a manganese alloying strategy. Bandgap and PL emission turnability were explored through halogen substitution (chlorine and iodine). An enhanced PL emission was observed for mixed halogen phases. Three emission pathways are investigated including band edge emission, emission stemmed from self-trapped excitons, and the unique energy transfer process of alloyed Mn^{2+} ions, which will be discussed.

9:45 AM BREAK

10:15 AM *EL17.09.04
Low Dimensional Metal Halide Perovskites and Hybrids for Light Emitting Diodes Biwu Ma; Florida State University, United States

Metal halide perovskites and perovskite-related organic metal halide hybrids have recently emerged as new generation light emitting materials with exceptional structure and property tunability. By controlling the morphological dimensionality of metal halide perovskites with ABX_3 structure, low dimensional perovskite nanocrystals, e.g. 2D nanoplatelets, 1D nanowires, and 0D quantum dots, have been developed to exhibit enhanced optical properties and stability as compared to 3D counterparts. Besides 3D ABX_3 perovskites, organic metal halide hybrids with low dimensional structures at the molecular level can be prepared by using appropriate organics and metal halides, in which metal halide building blocks form 2D, 1D, and 0D structures that are completely isolated and surrounded by organic cations. These organic metal halide hybrids exhibit unique properties that are different from those of 3D ABX_3 perovskites. For instance, tunable broadband emissions with near-unity photoluminescence quantum efficiencies have been achieved in a series of 0D organic metal halide hybrids. In this talk, I will present our recent efforts on the development and study of highly luminescent and stable low dimensional metal halide perovskites and organic metal halide hybrids. Their applications in electrically driven light emitting diodes (LEDs) will be discussed.

10:45 AM EL17.09.05
The Origin of Chiroptical Activity in Chiral Perovskite Sunihl Ma[1], Ji-Young Kim[1], Chan Uk Lee[2], Jooho Moon[2] and Nicholas A. Kotov[1]; [1]University of Michigan–Ann Arbor, United States; [2]Yonsei University, Korea (the Republic of)

Chiral perovskites have been extensively studied as a promising candidate for spintronic- and polarization-based optoelectronic devices due to their unusual spin-related properties such as strong spin-orbit coupling, long spin-life time exceeding 1ns and large Rashba splitting. However, the origin of chiroptical activity in chiral perovskites is still unknown, as the chirality transfer mechanism has been rarely studied. Since the chiral perovskite with the Sohncke chiral space group of $P2_12_12_1$ was reported in 2003, their chiroptical phenomena have been interpreted based on their crystallinity. Although (i) crystallization into a chiral crystal structure induced by chiral organic molecules, (ii) chiral distortion on the surface of chiral perovskite nanoparticles, and (iii) chiral dislocations can provide the explanation of their optical and electronic properties, the electronic interactions between the chiral organic molecules and achiral inorganic framework, should also be considered. Here, we discuss the possibility of the chirality transfer via electronic interaction between the chiral organic molecules and achiral inorganic framework related to the strength and direction of hydrogen bonding. We systematically consider the effect of asymmetric hydrogen bonding and related change in the chiroptical activity of chiral perovskite by inducing the conformational change of stacking order between the two chiral organic molecules. First, through the spatial confined growth of chiral perovskite in anodized aluminum oxide template, we can successfully impose the micro-strain into the lattice of chiral perovskite, resulting in rearrangement of chiral organic molecules. As a results, remarkable chiroptical behavior with different absorption of $2.0\ 10^{-3}$ and distinct photoluminescence of $6.4\ 10^{-2}$ for left- and right-handed circularly polarized light was observed in nanoconfined chiral perovskites even at room temperature. Theoretical calculations verify that the chirality transfer phenomena mediated by the asymmetric hydrogen bonding between the chiral organic molecules and achiral inorganic frameworks is critical factor for promoting the chiroptical activity of chiral perovskites. Furthermore, the incorporation of guest molecules into the lattice of chiral perovskite evoke the rearrangement of chiral organic molecules, which also can lead to change in chiroptical activity as well as electrical properties. Through solid-state nuclear magnetic resonance spectroscopic measurements and theoretical calculations, we verify the change in the degree of chiral lattice distortion associated with different electronic interaction between the inorganic framework and guest molecules. Finally, as a preliminary proof-of-concept, a vertical-type circularly-polarized light photodetector based on chiral perovskites was developed, exhibiting an outstanding performance with a distinguishability of 0.27 and responsivity of $0.43\ A\ W^{-1}$. Our findings suggest that electronic interactions between the building blocks should be considered when interpreting the chirality transfer phenomena and designing hybrid materials for future spintronic and polarization-based devices.

11:00 AM EL17.09.06
Large Optical Anisotropy Factors of a Chiral Bismuth Iodide Hybrid Organic-Inorganic Semiconductor Alan J. Phillips[1,2], Liang Yan[3], Yi Xie[4], Matthew Hautzinger[2], Heshansamuditha Hewawalpitage[5], Peter Sercel[6], David B. Mitzi[4], Z. Valy Vardeny[5], Wei You[3] and Jeffrey Blackburn[2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States; [3]University of North Carolina at Chapel Hill, United States; [4]Duke University, United States; [5]The University of Utah, United States; [6]Center for Hybrid Organic Inorganic Semiconductors for Energy, United States

Chiral materials are important tools for interconverting the spin angular momentum of circularly polarized light with electronic spin to help realize a wide variety of emerging spin-based technologies. Here we demonstrate that thin films of a Bismuth-based chiral 0D hybrid organic-inorganic semiconductor (HOIS) exhibit large anisotropy values for circularly polarized light emission (CPLE) that approach 50% circular polarization. The observed anisotropy is strongly correlated with the crystallographic orientation of the thin film and is also strongly temperature-dependent, with a marked anti-correlation with exciton transition linewidth. Detailed analysis of the CPLE anisotropy indicates large contributions from structure-dependent scattering that are analogous to the so-called "LDLB" effect observed for circular dichroism, caused by interactions between linear dichroism and linear birefringence. Although this effect has been observed for organic thin-film composites, this first demonstration in a HOIS system provides a unique route for enhancing carrier spin polarization and polarization-dependent emission in self-assembled hybrid semiconductors. These results provide a fundamental framework for understanding and harnessing the properties of low dimensional and low symmetry chiral HOIS materials for circularly polarized light applications.

11:15 AM EL17.09.07
Narrow Intrinsic Homogeneous Linewidths and Electron-Phonon Coupling of InP Colloidal Quantum Dots David B. Berkinsky, Andrew H. Proppe and Moungi G. Bawendi; Massachusetts Institute of Technology, United States

InP quantum dots (QDs) are the material of choice for QD display applications. They have been used as active layers in QD light-emitting diodes (QDLEDs) with high efficiency and color purity. Optimizing the color purity of QDs requires understanding mechanisms of spectral broadening. While ensemble-level broadening can be minimized by synthetic tuning to yield monodisperse QD sizes, single QD linewidths are broadened by elastic/inelastic exciton-phonon scattering and fine-structure splitting. Here, using photon correlation Fourier spectroscopy, we extract average single QD linewidths of 50 meV at 293K for red emitting InP/ZnSe/ZnS QDs, among the narrowest for colloidal QDs. By measuring InP/ZnSe/ZnS single QD emission lineshapes at temperatures between 4K – 293K, and modelling the spectra using a modified independent boson model, we find that acoustic phonon coupling and fine-structure splitting, which contribute similarly to the homogeneous linewidth, are most prominent at low temperature, whereas pure dephasing is the primary broadening mechanism at elevated temperatures, and optical phonon coupling contributes minimally across all temperatures. By measuring CdSe/CdS/ZnS QD emission lineshapes across the same temperature range, we find that optical phonon coupling is a larger contributor to the lineshape at elevated temperatures likely as a result of the more polar nature of CdSe/CdS/ZnS. For the first time, we are able to reconcile narrow low-temperature linewidths and broad room temperature linewidths within a self-consistent model that enables parameterization of linewidth broadening, for different material classes. Our findings reveal that red-emitting InP/ZnSe/ZnS QDs have intrinsically narrower linewidths than typically synthesized CdSe QDs, suggesting that these materials could be used to realize QDLEDs with unprecedented color purity.

11:30 AM EL17.09.08
Directional Light Amplification in Perovskite LEDs by Hybrid Photonic-Plasmonic Modes Zher Ooi[1], Alberto Jimenez[2,3], Yuqi Sun[1], Jordi Ferrer Orri[1], Hayden Salway[1], Krzysztof Galkowski[1], Changsoon Cho[1], Caterina Ducati[1], Samuel D. Stranks[1] and Miguel Anaya[1]; [1]University of Cambridge, United Kingdom; [2]Max Planck Institute for Solid State Research, Germany; [3]Universidad de Cordoba, Spain

Halide perovskites show excellent optoelectronic properties including bandgap tunability, high radiative recombination rates and narrow emission lines that make them promising candidates for the next generation LEDs. However, their thin film character is yet to be exploited to enable full control over the emission properties, opening avenues to surpass the luminous efficacies of conventional LEDs and facilitating their widespread adoption.

In this talk, we present a novel green perovskite LED architecture where enhanced emission and directionality on demand is achieved by means of a hybrid photonic-plasmonic structure. We show how a code based on the transfer matrix model boosted by a genetic algorithm identifies the best combination of materials and thin film thicknesses to maximise outcoupled light with very narrow and controllable angular dispersion; all in a realistic fashion compatible with the fabrication of efficient LEDs. This strategy leads to hybrid photonic-plasmonic modes highly confined throughout the whole cross-section of the perovskite emitter while ensuring a good band alignment of the building blocks for efficient charge carrier injection and radiative recombination.
The experimental realization of the optimum designs allows us to demonstrate devices with amplified green emission selectively enhanced at different angles. Our low temperature process can tune the perovskite thickness on a nanometric scale to enhanced electroluminescence on demand from forward direction (0°) to up to 40°. This approach expands the role of the perovskite film from a mere emitter to an active photonic layer participating in the strong interference phenomena arising from the designed photonic-plasmonic nanostructures. This strategy is truly unique as opposed to standard methods where emitters are just embedded into the optical cavities. Our methodology is versatile and easily integrable into cost-effective perovskite LEDs with emission lines covering the entire visible spectrum. Thereby opening avenues for their application in displays and light sources where control over angular dispersion of light is crucial.

Synthesis and Applications of Low-Toxicity Near-Infrared-Emitting Colloidal Quantum Dots Zhi Kuang Tan; National University of Singapore, Singapore

Many emerging technologies rely on near-infrared emitters for covert illumination and sensing. Examples include the facial recognition devices found on our smart-phones, sensing devices on fitness tracking watches, gaming consoles, robotic cleaners and self-driving cars. Colloidal quantum dots are excellent emitters that could be conveniently solution-processed, and could potentially find useful applications in these devices. Unfortunately, there are very few known colloidal quantum dots that operate in the near-infrared spectral range. Some examples include PbS and and CsPbI3, which contain restricted heavy metals. In this talk, I will discuss new strategies to prepare low-toxicity heavy-metal-free core-shell colloidal quantum dots with high luminescence efficiencies and with long emission wavelengths of above 900 nm. I will also present some of their applications in optoelectronic devices, such as in light-emitting diodes and in luminescent solar concentrators.

8:30 AM *EL17.10.02
Suppression of Ion Migration for Stable Perovskite LEDs Zhengguo Xiao; University of Science and Technology of China, China

The external quantum efficiency (EQE) of perovskite LEDs (PeLEDs) has dramatically improved to above 20% in the past few years. Operation stability becomes the most challenging issue for the application of perovskite LEDs. Ion migration was acknowledged to be one of the main causes of degradation of perovskite LEDs.

In this talk, we will present our efforts to improve the stability of perovskite LEDs, including 1) suppression of ion migration with incorporation of bulky organoammonium ligands, 2) enhanced operation stability in all-inorganic perovskite LEDs due to the suppressed ion migration, and 3) absence of ion migration in tin halide perovskite LEDs under device working conditions. and 4) Suppressed ion migration in perovskite single-crystal LEDs with enhanced operation stability.

9:00 AM *EL17.10.03
Bottom Surface Induced Phases Distribution of Quasi-Two-Dimensional Perovskite for Efficient Blue Light-Emitting Diodes Jingbi You; Chinese Academy of Sciences, China

Performance of blue perovskite light-emitting diodes (PeLEDs) is still lagging far behind green and red emissions. Inferior carrier injections, non-radiative recombination and random phase distribution mainly account for limited advances in quasi-two-dimensional blue PeLEDs. Here, we modulated of hole injection layer by addition alkali metal salt CsCl, a better band alignment and improved charge injection have been achieved. More interestingly, the modified substrate induced the following growth of perovskite layer with better phase distribution, which lead to the less non-radiative recombination and enhanced charge transport. Accordingly, a maximum external quantum efficiency of 16.07% had been demonstrated in the sky-blue PeLEDs, with a stable emission peak located at 486 nm and improved operational stability. This strategy contributes an effective way for the fabrication of high-performance and stable blue PeLEDs toward practical applications.

9:30 AM EL17.10.04
Enhanced Blue Emission in Rb_2HfCl_6 Double Perovskite via Bi^{3+} Doping and Cs^+ Alloying Haoyue Wan, Fengyan Jia, Filip Dinic, Benjamin Rehl, Muhammad Imran, Yanjiang Liu, Watcharaphol Paritmongkol, Pan Xia, Yuan Liu, Sasa Wang, Yakun Wang, Oleksandr Voznyy, Sjoerd Hoogland and Edward H. Sargent; University of Toronto, Canada

Lead-free double perovskites offer non-toxic properties and strong emission via alloying and doping. Herein we report the synthesis of pure Rb_2HfCl_6 microcrystals as well as Cs-alloyed and Bi-doped $RbCsHfCl_6$ microcrystals. While pure Rb_2HfCl_6 is almost non-emissive, alloying with Cs and Bi doping led to strong deep blue emission at 466 nm with the photoluminescence quantum yield increase from ~0% to 66%. Density functional theory studies attest to improved phase stability upon Cs alloying and link photoluminescence to Bi^{3+} dopant-induced localized states.

9:35 AM *EL17.10.05
2D Perovskite Passivation Strategy for High Efficient Solar Cells—What's Behind? Giulia Grancini; University of Pavia, Italy

Three-dimensional (3D)/low-dimensional (LD) perovskite solar cells (PSCs) offer an effective strategy to overcome the trade-off between perovskite solar cells device performance and stability. Improving the device longevity, while concomitantly simultaneously enhancing increasing the solar cell open circuit voltage and fill factor of the solar cell is the current challenge. Despite being one of the most popular and effective way processing techniques, whether the presence of this surface LDP layer would be - or not-represents the winning crucial path for the future of this technology remains elusive. In particular, atomic layer combined surface and bulk passivation using surface modifiers such as organic dopants, casts the doubts on the effective need for of having an homogeneous LDP cover capping layer. In this talk, I will discuss the interfacial passivation with different cations such as M-PEAI, M-PEABr, and M-PEACl, showing the role of the passivation and how different halides affect the device performance of the devices. In addition, I will compare recent results obtained in the 3D/LDP configuration with the surface cation passivation strategy, which can still pushes produce the performances to values comparable to the LDP/3D bilayers. I will providing a comprehensive perspective on the benefits from of the two different strategies, but also presenting how LDP interfaces can play a role in alternative new configurations, such as tandem solar cells [1,2].

SESSION EL18.01: Conjugated Polymers
Session Chairs: Ying Diao and Jie Xu
Monday Morning, April 10, 2023
Moscone West, Level 3, Room 3018

8:00 AM EL18.01.01
Polyborosiloxane-Conjugated Polymer Blends as a Self-Healing Material for Wearable Sensors Peter Finn and Bob C. Schroeder; University College London, United Kingdom

The need for durable and flexible electronics is emerging as a high research priority as electronic materials are being integrated into wearable devices for bioelectronic monitoring and sensing applications. Since silicon is rigid and brittle and not suitable for wearable technology, this has led to the use of organic materials as the active layer in flexible devices. However, organic materials still exhibit wear and tear after prolonged use and irreversible damage will lead to decreased device performance and eventual failure. Therefore, new properties need to be introduced to prevent this issue which will hopefully lead to a more reusable society.

Self-healing has received a lot of attention recently and is a strong candidate for improved durability and reusability. A self-healing material can reform and repair damage without the need of outside help and is split up into extrinsic and intrinsic systems. Extrinsic healing is governed by an external source embedded into the material that promotes reformation such as micelles releasing catalysts for new bond formation. Whereas intrinsic healing is governed by functionalities inherent to the structure of the material. A long list of intrinsic moieties have been used for self-healing including hydrogen bonding, ionic interactions, covalent bonding, π-π interactions and supramolecular structures which has lead to promising results. Many of these intrinsic functionalities have been implemented into polymers making them ideal candidates to combine with polymeric organic semiconductors as new self-healing electronic materials.

Herein, we have combined the semiconducting properties of conjugated polymers with polyborosiloxane, a polysiloxane polymer crosslinked with boric acid. Polyborosiloxane intrinsically contains dative B-O bonds enabling a reversible and dynamic system needed for self-healing. Via either blending or crosslinking the two polymers and exploring the electrical characterisation under mechanical stress, our findings show that this new class of viscoelastic materials have potential for durable and wearable electronics.

8:15 AM EL18.01.02
Redox-Active Polymeric Ionic Liquids for Semiconducting Polymer Dopants Saejin Oh, Phong H. Nguyen, Thi Tran, Kan Tagami, Audra J. DeStefano, Dafei Yuan, Andrei Nikolaev, Songi Han, Rachel A. Segalman, Javier Read de Alaniz and Michael L. Chabinyc; University of California, Santa Barbara, United States

Semiconducting polymers are attractive materials for flexible organic electronic applications due to their low cost and ease of processability. For such materials, controlling the doping level, conductivity, and device stability is important for improving the performance of organic electronic devices. Electrical doping is usually achieved through the introduction of small-molecules that undergo charge transfer leading to either *p*- or *n*-type doping. While there are various molecular *p*-type dopants that are widely used with semiconducting polymer doping, their range is relatively limited. The small-size of molecular dopants make it challenging to control the precise ion penetration depth into solid films and limits detailed understanding in how the ion penetration affects the charge transport. Here, an efficient *p*-type dopant with a radical-cation bearing polymeric ionic liquid (PIL) is introduced to dope poly(3-hexylthiophene) (P3HT). In our previous study, we have successfully designed a low T_g and charge conducting phenothiazine (PTZ) based PIL with partial oxidation of the PTZ units, with TFSI as the charge balancing counter anion. Upon formation of bilayers of the PIL and P3HT, efficient charge transfer occurs between the two polymer layers. The facile redox reaction at the phenothiazine-TFSI PIL and the semiconducting polymer interface enables efficient electron transfer while preventing the redox active unit from penetrating into the bulk. Furthermore, the electrical conductivity upon polaron generation in P3HT films is comparable to most known dopants. This new redox-active PIL not only induces facile charge generation to attain high electrical conductivity, but also opens up a new possibility to broaden the choice of *p*-type dopant for semiconducting polymers.

9:00 AM *EL18.01.04
Autonomous Platform (Polybot) for Electronic Polymers Discovery Jie Xu; Argonne National Laboratory, United States

In the past 40 years, conjugated polymers have been widely studied and used in many novel applications, such as printable electronics, wearable electronics and flexible energy devices, because of their unique characteristics of (opto)electronic property, mechanical softness and low-cost manufacturing. The high throughput production of conjugated polymer thin films at low temperatures is a critical processing step in the manufacturing of devices. However, the processing of these nanometers-thick layers generally occurs under strong deformations/stressors and rapid flows, conditions under which equilibrium thermodynamics does not apply, resulting in significant structural variabilities in ways that are hard to predict. As a result, it remains a central challenge to control the assembly of these conjugated polymers towards desired multi-scale morphological orderings, which critically impact their solid-state properties (e.g., electronic property, optical property, mechanical property, stability, etc.). I will introduce a new experimental paradigm we recently developed that combines the strengths of rapid and robust experiment acquisition from robotic technologies (i.e., high-throughput processing and characterization) and fast analysis of complex datasets using machine learning (ML) for autonomously controlling conjugated polymer assembly towards targeted structures for desired solid-state properties. Utilizing this autonomous platform (PolyBot, https://www.anl.gov/cnm/polybot), we were able to identify the processing path much more efficiently and extract the high-dimensional formulation-processing-property relationships for revealing the general design principles. This new experimental framework is amenable to continuous improvement, such that sophistication can be added over years to continually redefine the cutting-edge of autonomously conjugated polymer discovery.

9:30 AM EL18.01.05
From Chlorinated Solvents to Branched Polyethylene and Paper—New Materials and Methods for Sustainable and Greener Printed Electronics Simon Rondeau-Gagne; University of Windsor, Canada

Among the new semiconductors developed in the last decade, π-conjugated semiconducting polymers possess particularly outstanding properties, including good charge transport properties, low elastic moduli and high biocompatibility/low toxicity. As the impact of semiconducting polymers is increasing in various fields, limited attention has been given to their environmental footprint. From their manufacturing and processing using toxic high-boiling point solvents to their application in electronics that can accumulate in the environment, the environmental footprint of organic semiconducting materials is non-negligible; it is imperative to develop alternate manufacturing processes and molecular designs to improve current materials and make more sustainable technologies. Developing novel applications for these materials in environmental sciences is also a promising avenue to reduce their environmental footprint while simultaneously exploiting the unique chemistry of these materials to create new opportunities.

To tackle the emerging environmental and manufacturing challenges related to the utilization of semiconducting materials in printed electronics, our team recently developed new strategies to design and process semicrystalline semiconducting polymers in non-toxic solvents rather than high boiling points, toxic chlorinated solvents commonly used to generate printed electronics. The first part of this presentation will focus on the use of a low-molecular-weight non-toxic branched polyethylene (BPE) as a solvent to process diketopyrrolopyrrole-based semiconducting polymers. We exploited a solvent-induced phase separation (SIPS) technique to produce thin films of semiconducting polymers for the fabrication of organic field-effect transistors (OFETs). OFETs based on the semiconducting films processed from BPE showed similar device characteristics to those prepared from chloroform without thermal annealing, confirming the efficiency and suitability of BPE to replace traditional chlorinated solvents for green organic electronics. In the second part of this presentation, we will discuss the recent progress realized in our group to prepare thin film electronics on paper substrates from environmentally benign processes and materials. While there are numerous substrates used for the development of flexible organic electronics, paper has become a leading candidate as an environmentally sustainable substrate incorporating flexibility, thermal stability, and cost effectiveness. With various solution deposition techniques, fabrication and optimization of a paper-based organic thin film transistor is explored with the goal to integrate greener substrates into the production of large-scale organic flexible electronics.

Throughout this presentation, a detailed characterization of the solid-state morphology of the materials in thin films will be discussed, as well as the new structure-property relationships unveiled during our investigation. The results obtained from a multimodal characterization performed on both materials and devices will be highlighted, and a particular focus will be put on the molecular design of the materials and their synthesis.

9:45 AM EL18.01.06
Mixing-Induced Orientational Ordering in Liquid-Crystalline Organic Semiconductors of PE-BTBT-C_n Kiyoshi Nikaido[1], Satoru Inoue[1], Reiji Kumai[2], Toshiki Higashino[3], Satoshi Matsuoka[4], Shunto Arai[1] and Tatsuo Hasegawa[1]; [1]The University of Tokyo, Japan; [2]High Energy Accelerator Research Organization (KEK), Japan; [3]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [4]Nagasaki University, Japan

Recent reports show that several high-mobility organic semiconductors (OSCs), composed of rod-like π-electron cores linked with alkyl chains, exhibit thermotropic liquid-crystalline (LC) phases, which attracts considerable attentions. A typical example is 2-alkyl-7-phenyl-[1]benzothieno[3,2-*b*][1]benzothiophene (Ph-BTBT-C_n, where *n* represents the number of carbon atoms in alkyl chain) [1,2], which exhibits a field-effect mobility higher than 10 cm^2/Vs [1,3]. The compounds exhibit smectic liquid crystalline (LC) phases at elevated temperature [1,2]. However, the actual liquid crystal phases have not been understood in detail so far, in terms of emerging mechanism as well as the molecular arrangement structure. It should be significant to reveal the roles of substituents and the way to control the layered structure utilizing the LC phase for the development of the OSCs.

Herein we focus a novel series of OSCs of PE-BTBT-C_n, in which the phenyl group in Ph-BTBT-C_n is replaced with a phenylethynyl (PE) group of slightly longer length and rotational freedom [4]. The compounds show unique molecular arrangements closely related to LC phases: In cases where the alkyl group of PE-BTBT-C_n is longer than the PE group ($n \geq 8$), we obtained a typical bilayer-type herringbone (*b*-LHB) phase in which the orientations of the molecular long axes in each layer are aligned at room temperature, and observed a transition to the smectic liquid crystal (SmE) phase at a high temperature. However, when the alkyl and PE groups have approximately the same length ($n = 6$), the arrangement takes on a disordered LHB (*d*-LHB) structure, as revealed by a crystallographic analysis using electron diffraction [4]. In this case, the herringbone-type ordering between BTBT skeletons in the molecular layer is maintained, despite the random orientation of the molecular long axis. As the transition to the SmE phase disappears at high temperatures, we deduce that the *d*-LHB phase is the frozen phase of the SmE phase. Owing to the emergence of LC-like *d*-LHB phase at a particular alkyl chain length of $n = 6$, the compound provides a unique platform to investigate the competition between ordered and disordered phase depending on the alkyl chain length, and the way to control the layered ordering of rod-like OSCs.

With use of the material system, we successfully found that a drastic structural ordering from *d*-LHB to *b*-LHB phase can be induced by mixing a small amount of longer-alkylated molecule to PE-BTBT-C_6 through solution processes [5]. The mixing-induced ordering phenomenon was clearly observed by the change in the film morphology of the mixtures of PE-BTBT-C_6 and PE-BTBT-C_{12} which was probed by the combination of atomic force microscope, thin-film X-ray diffraction (XRD) and X-ray reflectivity measurements. The enhancement in the hole mobility in the single-crystalline organic thin film transistors (OTFTs) was also observed along with the mixing-induced ordering, which indicates that the method can be useful to achieve high-mobility OTFTs. The temperature-composition phase diagrams were systematically investigated by temperature-controlled powder XRD and differential scanning calorimetry (DSC) measurements. The phase diagrams and the entropy of transition from crystal to LC phase reveals that the emergence of *d*-LHB and *b*-LHB phase is determined by the competition of smectic LC phase and *b*-LHB phase. Based on the results, we discuss the origin of the mixing-induced phenomenon and the essential roles played by the temporary LC phase in the crystallization of layered crystal phases through solution processes.

10:00 AM BREAK

10:30 AM *EL18.01.07
Chiral Organic Semiconducting Materials for Next-Generation Flexible Optoelectronics Joon Hak Oh; Seoul National University, Korea (the Republic of)

Chiral organic semiconducting materials are expected to open new opportunities for next-generation flexible optoelectronics. I will introduce fabrication of chiral supramolecular assemblies using organic semiconductors and their structure-chiroptical property relationships. I will present synthesis of chiral supramolecular biocoordination polymers and their applications in various flexible sensors. I will also introduce a skeleton merging approach that can distort the planar semiconducting backbone, which enables high-performance broadband circularly polarized light detections up to the near-infrared spectral region. In addition, a simple yet powerful method to fabricate chiroptical flexible layers via supramolecular helical ordering of conjugated polymer chains will be introduced. These findings provide guidelines for enhancing chiroptical properties using supramolecular chirality and rational molecular design of organic semiconductors toward high-performance chiral optoelectronics. In addition, these results demonstrate an effective strategy to realize on-chip detection of the spin degree of freedom of photons necessary for encoded quantum information processing and high-resolution polarization imaging.

11:00 AM EL18.01.08
Optimization of Carbohydrate-Bearing Semiconducting Polymers: A Case Study toward Greener High-Performance Electronics Madison Mooney and Simon Rondeau-Gagne; University of Windsor, Canada

Semiconducting polymers are vital to the development of next-generation electronics due to their excellent physical and optoelectronic properties. These materials possess several advantages over current silicon-based electronics, including good mechanical features, synthetic tunability, and the potential for emerging properties such as self-healing and biocompatibility. Another major advantage of semiconducting polymers is their solution processability, which allows manufacturers to access a wide variety of new fabrication techniques such as spin-coating and inkjet printing to produce thin-film electronics. While solution processing offers many new avenues for electronics production, it also leads to a major ecological concern. Due to the extended π-conjugation of these materials, their solubility is often limited to toxic, halogenated solvents that can be extremely harmful to humans and the environment. As such, the significant environmental toll of processing these materials at an industrial scale needs to be proactively considered.

In recent years, several strategies have been proposed to avoid the use of such toxic solvents, either by careful selection of new solvent systems or engineering of polymer structures to alter their solubility. Using a molecular engineering approach, we developed alcohol-processable semiconducting polymers using carbohydrate side chains. These pendant groups were chosen because they are bio-sourced, non-toxic and contain many alcohol groups. The use of carbohydrates to improve solubility has been extensively used in the medical industry, but has not previously been applied to electronic materials. The extensive hydrogen bonding of these new side chains significantly improved solubility of the semiconducting polymer in more polar solvents, including n-butanol. The use of carbohydrate moieties was also found to have little impact on electronic performance in organic field-effect transistors (OFETs), making this a viable approach toward greener electronics fabrication without sacrificing performance. Interestingly, these new side chains were found to have significant impacts on thin film morphology and solid-state stacking when incorporated into the polymer in different ratios. Since morphology and packing can directly affect charge mobility, the use of these carbohydrate side chains has been systematically investigated in semiconducting polymers as not only an avenue toward eco-friendly device manufacturing, but also a novel way to improve charge transport for high-performance OFETs. This work presents an in-depth case study of the effects of polymer structure and processing conditions on electronic performance. This foundational study demonstrates that novel side chain engineering is key to the future of environmentally conscious next-generation electronics.

11:15 AM EL18.01.09
Highly Conductive and Stable N-Type Conducting Polymer Zhifan Ke[1], Ashkan Abtahi[1], Jinhyo Hwang[1], Ke Chen[1], Jagrity Chaudhary[1], Inho Song[1], Kuluni Perera[1], Kyle Baustert[2], Kenneth R. Graham[2] and Jianguo Mei[1]; [1]Purdue University, United States; [2]University of Kentucky, United States

The search for solution-processable, environmentally and thermally stable conducting polymers is warranted, due to their applications in displays, solar cells, touch screens, and emerging printed electronics. Here, we report an n-doped organic conductive ink from oxidative polymerization. The resulting conductive polymer thin films exhibit low sheet resistance with high optical transmittance. This conductive polymer can function as transparent conductors and electrodes in electrochemical devices.

11:30 AM EL18.01.10
High Optoelectronic Performance in PEDOT Thin Films Fabricated by Oxidative Chemical Vapor Deposition Meysam Heydari Gharahcheshmeh; San Diego State University, United States

Conjugated conducting/semiconducting polymers have attracted enormous attention because of their unique characteristics, such as metal-like conductivity, optical transparency, ionic conductivity, and mechanical flexibility. Engineering the texture and nanostructure of conjugated conducting/semiconducting polymers to enhance the interchain charge transfer integral is a promising approach to overcome the charge localization and electrical conductivity enhancement. Here, ultraconformal poly(3,4-ethylenedioxythiophene) (PEDOT) thin films were grown using antimony pentachloride ($SbCl_5$) oxidant via water-assisted (W-A) oxidative chemical vapor deposition (oCVD). Engineering the π-π stacking distance through tuning the oxidant saturation ratio (OSR) yields a high-record of electrical conductivity (ca. 7520 S cm^{-1}) in as-deposited PEDOT thin films grown by W-A oCVD method. In addition, the optoelectronic figure of merit () in the range of 94 was achieved in PEDOT thin films, which is 1.9× and 6.7× higher than its counterparts grown by vanadium oxytrichloride ($VOCl_3$) and iron chloride ($FeCl_3$) oxidizing agents, respectively. Furthermore, the recent integration of oCVD PEDOT in solar cell and electrochemical energy storage devices will be presented.

SESSION EL18.02: Wearable Systems

1:30 PM EL18.02.01
A Hemispherical Image Sensor Array Fabricated with Organic Photo-memory Transistors Yeongin Kim[1,2], Chenxin Zhu[1,1], Wen-ya Lee[1], Anna Smith[3], Haowen Ma[4], Xiang Li[4], Donghee Son[1,5], Naoji Matsuhisa[1], Jaemin Kim[1], Won-Gyu Bae[1], Sung Ho Cho[6], Myung-Gil Kim[1], Tadanori Kurosawa[1], Toru Katsumata[7], John W. To[1], Jin Young Oh[1,8], Seonghyun Paik[1], Soo Jin Kim[1], Lihua Jin[1,9], Feng Yan[4], Jeffrey Tok[1] and Zhenan Bao[1]; [1]Stanford University, United States; [2]University of Cincinnati, United States; [3]University at Buffalo, The State University of New York, United States; [4]Nanjing University, China; [5]Sungkyunkwan University, Korea (the Republic of); [6]Samsung Display, Korea (the Republic of); [7]Asahi Kasei, Japan; [8]Kyung Hee University, Korea (the Republic of); [9]University of California, Los Angeles, United States

Hemispherical image sensors simplify lens designs, reduce optical aberrations, and improve image resolution for compact wide-field-of-view cameras. To achieve hemispherical image sensors, organic materials are promising candidates due to the following advantages: tunability of optoelectronic/spectral response and low-temperature low-cost processes. Here, we developed a photolithographic process to prepare a hemispherical image sensor array using organic thin film photo-memory transistors with a density of 308 pixels per square centimeter. Our design includes only one photo-memory transistor as a single active pixel, in contrast to the conventional pixel architecture, consisting of select/readout/reset transistors and a photodiode. Our organic photo-memory transistor, comprising light-sensitive organic semiconductor and charge-trapping dielectric, is able to achieve linear photo-response (light intensity range, from 1 to 50 W m^{-2}), along with responsivity as high as 1.6 A W^{-1} (wavelength = 465 nm) for a dark current of 0.24 A m^{-2} (drain voltage = -1.5 V). These observed values represent the best responsivity for similar dark currents among all the reported hemispherical image sensor arrays to date. We further developed a transfer method that does not damage organic materials for hemispherical organic photo-memory transistor arrays. Our developed techniques are scalable and are amenable for other high-resolution 3-dimensional organic semiconductor devices.

1:45 PM EL18.02.02
Wearable Stretchable Microneedle-Based Patch for Online Detection of Multiple Biomarkers in Interstitial Fluids Rawan Omar and Hossam Haick; Technion-Israel Institute of Technology, Israel

With the increasing number of aging populations, the outbreak of new infections and diseases, and the stressed lifestyle, the need for sophisticated advanced technologies for online health monitoring is increasing. In this regard, measuring and evaluating health related biomarkers and physiological indexes have a considerable advantage and is considered an informative prognostic tool for health assessment. However, these biomarkers are usually measured and analysed using bulky laborious equipment, painful and time-consuming methods which require expert personnel to perform, may cause irritations and infections and are usually collected and analysed offline and not continuously. Using wearable biosensors for online biomarkers monitoring can be a promising approach to overcome this condition. In this regard, biosensors based on field-effect transistors (FETs) have promising advantages, including high sensitivity, quick response, and easy fabrication. Most of the currently developed FET designs are used only for sensing sweat and in-vitro blood/interstitial fluids (ISF). Using ISF for online detection of biomarkers and long-term health monitoring with FETs has not yet been fully resolved. In this work, we developed an innovative stretchable, flexible, skin-conformal and quick-response microneedle-based extended gate FET (MN-EGFET) biosensor patch for online and real-time detection of multiple biomarkers including glucose, sodium, cortisol, and pH in the ISF for minimally invasive health monitoring along with high sensitivity, low limit of detection, excellent biocompatibility, and on-body mechanical stability. On-body measurements were also carried out on a healthy individual to evaluate the long-term health monitoring performance of our wearable microneedle device against a gold standard commercial device. Both devices were found to show a similar performance and tendency, indicating the great promise for our device in clinical and on-body applications. This wearable microneedle device was also integrated with a flexible wireless data transmission chip including Internet-of-Things (IoT) cloud, to transmit the data continuously to a smartphone, demonstrating its effectiveness as a diagnostic and monitoring tool in primary and specialized healthcare, as well as its potential in real-life home healthcare and clinical applications.

2:00 PM *EL18.02.03
Air-Stable Ultra-Flexible Organic Photonic System for Health Care Application Tomoyuki Yokota[1], Kenjiro Fukuda[2] and Takao Someya[1]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan

Optical bio-imaging is a non-invasive method to measure biological information from outside of the body, such as fluorescent probes, photoacoustic imaging, and near-infrared spectroscopy have been widely used as medical devices. In recent years, along with the development of semiconductor technology, the miniaturization of these imaging devices has been progressing. In particular, organic optical devices are being actively applied to healthcare by integrating them into wearable devices due to the featured characteristics such as high efficiency, flexibility, lightweight. For example, a flexible device that integrates an OLEDs and an OPD can be attached to a finger and measure the pulse wave by measuring the light reflected in the body. It is also possible to measure the blood oxygen ratio by a two-color light source such as red and green, or red and near-infrared light. Other biometric data such as veins and fingerprints image can also be taken by using high-resolution imaging sensors. It is important to improve the adhesion between the device and the body in order to perform such in vivo imaging with high accuracy. In this study, we developed an ultra-flexible photonic system in which the organic light-emitting diode and organic photodiode are integrated on the same substrate by improving the air stability of ultra-flexible organic light-emitting diodes and photodiodes. By applying an inverted structure, the ultra-flexible organic light-emitting diode has been operated over 10 days even without a high-barrier passivation layer. The ultra-flexible OLED shows high air stability in which the current density is maintained at more than 50% of the initial state. The organic photodiodes also show high air stability, with less than 1% change in photocurrent and less than 10 nA/cm^2 dark current after 10 days. The sensor system that integrates these air-stable optical devices is extremely thin with a total thickness of 3 µm. Therefore, it can be directly attached to the skin, and the pulse wave can be measured simply. Furthermore, we succeeded in measuring the pulse wave propagation time by combining the optical system with an electrocardiogram. When the blood pressure value was calculated from the measured pulse wave propagation time, a high correlation coefficient of 0.89 was achieved with the value measured by a conventionally used cuff-type blood pressure monitor system.

2:30 PM EL18.02.04
Wireless Body Area Sensor Network Based on Stretchable RFID Design Simiao Niu; Rutgers, The State University of New Jersey, United States

Body area sensor network (BodyNET) is a promising platform for next-generation healthcare and realizing its full potential requires seamless hybridization between on-body sensors and both rigid circuits for signal readout, conditioning and wireless transmission components. Rigid sensors based BodyNET has already been demonstrated due to its fabrication compatibility with existing integrated circuit technologies while the integration of soft on-skin sensors into the BodyNET still remains a grand challenge. So far, the integration of rigid silicon circuits and stretchable sensors on a single substrate has only been realized through the introduction of rigid islands and stretchable interconnects. However, the weak interfaces between soft and rigid parts severely compromise the robustness of such systems. Therefore, physical separation of stretchable sensors from rigid readout circuits that completely eliminate all fragile interfaces may be an effective strategy towards an intimate and robust BodyNET system.
Here, we demonstrate a bodyNET system comprised of battery-free and chip-free stretchable sensors attached on multiple skin locations to gather human physiological and movement signals, which are wirelessly operated by silicon readout circuits attached to textiles. The physically-separated stretchable sensors and silicon readout circuit are communicated via passive radio frequency identification (RFID) technologies. The stretchable sensor tags are fabricated via printing intrinsically stretchable materials on elastic substrates, and are completely free from rigid silicon chips and batteries to avoid potential stress concentrated regions and improve system robustness. The main technical challenge encountered here is the strain-induced changes of both sensor antenna inductance and resistance that can affect readout effectiveness. We address this issue by adapting an unconventional detuned RFID tag design and verify its appropriateness by both simulation and experiments. Our design enables the bodyNET system to maintain full functionality even when the on-skin sensors are stretched to 50% strain. To further enable multiple sensors in one RFID tag, we have fabricated and integrated a high frequency intrinsically stretchable rectifying diode and low voltage driven intrinsically stretchable ring oscillators for RF energy harvesting and frequency modulation. Finally, the bodyNET is demonstrated by connecting multiple sensor nodes and smartphone through Bluetooth. Our hands-free bodyNET could continuously, simultaneously and accurately monitor human's respiration, pulse and body movements. Thus, this platform constitutes a powerful tool in analyzing relevant human activities and physiological signals, hence enabling critically-needed possibility for real-time physiological studies. [1]

2:45 PM EL18.02.05
Rechargeable Cyborg Insects with Ultrathin Organic Solar Cell Module Kenjiro Fukuda[1], Yujiro Kakei[1,2], Shumpei Katayama[1,2], Hirotaka Sato[3], Shinjiro Umezu[2] and Takao Someya[1,4]; [1]RIKEN, Japan; [2]Waseda University, Japan; [3]Nanyang Technological University, Singapore; [4]The University of Tokyo, Japan

Cyborg insects have been proposed for applications such as urban search and rescue. Body-mounted energy-harvesting devices are critical for expanding the range of activity and functionality of cyborg insects. However, achieving a power output of 10 mW or higher using energy harvesters mounted on living movable insects for wireless locomotion control remains challenging. To integrate devices into small animals with limited surface areas and carry loads29, device design and integration strategy of large-area solar cells is required to obtain sufficient power output and simultaneously maintain the basic behavioral abilities of insects. Because the output power of the solar cell is proportional to the area, both the load of the device and the contact between the device and the moving joints considerably impair motion abilities.
Here, we report a power-rechargeable cyborg insect that uses a mounted ultrasoft organic solar cell module that does not impair the insect's basic motion abilities and demonstrates recharging wireless locomotion control with all components integrated on insects. We developed a combined strategy of ultrathin film electronics and an adhesive–nonadhesive interleaving structure on the insect abdomen to secure their basic motion abilities, confirming their effectiveness quantitatively with traversing obstacles and self-righting ability from an upside-down orientation on the ground. These tests revealed that a 5 µm thick or less polymer (having Young's modulus of several GPa) adhered with an interleaving structure could secure unchanged motion abilities. The ultrathin organic solar cell module (3 series connection) adhered onto a 3D-printed curved insect surface model achieves a power output of 17.2 mW, which corresponds to power per weight of 8.69 W g–1. Finally, recharging and wireless locomotion control was realized using living cyborg insects that contained electronic components. After the simulated sunlight illumination was applied to the organic solar cell module on G. portentosa for 30 min, turn-right locomotion control was wirelessly conducted. The stimulation signals were wirelessly transmitted for 2.1 min with the charged battery. During this period, locomotion control was attempted multiple times, which confirmed that the wireless control was successfully performed repeatedly. The approach presented in this study contributes to expanding the range of activity and realizes diverse functions for the cyborg insects.

3:30 PM *EL18.03.01

Intrinsically-Stretchable Conductors for Conformal Tissue-Device Interfacing Dae-Hyeong Kim[1,2]; [1]Institute for Basic Science, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Recent advances in flexible and stretchable electronics have attracted great attention due to its potential applications in personalized bio-integrated healthcare devices. The mechanical mismatch between conventional rigid electronic devices and soft human tissues oftentimes causes various issues, such as a low signal-to-noise ratio of biosensors, inflammations on the tissue interfacing with the bioelectronics, skin irritations in the case of long-term wearing of the device, and ineffective electrical stimulations in feedback therapies. Ultra-flexible and stretchable bioelectronic devices have a low system modulus and intrinsic softness, and thereby have a potential to solve these issues. Nanomaterials and their composites with the elastomeric matrix are a particularly promising material candidate for realizing this soft bioelectronics concept. In this talk, the unique strategies in the synthesis of nanmaterials, processing as stretchable functional nanocomposites, seamless integration into soft bioelectronics, and their wearable and/or implantable device applications are presented. These efforts have combined recent breakthroughs in nanomaterials and soft electronics, and are expected to address unmet clinical challenges.

4:00 PM *EL18.03.03
Flexible Iontronics Using Neuro-inspired Ion Dynamics Do Hwan Kim; Hanyang University, Korea (the Republic of)

Creating artificial iontronics that shows the tactile recognition and memory-based motion tasks by tactile neural network of human somatosensory system has been a big challenge in wearable and stretchable neuromorphic optoelectronics as well as neuro-inspired robotic systems. In particular, biomimetics has emerged as a burgeoning area in the field of deformable tactile sensor and memory skins that has led innovations in material designing and device structure manipulation with the aim of imitating tactile encoding functionality of human, intelligently.
Herein, inspired by the sophisticated physiological ion dynamics of living cells as well as nerves, we describe a uniquely designed deformable iontronics. Novel bottom-up strategy employed here resulted into supramolecular polymer networks through non-covalent interactions between poroelastic artificial ions and viscoelastic polymer chains or through mechano-sensitive ion dynamics triggered by hydrogen-bonding and ion-dipole interaction, which endows effective tactile augmentation under mechanical stimuli, showing high signal-to-noise level without any interference. This design for neuro-inspired iontronic channel allows for high-performance synaptic plasticity as well as ultrasensitive mechano-transduction over a wide spectrum of pressure, which can serve next flexible, neuromorphic haptic interface platform for human-machine interactive real metaverse.

4:30 PM EL18.03.04
Nature Inspired Sensors for Liquid Environments Wen Cheng, Xinyu Wang and Benjamin C. Tee; National University of Singapore, Singapore

Liquid environments present significant challenges to accurate pressure sensing. Often, flexible materials in solid state pressure sensors grapple with optimization for sensitivity, hysteresis and linearity. In my talk, I will share some strategies to solve this tri-factor optimization problem for pressure sensing in liquid environments. Our proposed approach was inspired by organic hydrophobic surfaces in natural organisms such as the lotus plant (*Nelumbo nucifera*) and pitcher plants (*Nepenthes L.*). By utilizing a multi-species approach, we enabled the highest linearity pressure sensors to date while simultaneously achieving high sensitivity and low hysteresis.

4:45 PM EL18.03.05
Retina-Inspired Organic Optoelectronics for Intelligent Visual Systems Ke Chen, Hang Hu, Inho Song, Ashkan Abtahi and Jianguo Mei; Purdue University, United States

Retina is an important component in the human eye that help human beings get around 80% of knowledge from surroundings. As a type of bio-inspired optoelectronics, artificial retinas have been developed to mimic the functionalities of the human visual system. They are designed to function as bionic eyes for visually impaired persons or offer vision for advanced humanoid robots. To date, most of artificial retinas rely on silicon electronics, which are often rigid and brittle. This makes non-invasive implantation and seamless interfacing to soft biological tissues challenging. On the other hand, organic semiconducting materials have demonstrated biocompatibility, mechanical comfortability, and responsivity to the analytes in biological media, making them a promising candidate for next-generation artificial retina. Here, we report an organic optoelectronic device as an artificial retina. In the device, light can manipulate ion insertion into the bulk photoactive layer, enabling the modulation of multilevel nonvolatile conductance states at low operating voltages (~1 V) and the imitation of ion flux-regulated synaptic activity inherent in living systems. The nonvolatile properties are regulated by both light intensity and wavelength across the entire visible spectrum, demonstrating the capabilities of perceiving and memorizing various visual information of the device. Taking advantage of integrated function of light perception, processing and memorization of the device, we designed and simulated a single-layer synapse array as artificial retina that enables face recognition and a hardware convolution neural network for large-scale object recognition.

Nanocomposite Materials for Flexible Electronics Xiaodong Chen; Nanyang Technological University, Singapore

Flexible sensing devices not only enrich daily lives by providing enhanced smart functions, but also provide health information by monitoring body conditions. For example, patchable sensors have the potential to better interface with human skin, thus improving the sensitivity of detection of health indicators. However, the crucial aspects toward the advancement of such sensors rely on the development of novel nanocomposites with mechanically durable materials, which allow maintaining the function under the deformed states. In this talk, I will present our latest progress on developing nanocomposite materials to building electronic skin, including manufacturing of conformal bioelectronic interfaces, conformal sensor development and their integration of individual devices into systems for sense digitalization.

11:00 AM EL18.04.02
Stretchable Light-Emitting Polymers and Devices based on Thermally Activated Delayed Fluorescence (TADF) Sihong Wang; University of Chicago, United States

The vast amount of biological mysteries and biomedical challenges faced by humans provide a prominent drive for seamlessly merging electronics with biological living systems (e.g. human bodies) to achieve long-term stable functions. Towards this trend, one of the key requirements for electronics is to possess biomimetic form factors in various aspects for achieving long-term biocompatibility. To enable such paradigm-shifting requirements, polymer-based electronics are uniquely promising for combining advanced electronic functionalities with biomimetic properties. Among all the functional materials, stretchable light-emitting materials are the key components for realizing skin-like displays and optical bio-stimulation. In this talk, I will mainly introduce our research in imparting stretchability onto "third-generation" electroluminescent polymers that can harness all the excitons through thermally activated delayed fluorescence (TADF), thereby with a theoretical near-unity quantum yield and high OLED efficiency. Our developments of fully stretchable OLED devices show the promise of achieving all the desired EL and mechanical characteristics, including high efficiency, brightness, switching speed, stretchability, and low driving voltage.

11:15 AM EL18.04.03
Neuromorphic Sensorimotor Loop Embodied by Monolithically Integrated Low-Voltage, Soft E-Skin Weichen Wang; Stanford University, United States

Artificial skin that simultaneously mimics the sensory feedback and mechanical properties of natural skin holds significant promise for next-generation robotic and medical devices. However, achieving such a biomimetic system that can seamlessly integrate with the human body remains a challenge. Through rational design and engineering of material properties, device structures, and system architectures, we realize a monolithic soft prosthetic e-skin without rigid electronic components. It is capable of multimodal sensing, neuromorphic pulse train signal generation, and closed-loop actuation. With a tri-layer high-κ elastomeric dielectric, we achieved low sub-threshold swing comparable to poly-Si transistors, low operation voltage, low static power consumption, and medium-scale circuit integration complexity for stretchable organic devices.Our e-skin mimicked the biological sensorimotor loop where a solid-state synaptic transistor elicited stronger muscle actuation when increased pressure stimuli was applied.

11:30 AM *EL18.04.04
Multifunctional Use of Electrolytic Fluid for Distributed Energy, Hydraulic Actuation, and Data Transport Robert Shepherd and Chongchan Kim; Cornell University, United States

Animals are semi-discretized. Systems of organs that perform multiple functions and are spatially discrete from each other, yet interconnected chemically and electrically. The complexity of animals such as vertebrate mammals allow for adaptation within a single generation that has allowed many examples of species that have thrived without genetic modification even during periods of significant environmental change. In the search for generally adaptive robots, useful for far field exploration missions, we believe that a similar model of complex, multifunctional, and interconnected organ systems of animals should be embraced, rather than avoided. Of course, it is not yet that simple to be complex, but we will present approaches we have used to distribute sensing, actuation, energy, and computation in soft robots. The framework we use for guiding our design evolution is Autonomous Materials, where we push the manufacturing of robots towards forming processes, and multifunctional use of material chemistry. The resulting machinery presented will be organic both in chemical makeup and subsystem analogy to organisms.

SESSION EL18.05/SB09.03: Joint Session

Novel Devices and Fabrication Techniques for Bioelectronics George G. Malliaras; University of Cambridge, United Kingdom

Bioelectronic medicine provides a new means of addressing disease via the electrical stimulation of tissues: Deep brain stimulation, for example, has shown exceptional promise in the treatment of neurological and neuropsychiatric disorders, while stimulation of peripheral nerves is being explored to treat autoimmune disorders. To bring these technologies to patients at scale, however, significant challenges remain to be addressed. Key among these is our ability to establish stable and efficient interfaces between electronics and the human body. I will show examples of how this can be achieved by leveraging novel device architectures and fabrication techniques that led to high performance under demanding conditions.

2:30 PM BREAK

3:00 PM *EL18.05/SB09.03.03
Recent Progress of Nanomesh Electrodes for Continuous Monitoring of Skin Electrical Resistance Takao Someya[1,2], Akihito Miyamoto[3], Hiroshi Kawasaki[3], Sunghoon Lee[1], Tomoyuki Yokota[1] and Masayuki Amagai[3]; [1]The University of Tokyo, Japan; [2]Riken, Japan; [3]Keio University, Japan

We report on recent progress nanomesh electrodes that can be attached directly on the skin. In particular, we have continuously monitored the skin electrical resistance by nanomesh electrodes for a long period of time while maintaining the natural skin condition that does not inhibit water evaporation. The skin electrical resistance by nanomesh electrodes is inversely proportional to the transepidermal water loss, which is widely used as a method for directly evaluating the barrier function of the stratum corneum of the skin. Although transepidermal water loss could not be measured continuously for a long period of time, we have succeeded in visualizing dynamics of skin physiological functions by monitoring of the skin electrical resistance by nanomesh electrodes for 30 hours.

3:30 PM *EL18.05/SB09.03.04
Non-Fibrotic Bioelectronics and Devices on Diverse Organs Xuanhe Zhao; Massachusetts Institute of Technology, United States

Implanted biomaterials and devices face compromised functionality and efficacy in the long-term by foreign body reaction and subsequent formation of the fibrous capsule at the implant-tissue interface. Here, we demonstrate that an adhesive implant-tissue interface can avoid fibrous capsule formation by minimizing the establishment of the inflammatory microenvironment and subsequent infiltration of inflammatory cells at the implant-tissue interface. Histological analysis shows that the adhesive implant can preserve the implant-tissue interface without fibrous capsule formation on diverse organs including the abdominal wall, colon, stomach, lung, and heart over 12 weeks in rat models in vivo. In vitro protein adsorption, multiplex Luminex assays, quantitative PCR, immunofluorescence analysis, and RNA sequencing are additionally performed to validate the hypothesis. We further demonstrate long-term bi-directional electrical communication enabled by implantable electrodes with an adhesive interface over 4 weeks in a rat model in vivo. This finding may offer a promising strategy for long-term implant-tissue interfacing without fibrous capsule formation.

4:00 PM DISCUSSION TIME

4:30 PM *EL18.10.03
Printable Stretchable Electroactive Composites for Soft Electronics Pooi See Lee; Nanyang Technological University, Singapore

Stretchable and printable conductors play a crucial role in the design of soft electronics, textile electronics and the evolution of wearable technology. We have earlier demonstrated an extremely stretchable and printable conductor with high conductivity and durable stretching cycling with the incorporation of liquid metal. Recently, we further showed that through an in-situ polymerization approach, high volume fraction of liquid metal particles can be incorporated into the composites to obtain flexible printable thermal interface materials with anisotropic thermal conductivity.[1] On the other hand, designing electroactive composites based on urethane matrix with metal flakes has led to the formation of printable stretchable conductors on textiles that can be activated by sweat. A sweat-activated battery was demonstrated with the stretchable textile conductor.[2] In order to realize stretchable ionic conductors that are self-healable and thermally stable, organohydrogel based on chemically linked ionic side chain to the polymeric gel matrix was designed and synthesized. Inkjet printing of the organohydrogel on an elastomer can lead to high interfacial toughness. Applications of the electroactive gel composite in sensing, actuation and controllable manipulation for soft electronics will be illustrated.[3]

SESSION EL18.06: Poster Session I
Session Chairs: Ho-Hsiu Chou, Francisco Molina-Lopez and Sihong Wang
Tuesday Afternoon, April 11, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM EL18.06.01
Newly Achievable Diameters of Electrospun Nanoparticle-Containing Poly(3-hexylthiophene) and Poly(ethylene oxide) Nanofibres Driven by Viscosity Reductions for Organic Photovoltaic Applications. Ryan Schofield[1], Dillon McGurty[1], Colin Johnston[1,2], Barbara Maciejewska[1], Hazel Assender[1] and Nicole Grobert[1]; [1]University of Oxford, United Kingdom; [2]Oxford Materials Characterisation Service (OMCS), United Kingdom

Limiting the environmental impact of the world's ever-increasing energy demand is among the most pressing issues of our time, and photovoltaics provide an opportunity to help fulfil this. However, the thin active layers of Organic Photovoltaics (OPVs) deliver incomplete light harvesting, and so there has been considerable research in increasing absorption. Amongst successful approaches is electrospinning nanofibres of photoactive polymers, which produces highly crystalline, aligned polymer versus their film counterparts, and has been shown to improve optical absorption in OPVs.[1,2,3]

However, exciton diffusion lengths of these materials are short, and therefore most excitons formed within large nanofibres are quenched before reaching the fibre surface for separation. Only considering exciton diffusion, the ideal nanofibre diameter would be around 20 nm. However, due to the inherent difficulty in spinning conjugated polymers, only recently have poly(3-hexylthiophene) (P3HT) nanofibres been spun with diameters < 100 nm, through the addition of poly(ethylene oxide) (PEO) and a polar co-solvent.[4]

Here, we report a method to further reduce the achievable diameters of P3HT (and PEO) nanofibres through the addition of silver/gold nanoparticles. These nanoparticles induce a dynamic non-Einsteinian reduction in viscosity, allowing thinner fibres to be spun as the solution ages. Our studies reveal the viscosity may reduce by more than 90% depending on the loading and type of nanoparticles, and the aging time. PEO nanofibre diameters can be halved, with champion nanowebs of 70 nm, 30% thinner than the state of the art.[4] In the absence of nanoparticles, solutions with this reduced viscosity would be below the critical polymer overlap concentration and produce beaded fibres. However, our fibres retain a uniform morphology suggesting the nanoparticles impede beading. After 120 hours of aging, diameters of nanoparticle-doped P3HT/PEO nanofibres can be reduced by 60%, to < 100 nm. Following the removal of PEO, we yield the first instance of electrospun plasmonic photoactive nanofibres suitable for OPV applications, and at < 80 nm, the smallest reported electrospun P3HT nanofibres.

The combination of crystalline polymer nanofibres and plasmonic nanoparticles provide a dual enhancement in light absorption, and being thinner, are expected to provide more effective charge separation. This method of 'printing' is compatible with flexible substrates and has the potential to be adapted for roll-to-roll processing.

5:00 PM EL18.06.02
Hydrogen Bonding-Controlled Transfer-Printing of PEDOT:PSS Films for Flexible and Stretchable Electronics Carla Volkert[1], Renan Colucci[1], Pol Besenius[2], Paul W. Blom[1] and Ulrike Kraft[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]Johannes Gutenberg University, Germany

The conductive polymer poly(3,4-ethylenedioxythiophene): poly(styrene sulfonate) (PEDOT:PSS) is of great interest for a variety of applications in flexible and stretchable electronics. However, to advance novel applications on appropriate substrates, innovative, and reliable methods for processing conductive polymers are still needed. Here, we present a fast, dependable, and easy PEDOT:PSS transfer printing method on flexible, transparent, and biodegradable polyvinyl alcohol (PVA) targets. In contrast to previous work, this method neither depends on acid nor doping treatments nor surface soaking treatments. Furthermore, our approach is compatible with common strategies to induce stretchability and increase the conductivity of PEDOT:PSS. Key to this method is the chemical engineering of hydrogen bonds. To adjust the mechanical properties, glycerol is incorporated in varying amounts into the PVA targets. Moreover, the water-soluble targets allow for environmental-friendly decomposition.

5:00 PM EL18.06.03
Gold Nanowire Network Electrodes for Flexible Organic Thin-Film Transistors Toward Practical Use Satoshi Takane[1,2], Yuki Noda[1], Naomi Toyoshima[1], Takafumi Uemura[1,2], Yuki Bando[1,2] and Tsuyoshi Sekitani[1,2]; [1]Osaka University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

Flexible organic thin-film transistors (OTFTs) have gained substantial interest owing to their wide range of applicability in wearable healthcare devices[1], electric skins[2], and bendable displays[3]. However, the metal thin-film electrodes used in OTFTs have several drawbacks, such as the fragility under bending strain owing to the high Young's modulus of metal[4], or the poor material and process efficiency of their formation method by the vacuum deposition. In this context, metal nanowires are a promising alternative for OTFT electrodes because of their high flexibility[5] and low-cost solution processability[6]. Among the various kinds of metal nanowires, gold nanowires (AuNWs) are most suitable for practical applications such as healthcare devices, owing to their potential air stability[7] and biocompatibility[8]. In this study, a flexible OTFT using AuNW network electrodes as source/drain/gate (AuNW-OTFT) was fabricated and characterized. For the fabrication of AuNW-OTFT, AuNW network electrodes were successfully formed on a flexible thin-film substrate using the thermal pressing transfer method. The fabricated top-gate bottom-contact AuNW-OTFT demonstrated typical p-type characteristics (mobility: 6.0×10^{-2} cm^2/Vs, on/off ratio: 10^5, threshold voltage: 1.7 V) and lower contact resistance (0.99±1.2 MΩcm) than that of an OTFT with vacuum-deposited Au electrodes in the same device configuration (12±2.3 MΩcm). Moreover, the AuNW-OTFT exhibited high mechanical durability, which was proven by the absence of significant characteristic changes before and after bending (bending radius:0.8 mm)[9].

Indacenodithiophene-Based Polymer with Polydimethylsiloxane Side Chains for Fluid Semiconductor Yuto Ochiai, Kyohei Nakano and Keisuke Tajima; RIKEN CEMS, Japan

Wearable devices such as smartwatches have become a part of our everyday life. In order to provide greater wearing comfort and motion-following performance, mechanical flexibility and elasticity are the next demands of electronic materials. Therefore, the development of new stretchable semiconductor polymer (SCP) materials that combine high electronic functionality and mechanical flexibility is attracting more attention. In general, SCPs have an extended π-conjugated structure and are highly crystalline and brittle. At the same time, the structural ordering among the molecules such as crystallinity and aggregation structure largely affects their semiconductor properties. When the ductility of the materials is desired, lowering the structural order at the multi-scale is a common option but this leads to the trade-off relationship between the semiconducting properties and the stretchability, which would be the fundamental limitation of improving the mechanical properties by using highly crystalline SCPs. On the other hand, there have been reports of SCPs such as the indacenodithiophene-benzothiadiazole (IDTBT) backbone that exhibit high semiconductor properties similar to those of conventional highly crystalline and high charge mobility SCPs, even though they adopt an almost amorphous structure in the solid state. The long alkyl side chains of IDTBT introduced in a sterically overhanging the main-chain plane could disrupt intermolecular aggregation and the π-stacking. On the other hand, the main chain has high planarity with intramolecular structural order, which was proposed to contribute to the narrow distribution of density of states in thin films. Owing to the above characteristics, IDTBT exhibits high semiconducting properties despite its amorphous nature.
In this study, we have selected the IDTBT as the backbone structure to develop an intrinsically stretchable semiconductor materials that utilize intramolecular structural ordering. We designed and synthesized the polydimethylsiloxane (PDMS) side chain introduced IDTBT (PoSi100), improving mechanical ductility and significantly inhibiting intermolecular interactions. As the result, we successfully synthesized an intrinsically stretchable SCP with high conjugation planarity using the IDTBT backbone. Furthermore, we found that the backbone planarity is maintained even in a molecular design that significantly inhibits intermolecular interactions. The PDMS side chain improves mechanical flexibility and solves the reversibility problem that has been an issue in IDTBT. Thanks to those improved mechanical properties, Posi100 exhibited very stable semiconductor properties against mechanical deformation. This work demonstrates that utilizing the backbone structural ordering is an effective molecular design for creating novel semiconducting polymers with intrinsic stretchability.

5:00 PM EL18.06.05
Battery-Free, Wireless, Ionic Liquid Sensor Arrays for Continuous Monitoring of Pressure and Temperature at Skin Interfaces of Patients in Bed and Wheelchair Hyeonseok Han[1], Yong Suk Oh[1,2], Seokjoo Cho[1] and Inkyu Park[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Changwon National University, Korea (the Republic of)

Pressure injuries are a wound caused by prolonged pressure on skin tissue, deteriorated by an increase in local skin temperature. For the prevention of pressure injuries, clinical practice guidelines, recommended by the National Pressure Injury Advisory Panel (NPIAP), involve repositioning at regular intervals. However, frequent repositioning leads to decreasing the quality of sleep in patients, increasing a high risk for back pain or musculoskeletal injuries for patients or caregivers.

Recent advances in technologies of wireless platform offer physiological signals for prevention, diagnosis, and treatment of diseases at early stage. Among the wireless platforms with multimodal sensors, Near Field Communication (NFC) platforms have great potential for continuous monitoring of pressure and temperature at skin interfaces without a risk of secondary injuries caused by bulky batteries. However, it is challenging to continuously measure pressures with high accuracy and reliability on locations of interest due to a mismatch between the effective area of body weight and the interfacial area of the single sensor. A few reports suggest several pressure sensor arrays for measurement of pressure distribution at locations of interest. In this context, sensor arrays integrated with the NFC platforms and systems can support capabilities for continuous monitoring of pressure distribution at skin interfaces over full body coverage for long term monitoring.

For clinical applications, the pressure sensor should have a thin, soft form factor for conformal, irritation-free contact to skin, excellent sensitivity, negligible hysteresis, high linearity and cyclic stability over required pressure range. Furthermore, by collecting the pressure sensors in proximity to one another or using the pressure sensor arrays, capabilities for accurate, reliable, and continuous measurement of pressure distribution can provide a quantitative basis for the guideline of appropriate repositioning to resolve the issues associated with the mismatch in effective area. In addition, spatial temperature distribution measured on the skin surface can serve as one of additional indicators related to the skin breakdown arising from an increase in tissue metabolism and oxygen consumption.

This paper introduces a method for continuous multi-site monitoring of pressure and temperature distribution from strategically deployed sensor array at critical skin interfaces via a battery-free, wireless ionic liquid pressure sensor. The pressure sensor based on an internal flow of ionic liquid filled inside a roof collapsed microchannel shows excellent sensitivity as well as negligible hysteresis, high linearity, and cyclic stability over relevant pressure range. The characteristics of the sensor integrated with the NFC platform, verified by experimental measurement and numerical simulation, present technical foundations. In addition, the strategic deployment of the wireless, multiple devices in proximity to one another mounted at different locations of curved skin provides continuous, quantitative information for simultaneously capturing pressure and temperature distribution under change in posture. Clinical trials on two hemiplegic patients demonstrate the feasibility of the sensor arrays for decreasing local pressures and temperatures of patient under minimal repositioning confined on bed or wheelchair integrated with the battery-free, wireless system by providing medical staffs with accurate, statistical information of pressure and temperature at locations of interest in real time. The collected data support the medical team to achieve cost effective pressure relief (e.g., minimal repositioning) in respect of labor force, time, and disease management without frequent repositioning or rolling the whole body of the subject, which leads to a high risk for back pain or musculoskeletal injuries.

5:00 PM EL18.06.07
Large-area Ultrasonic Spray Deposition and Rapid Plasma Curing of Transparent Conducting Oxides for Printable Electronics Thomas W. Colburn, David W. Collinson and Reinhold H. Dauskardt; Stanford University, United States

Indium tin oxide (ITO), fluorine-doped tin oxide (FTO), and other transparent conducting oxides (TCOs) are pivotally important as electrode layers in optoelectronic devices. ITO thin-films have remained vital as n-type electrodes for perovskite solar cells, organic LEDs, and transparent flexible electronics. Commonly implemented solution based deposition methods of TCOs such as sol-gel processing utilize lengthy and thermally-intensive anneals at temperatures >400 °C which prevent high-throughput manufacturing and limit possible substrates for flexible applications. Sol-gel produced TCOs can also struggle from lower conductivity and lower film density which can inhibit performance as an electrode. As a result, sputtered TCOs are commonly used to generate films on both rigid and flexible substrates at the sacrifice of cost and throughput.

With growing interest in scalable manufacturing of large area electronics at lower fabrication costs, next-generation thin-film deposition techniques are required to mitigate the thermally and capital-intensive demands of traditional sol-gel and vacuum-based processes. Here, we present a fully vacuum-free, rapid deposition of large area TCOs utilizing ultrasonic spray printing at 10 m/min followed by a 5-10 minute forming gas plasma anneal to yield ITO thin-films with high figures of merit and low roughness. The spray deposition utilizes a solution containing metal nitrates and acetylacetonate salts with a chelating fuel source. The fuel source and nitrate ion reduce the required applied temperatures for solution fabrication by providing a local in-film energy source that is capable of yielding oxidation at temperatures as low as 200 °C. The cure is followed by an open-air forming gas plasma treatment to introduce oxygen vacancies and additional electron charge carriers. The resulting films on glass, with areas over 18 cm^2, have Haack figures of merit >9x10^{-3} 1/Ω with average transparencies >90% in the visible spectrum and sheet resistances of <40 Ω/■. Transferring the deposition approach to flexible substrates such as polyimide is the focus of on-going efforts. The resulting manufacturing platform allows for the rapid, open-air fabrication of TCOs on large areas as electrode layers and substrates for printable, flexible electronics.

5:00 PM EL18.06.08
Excitonic Transitions from the Γ to Γ and Γ to X Valleys in Surface Passivated $In_{1-x}Ga_xP$/ZnS Colloidal Quantum Dots Aritrajit Gupta[1], Justin Ondry[1], Margaret H. Hudson[1], Min Chen[1], Richard D. Schaller[2,3] and Dmitri V. Talapin[1,2]; [1]University of Chicago, United States; [2]Argonne National Laboratory, United States; [3]Northwestern University, United States

Crystal momentum k is not a good quantum number to describe band structures in quantum confined nanocrystalline systems, thereby blurring the distinction between direct and indirect semiconductors as conventionally defined in the bulk. A transition to indirect behavior in bulk $In_{1-x}Ga_xP$ alloyed phases with higher gallium content is well documented. However, the effect of quantum confinement on the direct to indirect transition in this system has yet to be established, because high-quality colloidal nanocrystal samples have remained inaccessible. Herein we report a molten salt In-to-Ga cation exchange to prepare $In_{1-x}Ga_xP$ nanocrystals and subsequent ZnS shelling protocol to achieve high radiative efficiency. The synthesis is rigorously oxygen-free, allowing us to obtain bright $In_{1-x}Ga_xP$/ZnS core-shell particles of decent emission color purity with photoluminescence quantum yields exceeding 80% and PL emission linewidths as narrow as 50 nm FWHM. Steady-state and time-resolved photoluminescence studies indicate that radiative decay lifetime in these highly emissive samples increases monotonically while the quantum yield decreases with higher gallium content. Transient absorption studies on these core-shell nanocrystals allow us to establish direct or indirect-like behavior in these samples in terms of the presence or absence of excitonic bleach features. These insights allow us to establish cation exchange in molten inorganic salts as a viable route towards synthesizing nontoxic high quality $In_{1-x}Ga_xP$/ZnS QD emitters with desirable optoelectronic properties.

5:00 PM EL18.06.10
In-Plane Electric Field Driven, Stretchable Alternating Current Electroluminescent Devices Seongkyu Song and Soon Moon Jeong; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Although significant progress has been made in the development of new techniques for emerging electroluminescent devices, leading to various technologies such as soft robots, actuators, flexible/stretchable/wearable electronics, and self-healable devices, most of the reported devices have coplanar structures, which require planar electrodes and a thin emitting layer (EML). This is particularly challenging in the case of stretchable electroluminescent devices, which require electrodes exhibiting both high transmittance and low resistance even in the stretchable state since thin EMLs have a low tolerance to external mechanical deformations. Here, we report an in-plane electric-field-driven, stretchable composite system capable of simultaneously producing intense electroluminescence and mechanoluminescence under an electromechanical stimulus.[1] The patterned silver-nanowires-array embedded into the PDMS-supported ZnS:Cu layer (ZnS:Cu/PDMS) used as an electrode in our device offers a unique advantage, that is, because the in-plane electric field generates electroluminescence in the EML, light need not be transmitted by the electrode.[2] This obviates the need of electrodes with high transmittance and stretchability. Furthermore, the in-plane electric field is unaffected by the ZnS:Cu/PDMS thickness; thus, a thick EML can be used, which contributes

to both electroluminescence and mechanoluminescence. Using the thick EML, a significantly high electroluminescence luminance (a factor of 2.08-3.79 compared to that of a coplanar-structured device) and high brightness of 1,324 cd/m^2 at 9.12 V/μm were achieved, which indicate that the electric field expands throughout the thick EML. Furthermore, the device with the thick EML exhibits strong mechanoluminescence and good durability under the simultaneous application of electromechanical stimulus. Our results represent a breakthrough in electroluminescence and mechanoluminescence research and that our findings provide important insights for the development of novel multimodal functional light sources, leading to unprecedented applications.

5:00 PM EL18.06.11
Gate-Deterministic Remote Doping Enables Highly Retentive Graphene-MXene Hybrid Memory Devices on Plastic Yonghyun A. Kwon, Seonkwon Kim, Soo Young Cho, Jung Woo Moon, InCheol Kwak, Dong Gue Roe, Seonmi Eom and Jeong Ho Cho; Yonsei University, Korea (the Republic of)

In this work, a highly retentive and synaptic-functional transistor memory device architecture based on the gate-deterministic remote doping of graphene via surface-oxidized $Ti_3C_2T_X$ MXene nano-floating-gates (NFG) is presented. By using solution-phase size-sorting followed by controlled surface oxidation process, a regulated distribution of MXene nanoflakes comprising metallic $Ti_3C_2T_X$ as the core surrounded by TiO_2-a high dielectric constant insulator-as the shell is achieved. The size-sorted core/shell-like MXene nanoflakes show a self-sustainable charge trapping/detrapping behavior, which is highly feasible for realizing non-embed NFGs for transistor memory devices. Interestingly, unlike the conventional NFG-embedded architecture, the introduction of core/shell-like MXene under an electrolyte-gated graphene field-effect transistor (GFET) architecture induces a cooperative evolution of the hysteresis loop associated with ionic motion in the electrolyte gates and charge trapping/detrapping in the nanoflakes, resulting in a deterministic remote doping of the graphene layer. The resulting device exhibited a highly retentive memory behavior, which can be optimized by the nanoflake size distribution. In addition, synaptic functions having mechanical flexibility can be successfully emulated using MXene-based GFETs fabricated on a flexible polyethylene naphthalate substrate.

5:00 PM EL18.06.12
Ultrasensitive and Shape-Reconfigurable Smart Strain Sensor with Tunable Sensitivity and Selectivity Seungjae Lee, Youngoh Lee, Cheolhong Park and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Bio-inspired sensors, mimicking the unique structures and superior sensory functions of natural creatures, have attracted intense research interests for applications in wearable devices, robotics, and human-machine interfaces (HMIs). Recently, inspired by the spider mechanosensory system, crack-based strain sensors have attracted intense interests due to high sensitivity and easy fabrication. However, previous strain sensors based on the randomly distributed cracks have limited sensitivity, strain range, and reproducibility. For a wide range of application, the ability to tune the sensitivity is important. Previously reported strain sensors with tunable sensitivities showed not only high sensitivity under low tensile strain, but also high stretchability over wide range. However, tunable sensitivities were not achieved in a single sensor and multiple sensors with different sensitivities were required. Tuning sensitivities in a single sensor in a simple way is required for diverse applications. For the ultrahigh sensitivity with tunable sensitivities in a single sensor, we propose a new design of crack-based strain sensor. Firstly, to increase the sensitivity under subtle stimuli, we utilized rectangular patterned cracks by introducing the nanoscale line pattern on the sensor, which allowed the precise control of crack, resulting in an ultra-high gauge factor (GF) of 2.23×10^9 at 2% strains. Secondly, for the tunable sensitivities in a single sensor, we employed a thermo-responsive shape memory polymer (SMP) as a stretchable substrate. As the SMP can be programmed into a temporary shape and recover back to the original shape in response to thermal stimuli, the crack asperity can be precisely adjusted, affecting the initial resistance and the resulting final sensitivity. Under 1% strain, the sensitivity increased after shape reconfiguration (GF = 3.54×10^7) and recovered to the original value (GF = 1.11×10^6). Our ultrasensitive smart strain sensor with tunable sensitivity can be applied to acoustic sound detection with the increased signal-to-noise ratio and rapid response time of 0.025 ms at high acoustic frequencies. Furthermore, it can be applied in wearable healthcare applications, including devices monitoring various human body signals.

5:00 PM EL18.06.13
Low Voltage Organic Transistors with Carrier Mobilities over 10 cm^{2}V^{-2}s^{-1} Using Six-Branched Organic Azide with Ultrahigh Crosslinking Efficiency Myeongjae Lee[1], Byung-il Choi[2], Jeong Ho Cho[3] and BongSoo Kim[4]; [1]Korea University, Korea (the Republic of); [2]Korea Testing & Research Institute, Korea (the Republic of); [3]Yonsei University, Korea (the Republic of); [4]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of)

The great demand for flexible and wearable electronics over the past few years has led to the development of solution-processable organic thin film transistors (OTFTs) possessing the outstanding advantages of large area, low cost, low processing temperature, and mechanical flexibility. To fabricate OTFTs in an industrial level, following requirements should be met: high carrier mobility, low-voltage-operation, compatibility with reliable high-resolution patterning process, and high mechanical and electrical stability. Here, we report the synthesis of six-branched crosslinker (6Bx) having an ultrahigh photo-crosslinking efficiency and its application to photo-patterning gate dielectric (GD) polymers and channel semiconducting (CS) polymers in polymer-based OTFTs. The use of 6Bx permits the generation of a high-resolution-patterned ultra-thin polymer gate dielectric with a low leakage current (7×10^{-9} A cm^{-2} at 1 MV cm^{-1}). Moreover, crosslinking the GD polymer interfaced with *p*- or *n*-type CS polymer induces alignment of CS polymer chains at the interface. This yields excellent hole and electron mobilities of 12.42 and 10.11 cm^2 V^{-1}s^{-1}, respectively, from p- and *n*-type OTFTs operated at < 3 V, which are remarkably improved carrier mobilities at substantially low operation voltages compared to those by conventional test beds. Further, the fabrication of logic gates and ring oscillators demonstrates the reliability of polymer OTFTs crosslinked with 6Bx. This work presents a universal strategy for high mobility, reliable, and low-voltage-operating OTFTs.

5:00 PM EL18.06.14
The Applications of van der Waals Assembly method in Solution-Processed Organic Monolayer Single-Crystals Transistor Zhenfei He[1] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, Hong Kong; [2]Advanced Biomedical Instrumentation Centre, Hong Kong

Solution-processed large-area 2D organic single crystals with high mobility, low contact resistance, and good uniformity, are decent players for high-performance organic field-effect transistors (OFETs). However, the deposition of large-area high-quality crystals is still challenging on various substrates because of the strict requirements on substrate conditions such as roughness, surface energy, and chemical compatibility. Besides, the thermal damage at the metal deposition would cause defects in the 2D organic crystals and hurt the device's performance. To overcome these compatibility issues during the fabrication process, we introduce a damage-free, mediate layer-assisted OFET van der Waals assembly method for as-grown, high-quality 2D crystals. First, we would introduce some applications of our van der Waals assembly method for the bottom gate top contact device structure. The assembled monolayer 2,9-Didecyldinaphtho[2,3-b:2',3'-f]thieno[3,2-b]thiophene (C_{10}-DNTT) OFET device with SiO_2/ octadecyl trichlorosilane (OTS) dielectric exhibits high mobility of 10.4 cm^{2}V^{-1}s^{-1} which is comparable to as-grown crystals. We further assembled monolayer C_{10}-DNTT to a hydrophobic dielectric where is hard to direct solution shearing. The bias stress stability of OFET gets significantly improved from a 55% current change to a 12% change for 10000 s bias stress on this high-κ hydrophobic dielectric with low trap state density and a small subthreshold swing (SS) of 63 mV/decade is achieved. Our

assembly method is suitable for the advanced circuit, and a depletion-mode flexible inverter with a high gain of 650 under the low power voltage of 4 V is demonstrated. We integrated this low operating voltage organic amplifier with gel electrodes as a potable Electrocardiography (ECG) sensor, which could be powered by coin cells. With a high signal-to-noise ratio of 34 dB, this sensor could detect a clear ECG pattern for diagnosis. It is believed that our ECG sensor manifests the prospect of continuous monitoring for human health management.
Second, we would explore the 2D organic semiconductor in the OFET device structure of bottom gate bottom contact. Bottom-contact device structure with a ramp source/drain contact edge, which favors side-wall injection, is a promising structure to break the bottleneck of contact resistance in OFET. However, this pre-patterned bottom-contact substrate would affect the crystallinity of the 2D organic crystals during the solution shearing. Our van der Waals assembly method is a decent technique to overcome this issue. Here, we would compare the contact resistance at the bottom-contact structure between the direct solution shearing and the assembly method and study the contact interface by electron microscope. We would treat the source/drain electrodes with various self-assembled monolayers (SAMs) to modify the work function and study the fermi-level pinning effect in 2D organic single crystals. We believe our work would offer some evidence to strengthen the faith in contact resistance improvement.

5:00 PM EL18.06.15
Synthesis and Characterization of Arylic Pressure Sensitive Adhesive with Novel Silane Derivatives based on Ethylene Glycol Chain for Foldable/Flexible Application Min Hye Seo, Ju Hui Kang, SangKug Lee and Ho Jun Song; Korea Institute of Industrial Technology, Korea (the Republic of)

Pressure sensitive adhesives (PSAs) are representative viscoelastic materials. Due to unique adhesion characteristics, PSAs have been widely used to the various application fields such as for electric/electronic process films, heat-resistant protection, display protection liquid crystal films and medical film. The acrylic PSA has excellent transparency and heat resistance, and is composed of soft segment, hard segment and functional segment. The soft segment affects the flexibility. The hard segment determines the cohesive properties of the adhesive. The functional segment determines its physical properties. It is easy to control the properties of PSA through processes such as the composition of the functional monomers. In this study, we designed and synthesized a novel acrylic PSA by introducing a silane group to an ethylene glycol-based acrylate and photopolymerization method. For silane acrylate, the chain length was controlled by using an ethylene glycol group. Introduction of silane group at the end of the structure would exhibit improved modulus property of acrylic PSA. The molecular weight of the synthesized PSA without silane acrylate is 870,000 g/mol (based on Mw), which increases to 1,140,000–1,440,000 g/mol upon adding the silane acrylates. the synthesized PSA showed the storage modulus of the high-temperature region because of hydrogen bonds of silane moiety. In the case of 100% strain of 3 wt% DESGA film, it showed excellent shear recovery properties of 96.7% because of the hydrogen bonding of the silane groups.

Computational Fluid Dynamics of Slot Die Coating of Alumina Nanoparticle Suspension for Ceramic 3D Printing Jeonghong Ha and Jong Wan Ko; Korea Institute of Industrial Technology, Korea (the Republic of)

Additive manufacturing of ceramics can be classified as slurry-based, powder-based, and bulk solid-based methods depending on the feedstock type. Among them, the slurry-based AM methods can obtain high-density ceramic parts by controlling the content of ceramic powder and the viscosity of the solvent. The coating quality of the slurry significantly greatly affects the final quality of slurry-based 3D printing parts [1]. A slot die coating is a coating method in which slit-shaped nozzle moves on a substrate with ejecting the slurry to form a film, and is mainly used for application of high-viscosity ceramic slurries. Slurry properties such as viscosity, contact angle, and surface tension, coater operating conditions such as feed rate and coating interval, and die shape such as die lip angle, die lip length, and nozzle spacing are the main variables that determine the coating quality [2]. In this study, the coating properties in the ceramic slurry coating process using the slot die coating method were evaluated using computational fluid dynamics. Coating characteristics was analyzed depending on the operating conditions of the coater, and process window was derived to obtain the uniform thickness of the ceramic slurry layer.

Printable Carbon Nanotube-Cellulose Ink Devices for Rapid Liquid Identification Rodrigo G. Lacerda; Univ Federal de Minas Gerais, Brazil

The development of a new generation of smart sensors that allow monitoring of industrial processes in real-time, and of wearable and flexible devices are paradigms of the current 4.0 industry. One can envision applications such as multi-component complex liquid and gas sensors, wearables for healthcare, paper-based sensors, and electronic solutions for Smart city applications. Another area of increasing demand is the rapid test, identification and monitoring of various liquid samples in various fields such as fuel adulteration, water quality, solvents and beverages. Usually, liquid testing requires conventional analytical techniques, such as absorption/emission spectroscopy (AAS/AES), X-ray fluorescence spectroscopy, and inductively coupled plasma mass spectrometry (ICP-MS), which are complex, expensive and require experts to carry them out (and often require several pretreatment steps with high-cost materials). Electronic tongue is a category of liquid sensor that could solve the problems cited. These devices comprise an array of non-specific sensors that, with an appropriate method of multiple data processing, learn and extract the desired information, constituting one of the promising candidates for developing smart sensor technologies. Additionally, the Internet of Things (IoT) also requires devices to be integrated into a variety of systems and different surfaces of our daily life, which demands the production of low-cost, reliable, and scaled-up production of sensors. However, the lack of reproducible large-scale production of liquid sensors, besides the constant need for sensor recalibration, has hindered broader commercialization of such devices.
Ink printing technology is one of the most promising approaches to fulfill all the demands and issues described above, which naturally leads to the challenge of developing new smart-ink-based materials for several applications. carbon nanotube ink films have been reported as field-effect transistors, transparent conductors, gas sensors, supercapacitors, pH sensing, among others. Different approaches to ink printing methods have been explored, such as aerosol jet, inkjet, syringe, roll-to-roll printing and stamp methods. It is also important to point out that scalable production methods for the growth and functionalization of carbon nanotubes would significantly reduce costs and make workable a printing technology based on this material.
In this work, a conductive ink based on micro fibrillated cellulose (MFC) and multi-walled carbon nanotubes (MWCNT) was used to produce transducers for rapid liquid identification. The transducers are simple resistive devices that can be easily fabricated by scalable printing techniques. We monitored the electrical response due to the interaction between a given liquid with the carbon nanotube-cellulose film over time. Using principal component analysis of the electrical response, we were able to extract robust data used to differentiate several liquid categories. We show that the proposed liquid sensor can classify different liquid systems, includingorganic solvents (e.g., acetone, chloroform, and alcohol) and is also able to differentiate low concentrations of glycerin in water (10-100 PPM). We have also investigated the influence of two vital liquid properties: dielectric constant and vapor pressure on the physical transduction mechanisms of MFC-MWCNT sensors, which were corroborated by independent heat flow measurements (thermogravimetric analysis). The proposed MFC-MWCNT sensor platform may help paving the way to rapid, inexpensive, and robust liquid analysis and identification. Our

flexible MFC-MWCNT ink can provide a step forward towards scale-up and commercialization of the technology that involves liquid identification and monitor of mechanical stress.

Open-Air Spray Deposition of Ultrathin Organic Bathocuproine Layers for Printed Electronics Justin P. Chen, Juliet Risner-Jamtgaard, Thomas W. Colburn, Margarita Golding and Reinhold H. Dauskardt; Stanford University, United States

Bathocuproine (BCP) is a small organic molecule that is typically used as an ultrathin hole blocking interlayer (< 10 nm thickness) in organic solar cells and perovskite solar cells. A popular method for BCP film deposition relies on a lengthy and expensive vacuum thermal evaporation process that introduces scalability challenges and high capital equipment costs at large-scale manufacturing levels. Solution spincoating is another method for BCP film deposition on small substrates, but it is incompatible with large-scale and in-line roll-to-roll manufacturing. Open-air ultrasonic solution spray deposition is an attractive alternative method utilizing only simple and low-cost equipment that is compatible with flexible substrates and roll-to-roll processing in large-area industrial fabrication.
We report on the successful open-air, room temperature ultrasonic spray deposition of an ultrathin (<7 nm) and highly transparent BCP film with low roughness. Unlike evaporated films that have an *in-situ* Quartz Crystal Monitor to measure film thickness, solution-processed BCP films lack a convenient film thickness metrology. We combine a suite of characterization techniques that span a range of equipment complexity, measurement time, and measurement sensitivity including: Ellipsometry, X-Ray Reflectivity, Angle-Resolved X-ray Photon Spectroscopy, Auger Spectroscopy, and Transmission Electron Microscopy. We discuss the advantages and disadvantages of each characterization technique but find strong agreement across this multi-faceted approach. Finally, we demonstrate our spray deposition technique by fabricating BCP films on perovskite solar cells at high-throughput linear processing speeds of up to 9 m/min and achieve solar power conversion efficiencies >18%.

5:00 PM EL18.06.21
Context Aware Mechanics and Electromagnetics for Chronically Wearable Devices Philipp Gutruf; University of Arizona, United States

The concept of digital medicine, which relies on streams of continuous information from the body to gain insight into health status, manage disease and predict onset health problems, is currently relying on biosensors with limited capabilities.[1][2] Key technological hurdles that slow the proliferation of this approach are means by which clinical grade biosingals are continuously obtained without frequent user interaction.[3] To overcome these hurdles, solutions in power supply and interface strategies that maintain high fidelity readouts and function chronically are critical. Current approaches for high fidelity recordings typically rely on adhesive interfaces that are subject to epidermal turnover, limiting sensor lifetime. Additionally, they rely on electrochemical power supplies which are subject to frequent recharge, add bulk and weight, require user interaction and introduce motion artefacts. Here we introduce a new class of devices that overcomes the limitations of current approaches by utilizing context aware mechanical and electromagnetic design facilitated through digital to create unique personalized devices optimized to the wearer. Specifically, we introduce new methods to use behavioral analysis of a user group to shape design to enable indefinite device lifetimes.[4] These elastomeric, 3D printed and laser structured constructs, called biosymbiotic devices, enable adhesive-free interfaces and the inclusion of high performance, far field energy harvesting to facilitate continuous wireless and battery-free operation of multimodal and multi device, high-fidelity biosensing in an at-home setting without user interaction. We present devices that can operate over weeks at the time, enable new sensing paradigms such as circumferential muscle strain, high fidelity absolute position sensing, mK resolution thermography and 3D printed optofluidics to capture an encompassing and evolving record of health.

Crack Suppression of Cu Interconnect by Twin Engineering for Improving Reliability of Flexible Devices Seongi Lee[1], Jun-Hyeok Hyun[2], Sang-Ha Shin[2], Eun-Jung Kim[2], Youngchang Joo[1] and So-Yeon Lee[2]; [1]Seoul National University, Korea (the Republic of); [2]Kumoh institute of Technology, Korea (the Republic of)

Recently, as the form factor of electronic devices has been diversified, the demand for commercialized flexible devices is rapidly increasing. Compared to rigid devices, flexible devices are much more susceptible to performance degradation and device failure because flexible devices cannot avoid fatigue deformation such as bending or stretching. In addition, flexible devices are evolving to have a large strain. For example, in the case of bending deformation, it is evolving toward reducing the bending radius. Therefore, the reliability of flexible devices is drawing great attention from the electronics industry and the design and fabrication of reliable flexible electrodes is one of the most important challenges these days.

In this study, we designed a fatigue crack-free Cu interconnect by introducing twin boundaries through alloying. We adapted alloying method for twin engineering because alloying can lower the stacking fault energy of the material, resulting in both growth twin and deformation twin in the material. The Cu-Al alloy interconnect was fabricated by Chip-On-Target sputtering method with a thickness of 150 nm on the polyimide substrate. A sliding bending test of 100,000 cycles (5 Hz) was carried out for fatigue deformation, and we applied various bending strains to the interconnects. Comparing to pristine Cu interconnect, Cu-Al 1.5 at. % interconnect showed 70 % decrease at the resistance change under bending strain with 1.5%. Moreover, the crack was not observed in the Cu-Al interconnect after the 100,000 bending cycles. We analyzed the microstructure of the Cu-Al interconnect before and after deformation, and observed grain refinement by twin-dislocation interaction during bending fatigue deformation. Based on the microstructure analysis, we can infer that the low stacking fault energy of Cu-Al induced abundant twin boundaries which generate microstructural change instead of surface cracking for the release of deformation energy, the Cu-Al interconnect shows low electrical change during bending fatigue. We suggest that the low amount of alloying of Al at Cu for lowering stacking fault energy can be an attractive solution for the reliability of the flexible device.

Highly Conductive and Strain-insensitive Nanocomposite Enabled by Adaptive Organization of Silver Nanomaterials Chansul Park and Dae-Hyeong Kim; Seoul National University, Korea (the Republic of)

Skin electronics require a stretchable conductor whose resistance is invariable under repetitive skin deformations. However, obtaining such a strain-insensitive electrode with high conductivity is challenging because those two properties have been considered mutually exclusive. Here we report on the highly conductive and strain-insensitive nanocomposite enabled by adaptive organization of nanomaterials. The nanocomposite is composed of multi-dimensional surface-modified silver nanomaterials and block copolymer elastomers. The surface modification of nanomaterials with 1-alkanethiols enables them to have mobility in viscoelastic matrix. The movable nanomaterials can be organized in the ordered form along various strain conditions. The organization of silver nanomaterials can stably maintain percolation networks, minimizing resistance change of nanocomposite. When multi-dimensional nanomaterials are mixed in an appropriate combination, the nanocomposite exhibits the negligible resistance variation (< 1% under 1000 cycles of 50% strain) under various strain conditions while attaining high conductivity of ~30,000 S/cm.

5:00 PM EL18.06.24

Origin of Improved Performance in Insulating Polymer Blend Organic Thin-Film Transistors Based on *mono*-Alkylated BTNTs Ryo Miyata[1], Satoru Inoue[1], Ken Nakajima[2] and Tatsuo Hasegawa[1]; [1]Tokyo University, Japan; [2]Tokyo Institute of Technology, Japan

In recent years, there has been significant progress in the development of a class of organic semiconductors (OSCs) composed of rod-like π-electron cores linked with alkyl chains, which show high layered crystallinity and are useful to produce high-performance organic thin-film transistors (TFTs)[1,2]. The materials are solution-processable and are expected to allow device processing under ambient temperature and pressure. A particular example is monoalkylated benzothieno[3,2-*b*]naphtho[2,3-*b*]thiophenes (*mono*-C_n-BTNTs) that present excellent solubility and thermal durability, showing high intrinsic field-effect mobility exceeding 10 $cm^2V^{-1}s^{-1}$ in the form of single-crystal TFTs [3]. However, the application of these OSCs is still limited in terms of the practical fabrications because the single-crystal thin films require a long time to produce. By contrast, polycrystalline thin films can be fabricated by simple methods, such as spin coating, although the device mobility of polycrystalline TFTs has degraded to 1/10 that of single-crystal TFTs.
We here focus on the trade-off problem: Is it possible to achieve compatibility between enhancing TFT performance and fabricating practical TFTs? We found that using binary blends of an insulating polymer and the OSC demonstrated that polycrystalline TFTs exhibit high mobility exceeding 4 $cm^2V^{-1}s^{-1}$, very sharp switching characteristics with the subthreshold swing of about 180 mV/dec, and small device-to-device variations in low-voltage operations [4]. Additionally, these polymer blended TFTs can be fabricated simply by combining spin coating and thermal annealing. The achieved performances of the polycrystalline TFTs are comparable to the highest level that has been reported so far[5,6]. To elucidate the origin of the improved TFT performances, we measured thin film morphology by bimodal atomic force microscopy (AFM) and investigated the effect of contact resistances on TFT performances by Kelvin probe force microscopy (KPFM). We successfully revealed the origin of improved performances in the polymer blended TFTs, where the phase-separated structure, formed spontaneously between the OSC and polymer, takes critical roles in obtaining enhanced TFT performances.
We utilized 2-C8-BTNT as the OSC and poly(methyl methacrylate) (PMMA) or polystyrene (PS) as insulating polymers. We fabricated bottom-gate bottom-contact TFTs by vacuum deposition of Au electrodes on SiO_2/Si substrates, followed by spin-coating and thermal annealing with the polymer-blended solutions. As a result, it was found that the TFT performances were found to be most enhanced when we blended PMMA into the OSC solution. We analyzed the phase separation structure of OSC/PMMA blended thin film and the origin of enhanced performances by bimodal AFM and KPFM. It reveals that the PMMA blend system exhibited well-defined vertical phase separation (top OSC layer/bottom PMMA layer). Constructing this phase separation structure enables forming a well-ordered and homogeneous semiconducting layer over a large area, which can maximize the electrical performances in polymer blended TFTs. We believe these findings are significant as they should accelerate the realization of printed electronics using high-performance printed organic TFTs.

Comparison of Ultraviolet-Initiated Crosslinkable Additives for Improved Stability in Organic Solar Cells by Modulating Main Chains Yelim Choi, Dae Hwan Lee and Taiho Park; Pohang University of Science and Technology, Korea (the Republic of)

UV-initiated crosslinkable additives in organic solar cells have the potential to fix metastable bulk heterojunction, hence resolving issues of burn-in loss and long-term instability. We present useful application for crosslinkable additives as solvent additives, radical scavengers, and stretchability enhancers and crosslinkers according to its main chain structure between -Br in end groups. We separated crosslinkable additive into two types of alkyl and siloxane main chain, predicting distinct roles. Initially, 1,8-dibromooctane (DBr-octane) provides enhanced thermal and light stability without sacrificing efficiency in fullerene system. The DBr-octane devices revealed burn-in free performance, maintaining 90% of their original efficiency after 600 miniutes at 85 degree celsius, and light stability, keeping 90% of their initial efficiency after 360 minutes under 1 SUN. To ensure stretchability, we treated crosslinkable additive with the siloxane main chain molecule, bis(3-bromopropyl)-terminated poly(dimethyl siloxane) (DBr-siloxane), in the active layer. After 1000 bending cycles at a bending radius of 1.8 mm, the DBr-siloxane-treated film stretched up to 70%, meanwhile the flexible device of the fullerene system maintained an initial efficiency of over 60%.

Highly Stretchable and Positive-Piezoconductive Silicone Composite Using Nickel Powder and Ionic Liquids Yuji Isano, Ryosuke Matsuda and Hiroki Ota; Yokohama National University, Japan

In this study, a new conductive rubber with positive piezoconductivity, whose conductivity increases 10 million times with tensile strain, and which can be elongated by up to 600%, is proposed. The proposed material consists of silicone (Ecoflex00-30) as a matrix, nickel powder as a filler, and ionic liquid as an additive. In previous studies, maximum extensibility of only 100% was achieved because the matrix elasticity was limited by the large amount of conductive material required for the positive piezoconductivity. In this study, Positive piezoelectric conductivity due to the inclusion of a large amount of filler and high stretchability were both achieved by the gelation of silicone by the addition of ionic liquid, which caused an increase in the matrix stretchability.

Conductive rubber is a composite of stretchable rubber and conductive filler, like carbon nanotube, graphene, and metal particles. This material has elasticity due to the rubber and conductivity due to the filler. Therefore, the material is used for wearable devices and soft robotics.

In general, conductive rubbers decrease in conductivity with elongation. This is caused by the breakdown of electrical contact between conductive particles inside the conductive rubber as it elongates. This property is called negative piezoconductivity. Conductive rubbers with negative piezoelectric conductivity can be used as strain sensors by measuring their resistance, and are utilized for feedback control in wearable devices and soft robots.

On the contrary, conductive rubbers with positive piezoconductivity, whose conductivity increases with elongation, have also been studied. Some of them show a rapid increase in conductivity under tensile strain. These positive piezoconductive rubbers are used as strain sensors as well as those with negative piezoconductivity, or as switches in stretchable circuits that take advantage of the rapid change in conductivity.

However, it is necessary to mix a large amount of conductive filler to induce a sufficient resistance change as a circuit element for a positive piezoconductive rubber. On the other hand, an increase in the amount of conductive filler mixed with the rubber material causes a decrease in the elasticity of the overall composite. Therefore, both sufficient conductivity enhancement by strain and high elasticity are required for positive piezoconductive materials for applications with high deformability, such as stretchable devices and soft robots.

The conductive rubber developed in this studyas a maximum elongation of 600%, comparable to that of raw silicon rubber, in spite of holding three times as much Ni powder as rubber by mass. This occurs due to the ionic liquid being held in the silicone rubber in a liquid state.

The conductivity of stretched composite was increased 10 million times higher than the non-stretched condition. The increase in conductivity can be explained by the decrease in composite cross-sectional area due to tensile strain, which caused the aggregation of Ni powder. In addition, the elongation ratio at which the resistance drop begins can be controlled according to the mass of Ni powder contained inside.

The composite was demonstrated for application to soft robots and wearable devices. The composite was incorporated into an electrical circuit to read the deformation of the soft robot and elbow bending in a single series circuit. Unlike existing conductive rubbers with negative piezoelectric conductivity, which require an external evaluation circuit to switch by strain, the conductive rubbers developed in this study realized a switch by elongation without an external circuit.

5:00 PM EL18.06.29
Stability of Ternary Interfaces in Printed Organic Thin-Film Transistors Showing Extremely Sharp Switching Operation Keito Murata[1], Gyo Kitahara[1], Satoru Inoue[1], Toshiki Higashino[2], Satoshi Matsuoka[1], Shunto Arai[1], Reiji Kumai[3] and Tatsuo Hasegawa[1]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]Condensed Matter Research Center and Photon Factory, Institute of Materials Structure Science, High Energy Accelerator Research Organization, Japan

Inverted-coplanar or bottom-gate-bottom-contact (BGBC) type has several unique advantages in fabrication and application of organic thin-film transistors (OTFTs), because it allows apply a variety of fabrication processes for dielectric and/or electrode components without bringing unfavorable influences on the channel organic semiconductor (OSC) layers. However, it is also generally known that it becomes more difficult to operate BGBC-type OTFTs, as compared to bottom-gate-top-contact (BGTC) type OTFTs. Recently, it was demonstrated that both high mobility and ideal on/off switching are successfully realized in BGBC-type printed OTFTs by adopting highly lyophobic gate dielectric layers that use amorphous perfluoropolymer of Cytop. However, peculiar channel material dependence is still observed in the device performance. Here, we report that one of crucial requirements for realizing excellent device performance is the stability of semiconductor/metal/insulator ternary interfaces in the BGBC-type OTFTs.
We manufactured semiconductor single-crystal thin films of various layer numbers and materials (phenyl/alkyl-substituted benzothieno[3,2-b]benzothiophene (Ph-BTBT-C$_n$) and phenyl/alkyl-substituted benzothieno[3,2-b]naphtho[2,3-b]thiophene (Ph-BTNT-C$_n$)) on highly lyophobic Cytop gate dielectric surfaces by extended meniscus-guided coating technique. We found that some TFTs exhibit notable time-dependent degradation, whose degradation speed depends significantly on the material, layer number, and also the encapsulation. For example, the single layer TFTs with Ph-BTBT-C$_n$ exhibited mobility as about 5 cm^2/Vs immediately after device fabrication, but decreased to 0.06 cm^2/Vs after 50 hours. In contrast, multilayer (3 layers) TFTs exhibited excellent time stability up to about 400 hours, and maintained initial mobility of 8 cm^2/Vs. Kelvin probe force microscopy (KPFM) measurements revealed that observed degradation is associated with the occurrence of contact resistance at around the source electrodes, whereas the degradation is dramatically reduced by stacking multilayer (two or more layers) OSC films. Microscopic characterizations by atomic force microscopy (AFM), and in-plane x-ray diffraction (XRD) indicated the sign of film deterioration at ternary interface, in case that contact resistance is observed. The results of this study suggest the importance of the quality of the semiconductor thin films at ternary interface and is expected to serve as a clue for improving the performance of BGBC-type OTFTs.

5:00 PM EL18.06.30
Low-Voltage Stretchable Electroluminescent Devices for Sound-in-Display Electronics Hyejin Lee, Dong-hee Kang, Young-Ryul Kim and Hyunhyub Ko; UNIST, Korea (the Republic of)

Synesthesia is a phenomenon of concurrent perception, where a particular sensory stimulation activates the other senses together. Recently, synesthetic electronic devices have attracted great attention for the precise and immediate perception of external stimuli. In particular, the visual perception of mechanical stimuli has potential applications in interactive display, electronic skins, and human-machine interfaces (HMIs). Although there have been many studies visualizing mechanical stimuli, only a few groups have demonstrated interactive displays combining loudspeakers with display devices for the visualization of sound. When visual information is accompanied by acoustic one or vice versa, humans recognize the external stimuli more efficiently by both visual and auditory senses simultaneously. For the visualization of sound waves, alternating-current electroluminescent (ACEL) devices have been used as sound-in-display electronics emitting light with corresponding sound waves. While the light emission is achieved by the field-induced electroluminescence (EL) which is emitted by the radiative recombination of electrons and holes in ZnS:Cu under the same applied AC voltage, the sound wave is generated by the dielectric elastomer actuation (DEA) under the applied voltage. Although ACEL devices having the synesthetic bimodal generation of light and sound have been previously reported, the high operating voltage and rigid properties still limit their practical applications. In this study, we propose stretchable sound-in-display electronics that can be attached to the human body and operated with a low operating voltage. Stretchable ACEL device comprises an EL phosphor of copper-doped zinc sulfide (ZnS:Cu) and poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP) as a high-*k* dielectric between stretchable electrodes. With the high-*k* dielectrics, the voltage focused on EL phosphor becomes higher than that on low-*k* dielectrics, enhancing the emission of bright light even under the same applied voltage. As a result, our stretchable ACEL loudspeaker with the high-*k* PVDF-HFP layer emits greatly enhanced brightness of light and sound pressure at a low operating voltage (87.68 cd/m^2, 79.70 dB at operating voltage 120 V, 10 kHz) even under various mechanical deformations. such as finger flexion and wrist bending. Our suggested ACEL loudspeaker with the intuitive and precise perception by visualizing the auditory systems can find diverse wearable and HMI applications.

5:00 PM EL18.06.31
MXene Thermoacoustic Loudspeaker for Directivity-Tunable Sound Generation Geonyoung Jeong, Jinyoung Kim and Hyunhyub Ko; UNIST, Korea (the Republic of)

Thermoacoustic (TA) loudspeakers have attracted great attention because of vibration-free, lightweight, and simple design compared to conventional speakers that require large space for the vibration and complex circuit design. However, previous TA loudspeakers have limited performances owing to the low heat emission into the air and large heat dissipation into the substrate. Herein, we demonstrated MXene TA loudspeakers (MTAL) based on a titanium carbide ($Ti_3C_2T_x$) MXene conductor with low heat capacity per unit area and an ultrathin parylene substrate with low thermal effusivity. Our ultrathin

MTAL with the thickness below thermal penetration depth exhibited improved SPL output in the low frequency regime and bi-directional TA sound generation in audible range (up to 20 kHz) with the highest SPL outputs of 73.7 dB at 15 kHz with 0.5 W input power. The low bending stiffness of ultrathin MTAL with the electrostatic interaction between negative MXene layer and positive poly-L-lysine treated substrate shows stable TA outputs under various structural deformations (concave, convex and folding) and maintained stable electrical conductivity under 1,000 bending cycles with 0.5 mm radius of curvature. In addition, conformal attachment of MTAL on diverse 3D shape (cylindrical, spherical, and parabolic shape) allows directivity-tunable TA sound generation. Particularly, a configurable design of kirigami structures enables stretchable MTAL, which exhibits stable TA sound outputs under 50% strain, bending and twisting deformation. In conclusion, we demonstrated bi-directional, omni-directional, stretchable, and highly focused directional sound generation based on film, spherical, kirigami-pattern and parabolic shapes of loudspeakers, respectively. Our MTAL with deformation-independent sound generation can be utilized as the next generation speakers with the user-desired functions.

5:00 PM EL18.06.32
Cu-Ni Core-Shell Micromesh-based Electrodes for Highly Robust, Transparent, and Flexible Heaters Han-Jung Kim, Yonghwan Lee and Yoonkap Kim; Gumi Electronics & Information Technology Research Institute (GERI), Korea (the Republic of)

In this work, we demonstrated the performance of metal mesh structures-based transparent electrodes (TEs), which is effectively improved for the thermal and chemical stability with electroplating nickel (Ni) on a copper (Cu) mesh/polyethylene terephthalate (PET) film, as highly robust, transparent, wearable heaters. For this, the Cu-Ni core-shell micromesh structure-based TE was prepared on a PET substrate by a combination of photolithography and Ni electroplating processes. The figure of merit of the Cu micromesh-based TE could be improved more than four times from ~230 (Optical transmittance at 550 nm : 85.7%, Sheet resistance : 10.4 Ω/sq) to ~950 (Optical transmittance at 550 nm : 80.7%, Sheet resistance : 1.8 Ω/sq) by Ni electroplating. And, the Ni electroplating could effectively enhance the adhesion (to PET substrate), thermal and chemical stability of the metal mesh structures. In addition, the Cu-Ni core-shell micromesh-based TE showed excellent response characteristics (fast response time, low power consumption, etc.) for a wearable heater. Based on the above the results, we expect that the TE based on the metal-Ni core-shell micromesh structures can be applied not only to wearable heaters, but also to electrodes for photovoltaic cells and displays.

This work was supported by the Technology Innovation Program (20006408) funded by the Ministry of Trade, Industry & Energy (MOTIE, Korea), and the Korea Innovation Foundation (INNOPOLIS) grant funded by the Korea government (MSIT) (2020-DD-UP-0278).

5:00 PM EL18.06.33
Self-Healable Films with Ion Accumulation Multilayer Structures for High-Performance Piezoionic Self-Powered Tactile Sensor Haryeong Cho, Young-Ryul Kim and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Piezoionic effect is the formation of electric potential and generation of current by the uneven local distribution of ions in ionic polymer composites in response to external mechanical stimuli. It has been utilized in electromechanical sensors for the simultaneous perception of static and dynamic forces, unlike other self-powered sensing mechanisms such as piezoelectricity and triboelectricity, which can detect dynamic forces only. However, piezoionic sensors have several limitations such as low-output signal and slow response time. Herein, we propose a multilayered piezoionic sensor with the I) ion-dipole interactive self-healable property for the enhanced device stability against mechanical deformation and II) ion accumulation layer to increase the piezoionic performance. Ion-dipole interaction between cation of ionic liquid (EMIM-TFSI) and anion of PVDF co-polymer (PVDF-HFP) enables to form the self-healable interface which can produce a stable multilayer structure under mechanical deformation. The optimized sensor (20wt% of ion contents) exhibits ~100% self-healing efficiency under 80 °C heat for 2 hours. Because the relatively light cations (EMIM) move rapidly in the strain direction which induces the ion polarization, our piezoionic sensor shows the recognition of deformation direction. The accumulated ions, which are located at the interface between the bilayer, activate ion exchange and generate the driving force for the ion moving to the interface, leading to the increase of output current signal and decrease of the response time. The sensor shows high stability under repeated bending stimuli over 1,400 cycles, and accurately distinguishes the surface roughness of rough sandpapers, paper, and glass. For applications, we demonstrate the multilayered pizoionic sensor array for the simultaneous perception of static and dynamic forces and discrimination of surface textures including braille shape and surface roughness.

Microfabrication and Surface Modification of 2D Materials for Flexible Chemical Sensor Platform Yeonhoo Kim; Korea Research Institute of Standards and Science, Korea (the Republic of)

Emerging novel technologies, such as flexible, foldable, and wearable electronics, need to meet their special requirements such as ease of controlling electronic properties, flexibility, and transparency. To date, metal and semiconducting materials have been used for conventional electronics, but the materials are brittle and nontransparent. In contrast, two-dimensional (2D) materials such as graphene and transition dichalcogenides have demonstrated great potential for flexible electronics and transparent electrodes due to their unique mechanical and electronic properties. In order to fully utilize the unique properties of 2D materials, geometric micropatterns of 2D materials on flexible substrates such as polymer substrates are essential to achieve technological purposes. However, due to harsh conditions such as cleaning, developing, and etching processes in the existing lithography procedures, defining elaborate micropatterns of 2D materials using the conventional photolithography processes on polymer substrates is difficult to achieve.
In this presentation, novel strategies to obtain micropatterned graphene on flexible substrates are discussed. After research on self-heating graphene micropatterns[1], direct polymer curing (DPC) transfer method was developed to overcome the low yield process. With the DPC method, entirely flexible, transparent, and self-activated graphene sensor arrays are stably fabricated on 4-inch wafer-scale polymer substrates. A sensor array composed of four graphene microchannels with different noble-metal decoration provides sufficient sensing information to discriminate gas species.[2-3] Finite element method simulations are employed to investigate the potential self-heating effect of this patterning technique. The calculation results demonstrate that the performance of the sensors can be highly enhanced when the active channels are suspended and nanopatterned. The DPC method is a state-of-the-art technique to define micropatterns of 2D materials on large-scale polymer substrates with a great potential for next-generation flexible electronics composed of 2D materials.

Electrospun Elastic Nanofiber Air Filter for Active Pore Modulation and Adaptive Machine Learned Face Mask Seongmin Jeong, Yeongju Jung

and Seung Hwan Ko; Seoul National University, Korea (the Republic of)

In history of technology, the change from traditional and static technologies to adaptable modality accelerated dramatic advances. Active and responsive means were required to deal with appropriately in the world with continuous changes. Likewise, this study reports the first actively adaptive air filter technologies which can be the cornerstone of the next trend for respiratory protection.
Until now, the perception of air filter has bean established as a static and fixed characteristic. After manufactured, existing air filters generally cannot adjust properties such as permeability, pore characteristics and filtration efficiency. The surroundings connected to air filtration, however, are not constant but fluctuate over time, frequently giving preference to one of permeability and efficiency, which are in a trade-off relationship. When breathing in polluted air, a person would prefer filtering effectiveness over permeability; nevertheless, this would be the complete reverse when the person started to have breathing difficulty as a result of increased physical exercise. As a result, we commonly see incompatibility between dynamic conditions and static air filters, which is also the reason why existing personal face mask are limited. Regardless of the type and performance of the mask, it cannot continuously show excellent usefulness in a variety of real-world situation.
Here, we report the advanced active air filter, a novel type of air filter that can dynamically adjust its operating characteristics in response to numerous internal and external circumstances, in order to overcome this restriction of static air filters. This paper details a whole development cycle, including 1) idea creation, 2) concept embodiment, particularly into a personal mask, and 3) human volunteer studies and thorough evaluation. The active air filter shows a predictively adaptable and personalized respiratory protection method, maximizing the innovative dynamic modality, in particular by integrating machine-learning (ML) algorithm for automatic modulation. The authors regard that this study will provide an innovative methodological approach for next studies on respiratory protection and air filtration.

5:00 PM EL18.06.36
Precise and Stable Alignment Method for Stencil Lithography via Transfer Printing Sangyeop Lee and Seok Kim; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Stencil lithography is a very attractive method in the micropatterning process but there are limitations in practical applications due to the difficulty for aligning the shadow mask, the shadowing effect due to the thickness of the shadow mask, and the blurring effect based on the gap between the shadow mask and the target substrate. To extend the potential applications of the stencil lithography process, we adopted ultra-thin silicon as the shadow mask material to reduce the shadowing effect. For alignment method, transfer printing by the microtipped stamp allows the facile and precise alignment and more conformal contact of the shadow mask on the target substrate and eliminates the gap in between to minimize any blurring effect. It is newly reported that 1 cm^2 shadow masks made of self-delaminated ultra-thin silicon substrates are precisely aligned and transfer printed without any damages by the microtipped stamp to enable multilayer stencil lithography processes.
The method of making an ultra-thin silicon shadow mask is followed. First, a photoresist (PR) is patterned on a silicon-on-insulator (SOI) wafer using a photolithography process. After dry etching the device layer using deep reactive ion etching (DRIE) process, the entire buried oxide layer (BOX) is etched by immersing it in a hydrofluoric acid (HF) solution. After that, when the patterned device layer and the handling layer are adhered by van der Waals force, it is put in an acetone bath for self-delamination. The floating ultra-thin silicon shadow mask is placed on a silane coated glass slide.
The microtipped stamp is fabricated with KOH wet etching and polydimethylsiloxane (PDMS) molding subsequently. KOH etching of the square array patterned SiN is performed to make a pyramidal pit array mold. Next, the mold is silane coated and PDMS precursor is poured on it. Finally, the fully cured PDMS is demolded.
For stencil lithography multilayer deposition process, the first pattern is sputtered on the silicon wafer through the shadow mask #1. The shadow mask #1 is then detached from the silicon wafer, either by submerging into the acetone bath or by the stamp. The shadow mask #2 is picked up from the silane-coated glass slide by the stamp. By observing through the microscope, the shadow mask #2 is aligned and placed on the first pattern. The second pattern is sputtered, and the mask is detached from the first pattern.
Two shadow masks are fabricated with different patterns, and the size of them is 10 mm x 10 mm with 15 mm thickness. The first pattern is 40 nm of chromium, and the second pattern is 40 nm of titanium. It is possible to conduct multilayer etching processes on silicon wafer with the metal deposited shadow masks. It was also possible to conduct multilayer etching process with the two masks. The alignment between two patterns from two shadow masks is inspected and it was found that the first and the second patterns have about 2~3 mm misalignment. It is presumably the human error since the aligning process was manually conducted.

5:00 PM EL18.06.37
Development of Stretchable Wearable Multichannel EMG Sensor with Outstanding Stretchability by Ultrarapid Laser Technique for Gesture Distinguishment and Human-Machine Interaction Jae-Seong Kim, Srinivas Gandla and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

Gesture Distinguishment and human-machine interaction with flexible and stretchable electronic devices that can measure the electrophysiological signal is inevitable for the future trend. To obtain high accuracy, effective operation, and easy manufacturing of wearable sensors, it is important to evolve competent strategies for devising diverse materials on stretchable electronic devices with outstanding mechanical and electrical properties. Herein, we show a large-area multichannel array surface electromyography(sEMG) sensor that is processed by the ultrarapid laser ablation technique. In this work, 8 channel stretchable sEMG sensor array was achieved by ultrarapid UV laser(355μm) which does not require a mask and is considered a promising tool to process for the treatment of a wide range of materials. When the stretching test was performed with a 0-30% strain rate to 10,000 cycles with uniaxial strain, the sensor showed a negligible relative resistance difference. Besides, a human-friendly skin patch made of Ecoflex_polydimethylsiloxane-polyethylenimine (Ecoflex_PDMS-PEIE) showed soft (low modulus, ~50kPa), remarkable stretchability (>100%), high permeability for water loss(gm^{-2}h^{-1}), and good adhesion to the skin(~3.3kPa). Using this armband which consists of 8 channel stretchable sEMG sensor and Ecoflex_PDMS-PEIE skin patch, we were able to distinguish finger, wrist vertical, and horizontal movement. Through these results, we confirmed the utilization of EMG signals with body movement decisions to control the movement of the robotic hand. We anticipate our results to be a starting point for electronic skin and healthcare.

5:00 PM EL18.06.38
Development of Dense Ceramic Additive Manufacturing Process via Novel Polymer-Free Alumina Slurry Jong Wan Ko, Jungsoo Nam and Kyung I. Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

The additive manufacturing (AM) process has been rapidly adapted in a wide range of industrial areas. For its ability to fabricate complex structures, AM is expected to satisfy the growing demands for complex parts that are difficult to achieve using conventional manufacturing processes. Furthermore, in the ceramic manufacturing field, AM process will provide a great opportunity to overcome the inherent low processability and expensive manufacturing cost of ceramic which hinder the manufacturing of complex parts. Unfortunately, contrary to polymer and metal, AM technologies for ceramics are still limited, especially for dense, monolithic structures. The most important challenge for dense ceramic AM is increasing ceramic contents in the feedstock while suppressing polymeric additives as low as possible. Since the polymeric additive was transited to gaseous species while in debinding process, polymeric contents in the green body apply internal pressure to the ceramic brown body, which can cause defects and cracks in the ceramic structure.

Herein, we introduce novel high alumina loading (over 50 vol.%) slurry with zero-polymeric additive compositionally designed for AM process. Instead of a polymeric binder and plasticizer, an aqueous “alumina-Sol” was applied as an inorganic binder and slurry suspension media. This “alumina-Sol” transit to an inorganic gel network and interconnect alumina particles by thermal curing, creating a dense green body consisting only of alumina and precursors of alumina. Since those slurries show viscoelasticity at every powder content, direct ink writing (DIW) was chosen as an AM process for our slurry. Through this process, ceramic structure with various geometry was successfully fabricated and sintered into a dense, monolithic structure with almost isometric shrinkage. Therefore, the chemical evolution of the developed slurry will be discussed first, and optimization of the DIW process by controlling the slurry composition and physical characteristics will be presented. The printing results using an optimized process and slurry would be demonstrated and the sintering results of the printed body would be presented.

5:00 PM EL18.06.39
A New Approach to Density Ceramic Additive Manufacturing: From Mechanism to Machine Implementation Jong Wan Ko, Dong-Hyun Kim, Chungsoo Kim and Jeonghong Ha; Korea Institute of Industrial Technology, Korea (the Republic of)

With the rapid development of 3D printing equipment and material technology, interest in industrial application possibilities is increasing. In the case of metals and polymers 3D printing technologies, are about to enter the rapid manufacturing stage beyond the rapid prototyping stage. However, in the case of photopolymer-based ceramic 3D printing(SLA or DLP type), which is currently widely used, due to the high content of photocurable polymer in the slurry used, defects (eg. pores, cavities, voids, etc.) in the 3D-printed green body during the debinding and sintering process, and in severe cases, the shape of the 3D printout is collapsed or destroyed.

In this research, we would like to introduce a new approach to ceramic 3D printing material-process-device development that does not use photocurable polymers. First, a ceramic slurry having a low polymer content (about 1 wt%) was prepared using alginic acid, a naturally-derived polymer, and an additive manufacturing process and device suitable for this slurry were developed. In particular, research was conducted with the aim of 3D printing of transition metal oxides (e.g. Al2O3, ZnO, CeO2 MnO2, etc.), which are widely used industrially as catalysts, high-temperature materials, and electric materials. Compared to the high polymer content (30 wt% or more) of the existing ceramic 3D printing slurry, a ceramic slurry containing only about 1 wt% of polymer (alginic acid) was prepared.

To realize the shape using the prepared slurry, a selective curing reaction was induced using metal ions (Al3+, Zn2+, Ce3+, Mn2+, etc.), and the additive manufacturing process was implemented by repeating these steps. The principle of forming a hydrogel by combining a carboxyl functional group on the surface of alginic acid with a metal ion was applied to the realization of a 3D printing shape. The metal ions used in the curing reaction were converted into identical oxides as the transition metal oxides in the slurry through the debinding-sintering process, thereby inducing bonding between the individual ceramic powders, resulting in dense ceramic parts. As a result, it has contributed to the improvement of the stability of the implementation of the ceramic additive manufacturing process by increasing the ceramic filling rate.

In addition to research on such ceramic slurry and hardening mechanisms, lamination mechanisms, and the additive manufacturing step process (slurry application-drying-curing reaction solution application) and machine development were conducted in parallel to enhance the industrial application potential of the technology. Through this, we intend to present the possibility of finally leaping to the rapid production stage of ceramic 3D printing technology.

5:00 PM EL18.06.40
Characterization of g-C3N4 as a Filler in the Photocuring 3D Printing Process Jong Wan Ko; Korea Institute of Industrial Technology, Korea (the Republic of)

3D printing or additive manufacturing (AM) technology is an uprising advanced manufacturing technology that possesses a high degree of design freedom to manufacture variously shaped products that were not possible with conventional manufacturing methods. Especially, this technology is actively researched in the polymer industry, which requires the fabrication of complex-shaped products, and there are polymer 3D printing methods such as fused deposition modeling (FDM), stereolithography (SLA), selective laser sintering (SLS), and digital light processing (DLP). DLP 3D printing, representative photocuring 3D printing the most widely used, has a very fast printing speed compared to other 3D printing processes because each layer is solidified and laminated by the light source of the plane unit, and the excellent precision and surface roughness of the printed product. However, DLP 3D printing has a limitation in that products have low mechanical strength owing to the inherent characteristics of photocurable resins such as low crosslinking density and difficulty in controlling the optimal curing irradiation time and anisotropy occurring during the 3D printing process. Therefore, in this study, we presented graphitic carbon nitride (g-C3N4) as a novel filler for general DLP acrylic resin to overcome the limitations of the strength of DLP products. g-C3N4 is a carbon nitride material with multiple hydrogen bonding motifs (-NH2, -NH functional groups) in the molecule, which could induce hydrogen bonding between matrix and g-C3N4, thereby increasing the intermolecular interaction, resulting in improved mechanical properties. Accordingly, we tried to investigate the characteristics of g-c3n4 as a filler and the feasibility of DLP composite products with process optimization. In the results, it was confirmed that the tensile strength of the DLP output of the composite material increased by 22% and the elastic modulus by 34% compared to the neat DLP polymer specimen respectively.

5:00 PM EL18.06.41
High Performance Flexible Organic Field Effect Transistor via Layer-by-Layer Fabrication Deng Zou[1,2] and Paddy K. L. Chan[1,2]; [1]University of Hong Kong, Hong Kong; [2]Advanced Biomedical Instrumentation Centre, Hong Kong

Organic field-effect transistors (OFETs) based on two-dimensional (2D) monolayer organic semiconductors (OSC) have demonstrated promising potentials for various applications, such as light emitting diode (LED) display drivers, logic circuits, and wearable electrocardiography (ECG) sensor. The fabrications of this class of highly crystallized 2D organic semiconductors (OSC) are dominated by solution shearing. As these organic active layers are only a few molecular layers thick, their compatibility with conventional evaporated top electrodes is restricted. Besides, sophisticated patterning techniques such as photolithography or e-beam lithography remain challenging for the organic active layers, which has also restricted their device density. In this talk, we will present our recent development on the integration of the damage-free electrode transfer stamp with a chemical-free patterning stamp to fabricate OFETs with channel lengths down to 3 mm over an area of 2 cm x 2 cm. These 2,9-didecyldinaphtho[2,3-b:2′,3′-f]thieno[3,2-b]thiophene (C_{10}-DNTT) monolayer OFETs show decent performance properties with a low threshold voltage (V_{TH}) for less than 0.5 V, a low subthreshold swing (*SS*) below 100 mV dec^{-1}, and intrinsic mobility of over 10 $cm^2\ V^{-1}\ s^{-1}$. The proposed patterning approach is also utilized to develop flexible OFET array on ultra-flexible parylene substrate with promising uniformity and conformability. By further reducing the channel length to 2 mm and utilizing it as a rectifier, the rectifying capability is up to 17.3 MHz at an input voltage of 4 V, which is capable of wireless communication. The proposed electrode transfer and patterning stamps have addressed the long-lasting compatibility problem of depositing electrodes onto 2D organic monolayer semiconductor patterning. It opens a new path to further reduce the fabrication cost and simplify the manufacturing process of OFET arrays for more advanced electronic or biomedical applications.

5:00 PM EL18.06.42
A Fully Self-Healing Multi-Sensor Patch with Bio-Inspired Adhesive Mihyeon Park and Jeong Sook Ha; Korea University, Korea (the Republic of)

Hydrogel-based self-healing sensors have been actively investigated for the flexible wearable devices with durability owing to the advantage of economic feasibility, environmental friendliness, and biocompatibility. However, solvent evaporation of hydrogels in ambient conditions results in the degradation of mechanical and self-healing performance to limit their practical application.
Here, we report on the fabrication of a fully self-healing multi-sensor patch consisting of a temperature sensor, pH sensor, and electrocardiogram (ECG) electrode with a bio-inspired adhesive. Our synthesized novel hydrophobic self-healing polyurethane (PU) with oxime-carbamate (OC) bonding is used as a substrate film to prohibit sweat-induced swelling. In the multi-sensor layer, carbon nanotube/polyaniline(CNT/PANI) is partially embedded in the self-healing PU and used as both temperature and pH sensors. In the adhesive layer, the self-healing PU with additional catechol group is patterned to have micropillar structures mimicking gecko pad and mushroom. Thus, the adhesive layer exhibits increased adhesion and self-healing efficiency via the combination of chemical and physical adhesion. Also, gold nanosheets are dry transferred to make a self-healing ECG electrode. The fabricated sensors exhibit excellent performance with high sensitivity in the temperature range between 25 °C and 45 °C, and pH values between 4 and 8, respectively, good for the detection of human body conditions. In addition, the ECG electrode shows distinguished PQRST peaks even after rinsing with water. The air-permeable micropiller adhesive exhibits strong adhesion onto skin and allows the accurate detection of biosignals even on sweaty skin. After a complete bi-section of the sensors and subsequent heating at 65 °C for 6 h, the temperature sensor fully recovers the sensitivity, and the pH sensor and ECG electrode also recover the pristine sensor signals. Furthermore, the whole patch system of vertically integrated multi-sensor layer and the adhesive layer is fully self-healed simultaneously by heating at 65 °C for 6 h, owing to the interlayer self-healing via OC bonding. This work suggests a high application potential of our fully self-healing multi-sensor patch in wearable health monitoring systems with longevity.

5:00 PM EL18.06.43
Self-powered Wearable Oximeter with Ultrahigh Responsitivity Based on CdS Nanoparticles /Tellurene Mixed-Dimensional Heterostructure
Ruifang Zhang[1,2] and Wenzhuo Wu[1,2,3]; [1]Purdue University, United States; [2]Flex Laboratory, United States; [3]Regenstrief Center for Healthcare Engineering, United States

Pulse oximetry sensors have been playing a key role in monitoring vital signs related to human health states. However, conventional pulse oximetry sensors have relatively large power consumption, rigid structure, and narrow spectral range of the photodetector. We demonstrated a dual-polarity photodetector for wearable oximeter in the form of a reflective patch-type pulse oximetry sensor, based on a mix-dimensional CdS nanoparticles (0D)/tellurene (2D) heterostructure. The heterostructure shows a photoresponsitivity of 6.7 A/W to 650 nm illumination and a photoresponsivity of 21.7 A/W to 950 nm illumination at 0V bias, much better than the reported p-n-junction-based self-powered photodetectors. More importantly, the wavelength-induced dual photoresponse extends to a broad spectral response and benefits the accuracy of oximeters. This photodetector with lightweight, small size, and low energy consumption can achieve self-powered light detection without an external power supply. Such an operation scheme, together with the ultrahigh photoresponsivity, enables the development and application of high-performance wearable oximeters that can monitor local tissue oxygenation and heart rate variability during real-time, continuous operations.

5:00 PM EL18.06.44
Self-powered Human-integrated Wearable Sensor Based on mixed-dimensional solid/liquid Heterostructures Jing Jiang[1] and Wenzhuo Wu[1,1,2]; [1]Purdue University, United States; [2]Regenstrief Center for Healthcare Engineering, United States

Self-powered sensors with high stretchability and biocompatibility are critical for next-generation wearable human-integrated applications. In this article, we reported a facile manufacturing scheme that integrates piezoelectric oxide nanowires on liquid metal electrodes for a soft piezoelectric wearable. The physical and chemical properties of the integrated mixed-dimensional sensors were systematically explored to achieve optimized sensor performance. The softness and the stretchability of the device made it possible to be worn conformably to different parts of human body, efficiently converting the subtle mechanical vibration from human physiological activities (e.g., voice, pulse, etc.) to measurable electric signals. Our work demonstrates a novel self-powered wearable device for monitoring human status, e.g., speech, cardiac health, etc.

5:00 PM EL18.06.46
Electrohydrodynamic Printing of Magnetic Alloys from Carbonyl Based Metal-organic Decomposition Inks Collin Miller and Owen Hildreth; Colorado School of Mines, United States

Iron – Cobalt alloys have important uses as magnetic cores in electrical and electronic devices. One drawback to these materials is their low ductility which limits part complexity. Designing a printable Iron – Cobalt functional ink could enable 3D printing and allow parts to have higher resolutions and more complicated geometries than traditional manufacturing methods. This work demonstrates the ability to electrohydrodynamically print magnetic alloy materials using a reactive ink precursor. Particle-free Iron – Cobalt reactive inks were made by dissolving organometallic metal carbonyls, such as Iron Pentacarbonyl and Cobalt Octacarbonyl, in organic solvents. These inks can be printed in an inert atmosphere using electrohydrodynamic printing then thermally decomposed into their metallic state using a heated bed at temperatures around 200 °C. The magnetic properties of this printed alloy are then compared to traditionally manufactured Permendur.

5:00 PM EL18.06.47
Fused Heterocyclic Aromatic Ladder Oligomers for Organic Semiconductor Applications Cameron Fiester[1], Phuong-Truc T. Pham[2], Amy Bradley[1], Amjad Nazzal[1] and Mamoun M. Bader[3]; [1]Wilkes University, United States; [2]Penn State Scranton, United States; [3]Alfaisal University, Saudi Arabia

We report the synthesis and characterization of a series of structurally related ladder oligomers composed of fused heterocyclic compounds for potential use as organic semiconductors in electronic devices. Specifically, the reactions of 2,3-dichloro-1,4-naphthoquinone and 2-aminophenol, and 2-aminothiophenol and their derivatives were employed to synthesize a series of fused heterocyclic ladder oligomers with various electron donor and acceptor groups in various configurations and molecular designs. These products were characterized using H-NMR, DSC, elemental analysis, and IR spectroscopy. Furthermore, UV-VIS and cyclic voltammetry were performed on these products to determine the optical and the electronic band gaps. We also report the single crystal structural analyses on a few of the products for which good quality crystals were successfully grown. Furthermore, results of our DFT calculations of the electronic structures of these molecules and the evolution of the calculated HOMO-LUMO levels as a function of structural modifications will be reported.

5:00 PM EL18.06.49
Carrier Mobility in Inkjet-Printed Semiconducting SWCNT Random Network Studied using Impedance Spectroscopy Manoranjan Manoranjan, Paramita K. Choudhury and Yashowanta N. Mohapatra; Indian Institute of Technology Kanpur, India

Large area printable electronics on flexible substrates is currently at a cusp of rapid development emerging as a technology with potential to transform many sectors of applications. The current suit of applications ranges from large displays, efficient lighting to generators, sensors, energy storage, e-textiles, in healthcare and biomedical applications to smart packaging. Nonetheless, despite encouraging recent advancement, there are several material challenges such as carrying out all the processes at low temperature, choosing an optimum flexible substrate, choosing a suitable solvent, stabilizers etc. in making ink functional and jettable, choosing an appropriate printing technique, and further efforts in developing suitable characterization methods.

Specifically, the realization of active devices such as printable arrays of diodes and thin film transistors (TFT) is common to most developmental efforts. Various solution processable-material systems including organic molecules, polymers, oxides such as InGaZnO, and nano-structures embedded in polymers are being tested widely. Recently, semiconducting single walled carbon nanotube(sc-SWCNT) wrapped with polymer is emerging as a material with significant application potential in the area of flexible transparent electronics due to its reasonably high carrier mobility, excellent chemical stability & mechanical flexibilities as well as compatibility with solution based processing. However, the processes and mechanisms controlling carrier transport in such films is not understood well as yet. This being critical to device application there is a need to study reliably carrier mobility in such films realized using realistic solution processes and feasible printable techniques. Attempts to measure mobility in printed layers in TFT structures is often fraught with problems of cross-sensitivities due to the quality of the device in terms of input-output characteristics, device architecture and associated contact resistances. To overcome these difficulties, we use fully ink-jet printed much simpler metal-semiconductor-metal (MSM) structures to determine mobility using impedance spectroscopy. We demonstrate determination of mobility by two different methods in which the capacitive and resistive components neatly separate out and there is no need to model I-V characteristics with assumptions regarding transport mechanisms.

In this study, we have demonstrated a fully inkjet-printed flexible sc-SWCNT based MSM structure. The semiconducting layer is printed using a commercially sourced ink (NanoIntegris IsoSol-S100), consisting of polymer wrapped sc-SWCNT. The source drain electrodes are printed using PVNanocell (PVN)-150T silver ink as a metal layer. The electrodes are sintered with optimized intense pulsed light sintering. The sample is printed on a PEN substrate. The printed layer is rinsed in toluene and annealed for 30 minutes at 100^0C to fuse and form a random network of sc-SWCNT. The effect of processing steps controlling the degree of polymer content embedded on the CNT network is investigated.

Current Voltage (IV) characteristics, Impedance (|Z|) with Frequency and Capacitance with Voltage (CV) & Frequency (CF) are investigated in the temperature range of 50-300K. We show that the two terminal devices can be modeled as a simple RC circuit with zero series resistance. We demonstrate that mobility can be obtained by different methods such as Cole-Cole plot, -Im(Z) vs Frequency and Phase vs frequency. The measured mobility is of the order of 10 cm^2/S-V which is similar to mobilities but is more reliable than those obtained in the TFT structures being independent of non-idealities due to device configuration. The temperature dependence of device characteristics and mobility is discussed in terms of possible transport models such as variable transport hopping, tunneling across distributed barriers and fluctuation induced tunneling at junctions in such printed random network of sc-SWCNT.

5:00 PM EL18.06.50
Development of a Low Cost Noninvasive Continuous Glucose Monitor Nicole Jeselson and Ahyeon Koh; Binghamton University, United States

Diabetes mellitus is an increasing public health issue that affects millions of people worldwide. To offer better control over diagnosis and treatment administration, continuous monitoring is utilized to detect glucose concentrations in the interstitial fluid (ISF) through electrochemical biosensors with reverse iontophoretic extraction. Traditional continuous glucose monitors (CGMs) involve subcutaneous microneedles which lead to complications such as biofouling and infections. To address these limitations, soft bioelectronics in a temporary tattoo platform offers a non-invasive, comfortable, and accurate method that can replace traditional invasive methods. These soft bioelectronic sensors contain an electrochemical electrode system fabricated through screen-printing that can conform to a patient's skin. We hypothesize that the detection accuracy and specificity of glucose concentrations is comparable to traditional CGMs while offering an affordable and non-invasive platform. The working principle of this sensor is to extract glucose through reverse iontophoresis after applying low-level electrical current to the epidermis. Then, the enzyme-based biosensor with glucose oxidase (GOx) detects ISF glucose concentrations via a hydrogen peroxide (H_2O_2) proxy. We fabricated the biosensors through a low cost screen-printing process utilizing conductive inks and three pre-burned 230 mesh count 18" x 20" screens to print the three layers of the biosensors. The first layer is silver/silver chloride (Ag/AgCl) ink for the counter and reference electrodes. The second layer is carbon-graphite Prussian blue mediator paste for the working electrode. Additionally, there is a third layer of insulating dielectric ink. Optical profilometry obtained the roughness of the biosensors to determine the variation in ink layer thicknesses. Results concluded the average roughness for the Ag/AgCl and carbon-graphite Prussian blue ink to be 8.68 µm and 7.90 µm, respectively. Results concluded the average thickness for the Ag/AgCl and carbon-graphite Prussian blue ink to be 57.95 µm and 98.24 µm, respectively. Electrochemistry experiments characterized the sensors including cyclic voltammetry, linear sweep voltammetry, and chronoamperometry. Characterization of the working electrode showed oxidation and reduction peaks consistent with previously reported Prussian blue electrodes, and the counter and reference electrodes showed comparable performance to commercially available alternatives. A developed linear response curve correlated varying levels of glucose in a target concentration range of 2 mM/L to 14 mM/L glucose to current output. This range covers normal, pre-diabetic, and diabetic levels of glucose. Once characterized, a skin simulator determined the ISF collection mechanism *in vitro* and evaluated the biosensor response to levels of glucose. UV-Vis Spectroscopy determined the peak wavelength and absorbance for each glucose concentration extracted into agarose gel by reverse iontophoresis. Additionally, interfering electroactive species present in the ISF were utilized to investigate the specificity of this system toward glucose. Overall, this proof-of-concept flexible biosensor is a promising alternative for continuous glucose monitoring in a non-invasive platform that offers an affordable fabrication process.

5:00 PM EL18.06.51
Skin-Interfaced, Soft Microfluidic Sweat Collection Platform with Dual-Valving Features Ji Hyun Yang[1], Uchechukuwu David[2], Yeonsik Noh[2] and Ahyeon Koh[1]; [1]Binghamton University, United States; [2]University of Massachusetts Amherst, United States

Skin-interfaced microfluidic devices have been advancing at a rapid pace, measuring various biofluids such as sweat and interstitial fluid using external or on-board sensing modalities. Current microfluidic platform relies on continuous sweat flow in the measurement of sweat analytes without temporal consideration and sample isolation. Microfluidic valving mechanism will provide temporal collection of sweat biofluid, eliminating any continuous flow requirements. Therefore, the analyzed information will reflect close to the actual information of our human body. Integration of expandable materials with traditional PDMS-based microfluidic soft-lithography techniques can offer soft microfluidic valving features. Additionally, electronics can be used to devise a controlled microfluidic platform for the advancement of skin-integrated microfluidic devices. Here, we develop a biocompatible, skin-interfaced microfluidic platform with temporal collection capabilities using thermal expandable microspheres. Additionally, we integrated electronics that allow discrete microfluidic valve control on demand through microheaters, capable of long-term biofluid collection. Soft lithography was used to produce polydimethylsiloxane (PDMS) based skin-interfaced microfluidic layers. Expandable microspheres were mixed with PDMS (1:2 weight ratio) and was included in the microfluidic device set up to provide the basis of the valving mechanism. Layers were joined together through oxygen plasma bonding. Electronics were transfer printed onto the Expandable layer for the controlled activation of the valves on the microfluidic platform. Thermal characterization of the microheaters was performed using infrared cameras. The burst pressure or the failure pressure required for the microfluidic valves was evaluated. Optical microscopic images were used to verify the closure of the microfluidic channels. Fluids of different pH were isolated and measured to simulate the temporal collection of biofluids at different concentrations. The fabricated microfluidic device could collect biofluids at skin-interfaced conditions. The transfer-printed microheaters were tested to show stable thermal energy delivery in a localized region where it is directly located at the entrance of the microfluidic chamber. Upon activation of microheaters, a rapid temperature increase was seen and the temperature rise along the conducting lines to the area of interest was minimal (less than 30°C). Characterization of both the passive valves and thermal valves shows that thermal valves have the highest pressure requirement for flow. Hence, the preferential microfluidic flow direction will be towards other capillary burst valves. Therefore, no flow towards the thermal activated valves is expected, indicating isolated fluid collection upon valve activation. Human study was also conducted to show the difference between the traditional collection method and the programmed time-controlled sweat collection method. The human study demonstrates improved sweat analyte data (sweat volume, pH, lactate, and cortisol) obtained from the traditional sweat collection method to a programmed time sweat collection device. The human study results also show an indication of a correlation between sweat rate and sweat lactate against aerobic and anaerobic exercises. Our approach can also be integrated with past and current advanced microfluidic systems and other chemical sensing modalities such as colorimetric and electrochemical measurement of sweat analytes that are present in current sweat devices for advanced on-board diagnostics.

Real-time Electrostatic Sensors based on Piezoelectric Nanogenerators and Polymer Field Effect Transistors Qun-Gao Chen and Wen-ya Lee; National Taipei University of Technology, Taiwan

With the increased attention in wearable tactile sensing devices. This study demonstrates a self-powered transistor-based tactile sensor based on micropillars made by poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP) electrospun nanofibers and a diketopyrrolopyrrole (DPP)-based conjugated polymer. The sensors containing PVDF-HFP-nanofiber-embedded micropillar shows a high sensitivity of 83.54 $VkPa^{-1}$ in a small pressure range (<1 kPa). The micropillar structure can generate a open-circuit voltage of up to 79 V. To collect the signals of static electrical potential in a portable device, we integrate an in-situ monitoring system consisting of a polymer-based transistor-type sensor and Arduino board to detect the changes of static electrical potentials. The transistor-based sensor circuit can gather the electrostatic signals generated by electrospun-nanofiber-embedded pollars and act as an amplifier to increase signals. Moreover, the mobility of the transistor-based sensors can operate in a low voltage of 5 V and show a mobility of 0.15 $cm^2V^{-1}s^{-1}$, the threshold voltage of 0 V, and the on-off ratio of 10^5. This device combined with the microcontroller can wirelessly control the real-time pressure monitoring sensor for tracking human health. This work demonstrate a new device design for wearable electronic circuits.

5:00 PM EL18.06.53
Healable N-type Naphthalenediimide-based Polymer Semiconductors with Dynamic Covalent and Non-covalent Bonding for Field-Effect Transistors Yueh-Chun Huang[1], Wen-ya Lee[1], Tomoya Higashihara[2] and Ho-Hsiu Chou[3]; [1]Department of Chemical Engineering & Biotechnology National Taipei University of Technology, Taiwan; [2]Yamagata University, Japan; [3]National Tsing Hua University, Taiwan

Stretchable semiconductors have been reported over the past decade. However, stretchable electronic devices with remarkable mechanical compliance still present challenges. Therefore, self-healing materials used in semiconductors are crucial for developing stretchable integrated circuits. Their self-healing ability can recover the degradation of devices performance caused by the breaking from mechanical deformation on the polymer semiconductor soft film. In contrast to non-covalent self-healing materials with relatively low mechanical properties and limited stability, we demonstrate a self-healing n-type polymer with multiple interactions, including light- and heat-induced dynamic covalent bonding and hydrogen bonding. The healable NDI-based polymer semiconductor, poly(naphthalene-bithiophene-co-isoindoline-1,3-dione), with maleimide group is blended with a stretchable polyurethane oligomer with conjugates anthracene moieties. Because of Diels-Alder and photochemical chemistry, the self-healed n-type field-effect transistors are achieved. The damaged n-type semiconducting polymer blend can be healed through a double dynamic network of the light-induced [4+4] and thermal-triggered [4+2] cycloaddition linkages. Moreover, the hydrogen bonding and elasticity of polyurethane oligomers assist to recover the electron mobilities of the polymer blend. This work shows that thermal and UV light triggering demonstrate self-healing n-type polymer semiconductors with dynamic covalently bonded double networks and hydrogen bonding. To conclude, these results provide new directions and applications for the development of self-healing materials. To our best knowledge, this work is the first self-healable n-type polymer semiconductor using dynamic covalent bonding.

Interfacial Stabilization via a Phase-Switched Bulk Heterojunction for Self-Powered Photodetector and Photovoltaic Applications Jihyun Lim, Min Soo Kim, Woongsik Jang and Dong Hwan Wang; Chung-Ang Univ, Korea (the Republic of)

Non-fullerene acceptor materials (especially Y6) have recently attracted much attention in organic photovoltaics due to their excellent optoelectronic properties that lead to high reproducibility performance.[1] Nevertheless, when fabricating devices based on the PM6:Y6 active layers with high efficiency, the use of chloroform (CF) with a low boiling point is unavoidable,[2] which is a major obstacle for large active-area device fabrication or modularization due to its fast evaporation. Although spin-coating is appropriate at the laboratory level, it is difficult to apply it to produce large active areas. For the first time, we succeeded in introducing a phase-switching process when forming a PM6:Y6 bulk heterojunction using relatively high-boiling chlorobenzene instead of CF. Phase-switching method using soft mold has been considered by advanced technology to overcome limits of the wet coating such as spin coating, which is composed of a deposition of large area and specific region, material loss, and penetration of solvents.[3] A phase-switching process was introduced to a PM6:Y6-based active layer to achieve a uniform surface with preferred Y6 acceptor-domain positioning. By designing the wetting coefficient-based process to fit the surface properties of a small-molecule Y6 acceptor-based bulk heterojunction, a highly reproducible phase-switched active layer was successfully formed over an area of 2.25 cm^2.[4] It improved charge transport ability and suppressed surface defects owing to a molecular orientation favorable for efficient charge separation and transport.[5] Furthermore, adding chloronaphthalene additive induced the domain growth of Y6 acceptors with dense molecular packing, enhancing the phase-switching process's effects. Uniformly distributed performance in the phase-switched active layer via the phase-switching process was demonstrated in fabricated large active-area devices. Furthermore, the process was utilized in a PM6:Y6-based self-powered photodetector, which improved detectivity owing to the suppression of the dark current density. Therefore, the phase-switching process is an important technology for forming high-quality thin films composed of small-molecule acceptors for efficient self-powered photodetector and photovoltaic applications.

Micron-sized GaN Domains Grown by Thru-Hole Epitaxy over Reduced Graphene Oxide and Directly Grown Graphene as Building Blocks for Flexible Devices Hyunkyu Lee, Gyuseock Ko, Jae Hun Kim, Jong Woo Ha, Hyung Beom Kim, Hyeonoh Jo, Hansol Kim, Jieun Yang and Chinkyo Kim; Kyung Hee University, Korea (the Republic of)

With the increased demand for high-performance micro-LED devices, it becomes more crucial to reduce the density of threading dislocations, suppress leakage currents on the side walls, and improve the transferability of individual devices as their size is required to be decreased. Recently, thru-hole epitaxy, similar to conventional epitaxial lateral overgrowth but with a 2D material, containing extremely small openings, as a mask was reported to be one of the intriguing candidates for this purpose. For this growth method to be more controllably utilized to produce micron-sized domains as building blocks for flexible devices, however, there are some issues to be resolved such as the control of size, distribution, and density of thru-holes in 2D material. In this study, we carried out the thru-hole epitaxy of GaN on a graphene-coated *patterned* sapphire substrate to make position-controlled micron-sized domains, which can be utilized as platforms for individual micro LEDs. The advantage of thru-hole epitaxy over conventional epitaxial lateral growth is that the opening area of the substrate can be as narrow as several nanometers in such a way that the density of threading dislocations in each domain can be significantly reduced as well as those domains can be readily detached by a thermal release tape. Coating the substrate with graphene was made possible either by directly growing graphene or reducing sprayed graphene oxide. In contrast with transferred graphene, either reduction of sprayed GO films or direct growth of graphene allowed us to better control the hole density and distribution of graphene. The GaN domains grown on graphene-coated sapphire substrates were found to be well aligned with the underlying substrates and readily exfoliated by a thermal release tape. AFM topography and TEM analysis were utilized to characterize the existence, distribution, and position of thru-holes, which were responsible for the reduction of threading dislocation density and the easy detachment of GaN domains.

Selective Assembly of Monolayer Two-dimensional Single Crystalline Metal Nanosheets via Ultrasonochemical process Seungyeon Kim, Ho Kwang Choi, Young-Seok Song and Tae-Wook Kim; Jeonbuk National University, Korea (the Republic of)

The ultrasonication process has been widely used as a representative cleaning method to remove undesired particles or residues on substrates for the fabrication of electronic devices or as a dispersing method for the particles in a desired solvent. Recently, ultrasonochemistry was introduced to enable the formation of a thin film in a solution by attaching nano-sized metal spherical particles on a ceramic or polymer substrate. However, there were negligible reports on conductive thin films by using monolayer assembly of giant two-dimensional (2D) single crystalline metallic nanosheets.
In this study, giant 2D single-crystalline nanosheets were assembled on a substrate by an ultrasonic deposition method that enables the formation of a uniform and monolayer assembled metallic film. We have demonstrated the various monolayer copper nanosheets film with different surface coverages via ultrasonochemical process. According to the surface properties of the substrate, concentrations of the nanosheets solution, processing time, and the polarity of the solvent, the degree of surface coverage of the 2D metal nanosheet on a substrate is systematically controlled. Especially, we achieved max. 88 % of surface coverage of copper nanosheets on a glass substrate, exhibiting ~ 65 ohm/sq of sheet resistance value. Also, it was possible to form monolayer assembled metal sheets on the surface of complexed 3D structures. Additionally, we demonstrated simultaneous patterning of the Cu nanosheet films by controlling the surface energy of the selected area of the substrate. From the above results, we identified that the ultrasonchemical process is useful for large-scale assemble of conductive fillers on both 2D and 3D substrates. Our monolayer assembled 2D metal nanosheet film is applicable for the promising functional conductive films.

5:00 PM EL18.06.57
Optical Memory Transistor—From Fabrication to Characterization Lizhi Yan[1] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, Hong Kong; [2]Advanced Biomedical Instrumentation Centre, Hong Kong Science Park, Hong Kong

Optical memory transistor (OMT) is a emerging branch of the memory transistors, which involves optical signals in the programing or erasing process. Memory transistor is a promising candidate for the next generation memory devices towards in-sensor neuromorphic computing applications. In this study, we developed nonvolatile optical memory transistor by using 2,9-Diphenyl-dinaphtho[2,3-b:2',3'-f]thieno[3,2-b]thiophene (2,9-Dph-DNTT) organic semiconductor as the active layer. The fabricated OMT is based on the intrinsic optical memory property of the semiconductor layer. Compare with traditional memory transistors, this can simplify the fabrication process without functionalizing the dielectric layer or the embedding charge trapping sites as the floating gate. By combining with the high-k dielectric material Al_2O_3, the memory transistor can operate at a low voltage during optical-electrical programming and electrical erasing process (less than 4V). Additionally, the transistor shows a field effect mobility up to 3 $cm^2V^{-1}s^{-1}$ and excellent data retention for more than 12 hours with a current ratio higher than 10^4 between the two binary states, which is a promising value for the OMT.
In this talk, the mechanism of the optical-electrical memory phenomenon will be discussed in detailed. With the characterization methods such as TGA/DSC, X-ray diffraction, Kelvin probe force microscope, conductive atomic force microscope and etc, we confirmed that the effective charge trapping centers introduced by the metastable nanosprouts structure of the organic active layer are corresponding directly to the memory performance. At last, a demonstration of converting 2D information array to 3D information array will be introduced, with the large tunability of the OMT memory performance introduced by the substrate temperature difference in the evaporation process (larger than one order), we fabricated memory transistors array with patterned memory performance pixels. Then the 2D information array can be converted into 3D information array with the additional dimensionality of the pixel memory performance difference.

5:00 PM EL18.06.58
Poisson Effect-Assisted Replication Lithography for Repetitive Fabrication of 3D Microstructures Minsu Kim, Dokyung Kyeong, Han Jun Park, Gain Lee and Moon Kyu Kwak; Kyungpook National University, Korea (the Republic of)

It has become possible to manufacture complex three-dimensional structures easily with additive manufacturing technology. The production of submicron structures has also become possible through the development of a multi-photon polymerization lithography system. However, due to the slow manufacturing speed and the need for expensive equipment, the actual application of micro-scale 3D printing has been limited to the production of small prototypes and laboratory-scale samples.
Meanwhile, with the development of an imprint-based microstructure replication system, large-scale and continuous fabrication processes for the mass production of functional microstructures are becoming possible. Although there is a limit to the structure that can be fabricated with the conventional imprint processes, the productivity of imprint-based microfabrication is relatively superior to that of 3D printing systems.
In this study, a 3D microstructure replication method is proposed and demonstrated with the assist of the Poisson effect. A soft stamp mold replicated from the original mold fabricated by a two-photon polymerization 3D printing system is pressurized to form the intended 3D structural cavity. After resin polymerization, the pressure is removed to release the cured 3D structure from the mold cavity. By using the imprinting and 3D printing hybrid method proposed in this study, it is possible to replicate 3D microstructures that cannot be replicated with the conventional imprinting method. It might also be applied to large-scale fabrication, repetitive replication, and continuous fabrication of 3D microstructure surfaces, which were greatly limited by the existing 3D printing system.
The original master mold was fabricated with a 2PP 3D printing system considering the intended deformation. From the master mold, the soft mold was replicated using elastomeric materials showing sufficient lateral deformation from the Poisson effect. After applying resin for the replication on the prepared soft mold, normal pressure was applied to the soft mold to induce lateral deformation. The resin was cured into the intended 3D microstructure in the cavity.
The replication quality of the resultant microstructure was investigated according to the normal strain of the soft mold. It is confirmed that various

elastomeric materials can be used for the preparation of the soft mold if the material shows sufficient lateral deformation from the Poisson effect. In addition, it is also confirmed that various resin materials, heat- or UV-curable, are available for the 3D microstructure replication including hard PUA, soft PUA, NOA, PDMS, and PFPE.
The hybrid fabrication method demonstrated in this work is expected to significantly improve the productivity of the 3D microstructure surface simply by applying additional pressure in the conventional soft-lithographic imprint process.

Intrinsically Stretchable and Non-Halogenated Solvent Processed Polymer Solar Cells Enabled by Hydrophilic Spacer-Incorporating Polymers Chulhee Lim, Jinwoo Lee, Sun-Woo Lee, Yeonji Jeon, Seungjin Lee, Taek-Soo Kim, Jung-Yong Lee and Bumjoon Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

A new series of P_Ds with oligo ethylene glycol-based flexible spacer (OEG-FS) is developed and demonstrate efficient PSCs with high power conversion efficiency (PCE) of 17.74% processed by hydrocarbon-solvent (toluene) process. This hydrophilic FS alleviates excessive backbone rigidity of the polymer donors (P_Ds), while retaining sufficient aggregation in toluene. Also, the FS enhances P_D/SMA interfacial interactions and improves the blend morphology, affording efficient charge generation and mechanical stress dissipation. Therefore, the resulting PSCs with FS incorporated P_D showed superior PCE (17.74%) and crack-onset strain (10.50%) values, outperforming the PSCs without the FS (PCE = 15.7% and COS = 2.99%). More importantly, we develop intrinsically stretchable PSCs (IS-PSCs) with the OEG-FS containing P_D, accomplishing the best performances in terms of both PCE (12.05%) and stretchability (retaining 80% of the initial PCE after 22% strained). This work provides a simple and effective strategy to design P_Ds for the efficient, green-solvent processed, and mechanically robust PSCs.

5:00 PM EL18.06.61
Stretchable-Gradient Interface of Flexible and Stretchable Electronics for Wearable Health Monitoring Sunju Kang and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

With the rapid development of wearable electronics, the robust interface of flexible and stretchable electronics is also demanded. Currently, flexible printed circuit boards (FPCBs) and stretchable physiological monitoring sensors are assembled by a conventional anisotropic conductive film (ACF) bonding technique. However, the interface can still be prone to delamination issues under repeated external strains subjected to human body movements. Here, a stretchable-gradient interconnect, a novel design and fabrication for integrating the FPCB and stretchable temperature sensor, is reported. The interconnect is designed to have adequate stretchability from the FPCB to the stretchable temperature sensor, establishing a stable transition of internal mechanical stress compliances. In addition, we performed electrical and mechanical stability tests of the proposed body temperature monitoring system with the stretchable-gradient interconnect by applying the device to the wrist with a high bending angle in the human body, and the results show a linear response and high robustness properties over multiple strain tests. This approach enables extended opportunities to develop FPCB-compatible on-skin stretchable sensors with high accuracy and robust mechanical properties.

5:00 PM EL18.06.62
A Single Microtip Shape Memory Polymer Surface with Reversible Dry Adhesion for Transfer Printing Junhyung Kim and Seok Kim; Pohang University of Science and Technology, Korea (the Republic of)

Transfer printing enables a deterministic assembly of micro-scale heterogeneous materials (herein called ‘inks’) fabricated from mother substrates using a polymeric stamp with reversible dry adhesion. During transfer printing, the strong adhesion between stamp and ink allows for the retrieval of the ink from the mother substrate and the weak adhesion in between allows for the release of it to the desired target substrate.
A shape memory polymer (SMP), one of the polymeric materials for transfer printing has a dynamic variation of rigidity upon thermal stimuli. This characteristic divides SMP into two states across the glass transition temperature (T_g): glassy state (under T_g) and rubbery state (over T_g). In the rubbery state where SMP is heated, SMP can freely change its shape. Then, the glassy state SMP after cooling under T_g keeps its deformed shape, and the adhesion of SMP increases dramatically. Thereafter, SMP may recovers its permanent shape to lose its strong adhesion when reheated over T_g.
Employing these characteristics of SMP, a single microtip surface is designed as a polymeric stamp with extreme adhesion reversibility. The transfer printing procedure using a single microtip SMP surface consists of flattening, picking up, and placing. The flattening process changes the microtip to be with a flat region, and thus transparent, which allows precise alignments. Then, an elaborate vertical approach is implemented using a custom mechanical stage. Here, the flattened surface helps easy and conformal contact with an ink depending on the shape of the ink. Once forming a conformal contact, the SMP surface is cooled and generates substantially strong adhesion (20.5 atm) because of the drastic rigidity change. For placing an ink onto the desired target substrate, the deformed microtip SMP surface is reheated over T_g in order to recover its original shape, which makes a point contact with an ink. Since the point contact causes approximately zero adhesion in viscoelastic materials, precise placing is possible.
To demonstrate its outstanding transfer printing ability, the adhesion tests for an single microtip SMP surface to pick up and place are conducted. Also it was shown that the single tip SMP surface can freely manipulate inks regardless of their 3 dimensional shapes. This transfer printing strategy using a single microtip SMP surface presents the highly desired potential for the assembly of microelectromechanical system (MEMS) and other device-level architectures.

5:00 PM EL18.06.63
***In Situ* Patterning Method of Hydrogel for *In Vivo* Applications** Minjeong Kim[1,2] and Dae-Hyeong Kim[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute of Basic Science, Korea (the Republic of)

Despite recent advances in hydrogel applications for bioelectronics and tissue engineering, especially for implantable use, their advanced applications as functional devices are still largely limited without a patterned structure. Several *in vitro* patterning methods for hydrogel have been developed. Still, for implantable use of patterned hydrogel devices, the incision surgery that could be a significant burden to the patient should be accompanied. Here, we present a novel patterning methodology that enables *in-situ* patterning of the hydrogel *in vivo* through the minimally-invasive administration. The *in-situ* patterning method could be deployed based on the distinctive properties of the hydrogel such as appropriate mechanical strength, facile solute diffusion, and various crosslinking mechanisms. Also, with the filler integration, we successfully demonstrated the *in-situ* fabrication and operation of the hydrogel device and the hydrogel tissue scaffold, showing the feasibility, generality, and practicality of the method. This patterning method would facilitate the implantable use of the structural hydrogels by presenting a novel administration method.

5:00 PM EL18.06.64
Integration of Conductive Nanocomposites and Nanomembranes for High-Performance Stretchable Conductor Hye Jin Kim[1,2], Dongjun Jung[1,2], Sung-Hyuk Sunwoo[1], Sonwoo Jung[2] and Dae-Hyeong Kim[1,2,2]; [1]Center for Nanoparticle Research, Institute for Basic Science (IBS), Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Stretchable metallic nanocomposites have been viable material candidates for high-performance soft bio-interfacing electrodes. However, it is still challenging to fabricate a stretchable metallic nanocomposite that features outstanding charge transfer capability and low impedance as well as high conductivity and mechanical stability. Here, we present a material strategy for a stretchable conductor that meets such requirements by integrating stretchable conductive nanocomposites with stretchable conductive nanomembranes. The silver nanowires (Ag NWs) nanomembrane fabricated by the float assembly method is integrated with the Ag NWs nanocomposite prepared by the drop casting method. The compactly assembled NWs in the nanomembrane maximize conductivity by reinforcing the percolation networks of the nanocomposite. Moreover, the nanomembrane lowers impedance by allowing efficient charge transfer to the target tissue through the exposed NWs. After their integration, a high conductivity of ~ 35,700 S cm^{-1} is obtained, and the impedance is decreased by ~88.9% (at 1000 Hz) in comparison to the original Ag NWs-based nanocomposite (i.e., without integration of the nanomembrane). The soft bioelectrode using the stretchable conductor successfully records electrograms from the rat heart, recognizes various arrhythmic events, and applies feedback pacing.

5:00 PM EL18.06.65
Core-Shell Structured Liquid Metal-Nanocomposite Microfiber for Minimally-Invasive Implantable Bioelectronics Seonghyeon Nam[1,2] and Dae-Hyeong Kim[1,2,3]; [1]Center for Nanoparticle Research, Institute for Basic Science (IBS), Korea (the Republic of); [2]School of Chemical and Biological Engineering, Seoul National University, Korea (the Republic of); [3]Department of Materials Science and Engineering, Seoul National University, Korea (the Republic of)

Stretchable conductive fibers have attracted great interest for their distinctive advantages in biomedical electronics. Among them, due to the high electrical conductivity, excellent stretchability, and strain-insensitivity, liquid metal-based fibers have been highlighted as promising material candidates. However, practical biomedical application of liquid metal-based fibers, especially for implantable electronics, has been limited mainly owing to the leakage of toxic metal ions and poor electrochemical property. Here, we present core-shell structured microfiber consisting of a liquid metal alloy as a core and Ag-Au nanowire composite as a shell, along with its minimally-invasive implantation strategy. The proposed microfiber is intrinsically soft, stretchable, biocompatible, and thin, which is ideally applicable to organ interfaces. By solidifying the liquid metal core, such a thin microfiber becomes rigid enough to pierce the skin and can be deployed into the organ by minimally-invasive procedure. Moreover, functionalization of the microfiber by introducing additional micro/nanoparticles into the nanocomposite surface facilitates either lowering impedance or sensing biochemical, showing its broad applicability for strain-insensitive electrophysiological sensor, electrical stimulator, and electrochemical sensor. The microfiber is implanted on the heart and stomach in rodents by the freezing method and performs high-quality biosignal recording and electrical stimulation, offering the capability for a promising platform as implantable bioelectrodes.

5:00 PM EL18.06.67
4D Nanocellulose Printed Circuit Boards Jonathan D. Yuen, Joyce C. Breger and Jonathan A. Yuen; Naval Research Laboratory, United States

Due the nascency of 4D printing, integration of electronic capabilities into 4D printed structures presents opportunities barely explored. We demonstrate microbially-grown, nanocellulose-based, flexible printed circuit boards (PCBs) that can self-fold from flattened 2D forms into a variety of 3D forms - thereby creating 4D nanocellulose PCBs. This can be achieved by printing an SU8 layer on a nanocellulose PCB affixed on rigid surface, and then inducing a strain between the SU8 layer and nanocellulose. When the PCB is selectively cut and then released, the PCB will flex and fold into a 3D shape. This process allows for complexity in both form and electronic capability that has not been previously demonstrated, of which we will present various examples, including kirigami-based patterns.

5:00 PM EL18.06.68
No hysteresis TIPS-pentacene:polystyrene Blend-Based Organic Field Effect Transistor by Extruded Direct Ink Writing and the Application in Resistive Load Inverter Circuit Huiwen Bai, Yi Yang, Richard M. Voyles and Robert A. Nawrocki; Purdue University, United States

As low-cost, low-temperature, large-area, and easy-to-process electronic devices, organic field effect transistors (OFETs) have gained tremendous research interest.[1] Compared to organic semiconductors (OSCs) made with traditional vacuum or photolithography methods,[2] the solution-processed OSCs are promising due to their lower fabrication costs, larger area, and higher feasibility for customization. Over the past few decades, various solution-based fabrication methods for OSCs, such as spin-coating, dip-coating, drop-casting, zone casting, spray-coating, inkjet printing, and roll-to-roll printing, have been investigated.[3] When it comes to distinguished printing methods in the industry, inkjet printing is the most commonly used because its droplet volume can reach the femtoliter range to reduce the destructive effect of solvents and significantly improve the printing resolution. However, inkjet printing can only print low-viscosity materials and limit the utility of printable materials. Furthermore, the so-called coffee ring effect appears when the suspension's concentration is low, resulting in the non-uniform distribution of particles. As an alternative method, the extrusion-based Direct Ink Writing (DIW), due to its low energetic extrusion, can produce a smooth printing surface.[5] In addition, the extrusion-based DIW is considered a simple, adaptable, and low-cost method that is applicable in ambient conditions with moisture and oxygen.[6] Besides supporting a broad range of depositable feedstock materials, such as polymers, alloys and ceramic materials, extrusion-based DIW is also less likely to clog the printing nozzles compared with inkjet printing.[7] These advantages of extrusion-based DIW can facilitate the large-scale production of organic electronics through the automation of industrial process.
We report on fabricating solution-processed bottom-gate/top-contact OFETs with motor-controlled extrusion-based DIW printed semiconductor layer, which is believed to be the first such demonstration.[8] Based on the blend solution of an organic semiconductor, 6,13-bis (triisopropylsilylethinyl) pentacene:polystyrene (TIPS-pentacene:PS), we printed p-type OFETs using extrusion-based DIW method at different in-situ annealing temperatures. We found that the organic semiconductor deposited at 25 degree displayed the best performance with maximum mobility of 0.14 cm^{-2} V^{-1} s^{-1}, I_{ON}/I_{OFF} ratio of 2.7×10^3, threshold voltage of 0.14 V, and minimal hysteresis. The X-ray diffraction spectra and polarized optical microscopic images of the TIPS-pentacene:PS films revealed the changes of crystallinity and thermal cracks at different in-situ annealing temperatures. Static characteristics and long-term stability of resistive load inverters are reported. In addition, bending test was conducted of an OFET under three different bending radii. The pre-bent and post-bent characteristics of the OFET are analysed in this study.

Influence of Channel Thickness on the Electrical Property and the Stability of Amorphous SiZnSnO Thin-Film Transistor Ji Ye Lee[1], Ji Won Kim[2] and Sang Yeol Lee[2]; [1]Korea University, Korea (the Republic of); [2]Gachon University, Korea (the Republic of)

Transparent amorphous oxide semiconductors based thin film transistors (TFTs) are suitable for flexible displays, such as rollable and foldable displays. The electrical property and the stability of amorphous SiZnSnO (a-SZTO) TFTs depending on the channel thickness will be investigated, by using temperature stress (TS) and negative bias temperature stress (NBTS). Also, the Debye length of a-SZTO TFT will be calculated by observing the thickness effect on the performance of TFTs, and the change in the effective carrier concentration will be confirmed. As the channel thickness increases, the threshold voltage (V_{TH}) of a-SZTO will shift in the negative direction. This is mainly due to the increase of carrier concentration. During TS and NBTS, the threshold voltage shift (ΔV_{TH}) will increase steadily, as increasing channel thickness. These results can be explained by the total trap density (N_T) increase due to the increase of bulk trap density (N_{Bulk}) in a-SZTO channel layer.

5:00 PM EL18.06.70
Stretchable Display with Negative Poisson's Ratio Using an Auxetic Structure Beomgil Ha and Byung Yang Lee; Korea University, Korea (the Republic of)

Many studies on stretchable devices that form electrodes on flexible substrates have been reported recently. In this study, a flexible substrate with negative Poisson's ratio characteristics was fabricated to solve problems such as image distortion and electrode deterioration due to Poisson's ratio of existing flexible devices. A flexible substrate was used for the substrate, and a stretchable substrate was completed by inserting a frame having an auxetic structure to realize a negative Poisson's ratio in a sandwich structure. The result of this study is that the Poisson's ratio can be controlled by inserting an auxetic structure into the substrate, thereby minimizing the mechanical strain that occurs when the substrate is stretched. As a result, a flexible substrate with a horizontal elongation of more than 30% and a Poisson's ratio close to zero was obtained. Additionally, LEDs were added on the substrate to realize a display without image distortion when stretched. The development of stretchable substrates with auxetic structures and displays using them can contribute to the development of the stretchable display market in the future.

5:00 PM EL18.06.71
Recoverable, Flexible and Stretchable Liquid Metal Based Electrodes Dong Jin Han and Byung Yang Lee; Korea University, Korea (the Republic of)

With the development of new devices such as wearable devices, soft robots, biomedical devices, and flexible display applications, the need for flexible electrodes or electrodes with little resistance change during tension is increasing. However, many of the obstacles of flexible or stretchable electrodes are large resistance changes or problems with large-area use. In this study, we developed a flexible electrode with little change in resistance even in a tensile state of up to 300% by focusing on increasing the conductivity of the electrode by adding copper and iron nanoparticles to the liquid metal. We have developed an elastic electrode that can be restored in case of damage. Electrodes were connected to LEDs to verify their ability to operate under tension and recover in case of damage.

8:15 AM EL18.07.01
Ambipolar Transcap Based on Graphene Acid Films Applied on an Impedimetric Biosensor Rafael C. Hensel[1,2], Biagio Di Vizio[2], Jijin Yang[2], Francesco Sedona[2], Mauro Sambi[2], Stefano Agnoli[2], Andrea Cester[2], Osvaldo N. Oliveira Jr.[1] and Stefano Casalini[2]; [1]University of São Paulo, Brazil; [2]University of Padua, Italy

The ever-increasing demand for portable electronic devices has brought the need for smaller and more efficient energy storage systems. In this context, transcaps are attractive because they combine the electronic features of a field-effect transistor (FET) and a supercapacitor.[1] Apart from the high efficiency of storing/delivering charge within a few seconds, its charging process controls the channel conductivity. Here, our transcap is composed of a coplanar electrolyte-gated FET on Si/SiO_2.[2] Source and drain are based on interdigitated electrodes (IDEs), which were covered by drop-cast films of graphene acid (GA).[3] GA shares the same wet processability of graphene oxide (GO) due to its stability in aqueous dispersions, but with the advantage of exploiting its satisfactory conductivity, thereby avoiding any reduction step. Moreover, the gate electrode was coated by GA to increase its surface area. The systematic investigation of the current-voltage characteristic in 0.1M NaCl showed that this layout presents ambipolar charge transport. The galvanostatic charge-discharge demonstrated that the delivered energy and power are up to 17.5 mWh/kg and 7.7 W/kg, respectively. This versatile layout was successfully implemented in paper fluidics, demonstrating that it can be applied even to real-time monitoring of an aqueous flux, thereby exploiting both p-type and n-type conduction. Another advantage of GA is its high concentration of carboxyl groups (three times higher than GO),[3] which turns GA promising for biosensing, also improving the adsorption of antibodies on carboxylic acid groups. Proof-of-principle experiments showed the feasibility of implementing the GA-covered IDEs on an impedimetric biosensor to detect cancer biomarkers. Therefore the versatile processability of such devices turns them suitable to be further exploited on portable flexible electronics and sensing applications.

Stretchable Multichannel Polymeric Electrode Array for Large-area and Chronic Surface Electromyographic Signal Recording
Vittorio Mottini and Jinxing Li; Michigan State University, United States

Electromyography (EMG) is a technique employed in clinical and research settings for recording and monitoring the electrical activity produced by skeletal muscles. Conventional EMG recordings are performed with microneedle electrodes implanted in the muscle. To reduce the invasiveness of the technique, surface electromyography (sEMG) is employed. However, a remaining challenge is performing long-term and large-area sEMG recordings while maintaining inter- and intra-patient signal reproducibility. We developed a new stretchable, multichannel, and high-density electrode array based on a novel intrinsically stretchable conductive material based on conductive polymer PEDOT. The new material, combined with scalable laser-based fabrication techniques, allows for low-impedance, stretchable (1500% stretchability), and large-area sEMG monitoring.
Moreover, thanks to the excellent conformality of the device to the skin, the electrodes can record chronic sEMG signals with high signal-to-noise ratios and low motion artifacts and noise for more than 24 hours. This device will allow clinicians to monitor neuromuscular diseases' progression chronically, non-invasively, and accurately.<div id="accel-snackbar" style="left: 50%; transform: translate(-50%, 0px); top: 50px;"> </div>

8:45 AM *EL18.07.03
Flexible Bioelectronic Systems for Treating Pain John A. Rogers; Northwestern University, United States

Managing pain represents an essential aspect of patient care. Current approaches rely primarily on opioids, which present significant risks of addiction and various other adverse side effects. The increasing societal burdens associated with opioids motivates the development of non-addictive alternatives. Engineering-based approaches that leverage implantable electronic devices to eliminate pain in an on-demand fashion have significant potential. This talk summarizes two such technologies, both built in flexible/stretchable forms using bioresorbable electronic materials and targeted for the elimination of post-operative pain over a timescale relevant to the recovery process. The first uses high voltage electrical stimulation; the second relies on local cooling. Both schemes allow for reversible blocking of pain signals in specific targeted peripheral nerves, in a manner that avoids drawbacks of previous technologies based on similar biological mechanisms. The advanced materials aspects, the device designs, and the animal model validation studies will be discussed.

9:15 AM EL18.07.04
Wireless Smart Bandage with Integrated Sensors and Stimulators for Advanced Wound Care and Accelerated Healing Yuanwen Jiang; University of Pennsylvania, United States

Chronic non-healing wounds represent a significant healthcare burden, with more than 6 million individuals affected in the United States alone. A chronic wound is defined as a wound that has failed to heal by 8-12 weeks and is unable to restore function and anatomical integrity to the affected site. These wounds are associated with loss of function and mobility, increased social stress and isolation, depression and anxiety, prolonged hospitalization, and overall increased morbidity and mortality. In addition, management of chronic wounds has been estimated to exceed $25 billion annually. While interventions exist, such as growth factors, extracellular matrix, engineered skin, and negative pressure wound therapy, these treatments are only moderately effective. Current standard-of-care wound dressings are passive and do not actively respond to variations in the wound environment. 'Smart' bandages based on wearable devices hold great potential in advancing treatment of chronic wounds. However, there has been limited development in incorporating both sensors and stimulators for real-time physiological monitoring and active wound care.

For improved therapeutic outcomes, an ideal smart bandage platform needs to meet the following requirements. First, it needs to be mechanically flexible and wirelessly operated to avoid any undesired tethering and discomfort caused by conventional rigid, battery powered devices. Next, it should integrate both sensing and stimulation modalities for autonomous, closed-loop wound management. Finally, it should have on-demand skin adhesion with a tight interface for robust signal transduction and energy delivery during operation, while providing easy detachment to avoid secondary skin damage during device removal.

To address these requirements, we developed a miniaturized flexible printed circuit board (FPCB) capable of dual channel continuous sensing of wound impedance and temperature, as well as delivering programmed electrical cues for accelerated wound healing. To ensure efficient signal exchange and energy delivery between the circuits and the soft skin tissue, we designed a low-impedance and adhesive hydrogel electrode based on electronic-ionic dual conducting polymers. Compared to well-established ionically conducting hydrogels, our dual-conducting hydrogel has lower impedance across the entire frequency domain, giving rise to more efficient charge injection during stimulation. To mitigate secondary skin damage when peeling off the adhesive electrodes, we introduced a thermally controlled reversible phase transition mechanism to the hydrogel backbone and achieved two orders of magnitude lower adhesion at elevated temperature when compared to the normal skin temperature. Using multiple pre-clinical animal models, we found that our smart bandage could continuously monitor skin physiological signals and deliver directional electrical cues, leading to accelerated wound closure, increased neovascularization, and enhanced dermal recovery. Finally, the wireless nature of our smart bandage allowed us to utilize complex animal models, such as parabiosis, to investigate the possible underlying mechanisms behind the observed effect of electrical stimulation. Our data suggests that the beneficial wound healing outcomes could be attributed to the activation of pro-regenerative wound healing genes.

9:30 AM *EL18.07.05
Functional Materials and Devices for Emerging Bioelectronic Interfaces Luisa Petti, Martina Aurora Costa Angeli, Pietro Ibba, Manuela Ciocca and Paolo Lugli; Free University of Bozen-Bolzano, Italy

Thanks to the extraordinary advances recently experienced in the field of materials, manufacturing processes, device designs and architectures, and system integration, it is now possible to realize electronic devices featuring not only standard electrical properties, but also more unique and novel capabilities, such as flexibility, stretchability, twistability, or biocompatibility and biodegradability. Smart functional devices which can ubiquitously conform to complex 3D surfaces, dissolute and degrade in relevant environments, and/or be interfaced with biological systems are extremely important to develop environmental sensors, on-body wearable, or even implantable devices, as well as sustainable precision agriculture solutions. In the realization of all these systems, printing technologies play a key role offering advantages such as cost-effectiveness, large-area scalability, as well as availability of a wide range of sustainable substrates and materials. Very recently, bio-printing is gaining increasingly attention, especially for the realization of bio-derived sustainable devices, as well as bioelectronic interfaces to be used in regenerative medicine and tissue engineering, as well for advanced bio-hybrid devices.

Here, our most recent work on printed (and bio-printed) materials and devices for emerging bioelectronic interfaces – spanning from wearable devices to plant bio-hybrids - will be discussed.
First, we present how printed physical, chemical, and self-powered sensors can be utilized for wearable sports and rehabilitation applications. Specifically, we present (i) the development and validation of printed textile-based strain sensors able to monitor the breathing rate during different activities (ii) the design and fabrication of flexible electrolyte gated field-effect transistors functionalized with an ion-selective membrane for the detection of ammonium in

sweat, and (iii) the development of wearable and soft triboelectric pressure sensors for real-time pulse monitoring and gait analysis.
Next, we move from human wearables to plant wearables, demonstrating how bioimpedance methods can be employed for an effective monitoring of the health status of plants, thanks to the combination of customized printed electrodes, portable impedance analyzers, and ad-hoc developed machine learning classification algorithms.
Subsequently, we show how plants (in particular Arabidopsis thaliana plants) can be interfaced with conjugated polymer nanoparticles (CP-NPs) for a bio-engineered control of photosynthesis and thus plant growth. We show that the roots length of Arabidopsis thaliana plants grown in a medium mixed with CP-NPs yield a 45% increase (as compared to the controls, grown in the absence of CP-NPs) after 9 days of germination.
Finally, we also show how CP-NPs can be mixed with hydrogels to bio-print light-sensitive 3D cell scaffolds for applications in bio-photonics and light-control of living cells.

Tissue-Mimicking Neural Interface Yuxin Liu; National University of Singapore, Singapore

Despite the advancement of neurotechnology, the mismatch between the soft and developing neural tissue and rigid electronics causes adverse immune response, motion artifact and tissue constraint. I will share our recent works on high-density neural electronics, soft neural interfaces that can accommodate biomechanical motion in dynamically moving tissues, and morphing electronic that is shape-shifting and self-adapting with growing neural organoid in vitro and growing nerve tissue in vivo.

11:00 AM EL18.07.07
Achieving Tissue-Level Softness on Stretchable Electronics Through a Generalizable Soft Interlayer Design Yang Li, Nan Li, Yahao Dai and Sihong Wang; The University of Chicago, United States

Stretchable electronics are promising tools for biomedical diagnosis and biological studies because of their high stretchability which can accommodate deformation and promote intimate contact with the human body. However, most existing stretchable electronic devices are relying on electrically functional materials with high Young's modulus in the range of GPa. On one hand, low-modulus substrate/matrix (e.g., hydrogels and ultrasoft silicones) cannot be integrated with high-modulus functional materials to reduce the effective modulus of the entire device, because the modulus mismatch induced unstable interfaces and cracks propagation in the functional layers. On the other hand, building stretchable electronics with conventional high-modulus elastomers still causes 4 orders of magnitude higher in modulus than the soft bio-tissues, which impedes forming the stable interfacing with soft, dynamic living tissues. Here, we present a generalizable soft-interlayer design that, when added between the functional layer and the substrate, can effectively solve the challenge of using existing stretchable electronic materials to build tissue-level-modulus devices (e.g., transistors, active matrix, sensors), while achieving high stretchability. With a soft interlayer of intermediate modulus, the lower modulus mismatch and inherently formed tough bonding at the interfaces synergistically improve the stretchability of functional materials on ultrasoft substrates. High-modulus conductive materials such as carbon nanotubes (CNTs), silver nanowires (AgNWs), and PEDOT: PSS composites are developed into stretchable interconnections with both high stretchability and ultra-low modulus when integrated with ultrasoft silicone substrate using different soft interlayers. Also, a transistor device with an ultralow modulus of 6.7 kPa and stretchability up to 100% is successfully demonstrated on a thin hydrogel substrate through the soft interlayer design. Furthermore, using the laser-based selective etching of the soft interlayer, a 5x5 transistor array device fabricated on the patterned soft interlayer with hydrogel substrate can even achieve a lower modulus of 3.6 kPa, which is 3 orders of magnitude softer than previously reported stretchable transistor arrays on SEBS substrate. Benefiting from the tissue-like softness, our ultrasoft stretchable devices can form more stable and imperceptible contact with dynamic, soft nonzero Gaussian surfaces (e.g., organ surfaces) as compared to the conventional devices with the modulus in the range of MPa range.

11:15 AM EL18.07.09
Flexible and Biocompatible Pectin-Graphene Thin Film Sensor Arrays for Ultra-High Sensitivity Temperature Sensing Ezekiel Hsieh[1] and SungWoo Nam[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of California, Irvine, United States

Pectin films have recently emerged as a promising artificial membrane material for wearable sensing, human-robot interactions, and prostheses owing to their mechanical flexibility and extremely high temperature sensitivity. These films are composed of poly-galacturonic acid chains crosslinked via their carboxyl groups by Ca^{2+} ions, resulting in optically transparent thin films exhibiting temperature dependent ionic conductivity. Previous studies have demonstrated pectin film-based temperature sensor arrays with temperature sensitivities several orders of magnitude higher than traditional semiconductor temperature sensors over a wide functional range relevant to human activities (0 – 45 °C). However, though prior works have established the basic working mechanisms of pectin temperature sensor arrays, flexible and wearable device configurations based on pectin films have not yet been realized. Here, we demonstrate a pectin film design with patterned graphene electrodes in a sandwich configuration across the thickness of the films. This enables not only mechanical flexibility but also individual interrogation of each pixel, greatly reduces the input voltage requirements for measuring the temperature-dependent ionic conductivity, and improves the sensor response time. We additionally leverage the optical and infrared transparency of graphene to result in fully optically transparent devices. The resulting pectin-graphene arrays are also biocompatible and mechanically flexible offering unique opportunities for prosthetic and wearable applications where rigid semiconductor-based temperature sensors would be inadequate. The extremely high temperature sensitivity enables not only surface contact temperature sensing but infrared and convective sensing of warm objects in the vicinity of the sensor. We evaluated these arrays for wearable applications as transparent bandages capable of continuously monitoring skin temperature for wound healing with limited spatial resolution but extremely high temperature sensitivity. We have additionally investigated the use of these arrays for electronic skins in human robot interactions, capable of detecting human contact without requiring force-feedback sensing. Altogether, these flexible pectin-graphene thin film sensor arrays demonstrate a uniquely advantageous means for thin film flexible temperature sensing.

11:30 AM EL18.07.10
Cold Atmospheric Plasma Deposition of Conductive Antibacterial Coatings for Wearable Devices Ulisses Heredia, Sina Nejati, Akshay Krishnakumar and Rahim Rahimi; Purdue University, United States

Silver-based antibacterial coatings are extensively used in the medical industry to prevent the transmission of infectious deceases caused by harmful bacteria. Despite the well-known antibacterial properties of silver nanoparticles, their poor adhesion to target substrates severely decreases the lifetime and efficacy of silver-based antibacterial coatings. Moreover, in traditional coating techniques such as dip coating, the amount and distribution of silver compounds are difficult to control. As a result, the safe use of medical devices is compromised due to a limited antibacterial effect (low silver amount) or a lack of biocompatibility (high silver amount). Therefore, silver-based antibacterial coatings with long-lasting action and optimized silver concentration are highly desirable. Currently, cold atmospheric plasma deposition (CAP) has emerged as an eco-friendly alternative to produce silver-based coatings with customized long-lasting antibacterial properties. In CAP, silver-based antibacterial coatings are produced by the concurrent formation of a polymer matrix and the synthesis of silver nanoparticles. The resulting highly crosslinked polymer matrix provides a strong fixation of the embedded silver nanoparticles thus, extending their sustained release. Here, we demonstrate the direct deposition of antibacterial Polypyrrole-silver nanocomposites by cold atmospheric plasma deposition. The silver content of antibacterial coatings was controlled by the amount of silver nitrate used as a precursor (0.5wt%, 1.0wt%, 2wt%, and 4wt%). The antibacterial properties of polypyrrole-silver nanocomposites were verified through the inhibition zone and contact-killing test showing a good bactericidal effect against *Escherichia coli* and *Staphylococcus epidermidis*. As proof of concept, polypyrrole-silver coatings are directly deposited on carbon-based textiles and used in wearable electrodes with antifouling properties.

SESSION EL18.08: Mixed-Conducting Polymers and Devices

Molecularly Hybridized Conduction in Conjugated Polymers Towards Next-Generation Iono-Electronic Devices Aristide Gumyusenge; Massachusetts Institute of Technology, United States

The implementation of smart body-machine interfaces is attractive for both healthcare applications and future consumer products. Fusing the body and machines, however, requires electronic hardware with i) excellent mechanical compliance, ii) operational stability in physiological environments, iii) reliable harnessing, discerning, amplification, and transduction of physiological information, and iv) ability to adapt or learn from physiological surroundings and execute tasks accordingly. For this highly demanding task, iono-electronics, where a semiconductor responds to incoming ions and undergoes a property change (electronic, optical, mechanical) which is in turn detected or utilized for a specific application are promising candidates. Though conjugated polymers have shown to be ideal conductors for such applications, only a few mixed conductors are studied to date and a one-material-fits-all bottleneck continues to hamper rapid advancements. The challenge lies in the lack of a cross-disciplinary design approach of high-performance materials. Establishing the needed balance between the two antagonistic modes of transport (ion permeability and electronic charge transport) to yield high performance devices has not only become an exciting field of fundamental research, but also a conduit towards advanced electronics. My lab at MIT (the laboratory of organic materials for smart electronics, OMSE Lab) employs molecular design to meet performance requirements in polymer-based iono-electronics. In this talk, I will share our ongoing efforts in designing novel semiconductors with varying degrees of ion-responsiveness and the scope of applications enabled by molecular tuning. We utilize copolymerization as a facile route to yield a library of mixed conductors enabling a variety of applications ranging from rapidly switching electrochemical transistors to high-fidelity artificial synapses. We have shown that by systematically tethering polar side groups onto known excellent electron conductors, we can probe the contribution from both ionic and electronic conduction to the resulting device performance and determine suitable applications. Lastly, my talk will introduce how we are utilizing these novel conductors to design redox-active nanocomposites combining biocompatibility, electrochemical sensitivity, and neuromorphic signal processing capabilities towards high performance bio-electronics.

2:15 PM *EL18.08.02
High-Performance, Printed and Low-Power Complementary Electrochemical Transistor Circuits for Sustainable IoT Applications Magnus Berggren; Linkoping University, Sweden

The realization of electrochemical transistor circuits is reported, targeting an array of different IoT applications. Future IoT circuit technology must be robust, manufactured using easy and sustainable production techniques and must also include materials that are eco-friendly with a minimal CO_2 footprint. This talk will emphasize the material, manufacturing and power consumption properties from application performance and sustainability points of view.

2:45 PM BREAK

3:30 PM *EL18.08.05
Soft Mixed Conductors Towards Bioelectronics with Unconventional Form Factors Jonathan Rivnay; Northwestern University, United States

Direct measurement and stimulation of ionic, biomolecular, cellular, and tissue-scale activity is a staple of bioelectronic diagnosis and/or therapy. Such bi-directional interfacing can be enhanced by a unique set of properties imparted by organic electronic materials. These materials, based on conjugated polymers, can be adapted for use in biological settings and show significant molecular-level interaction with their local environment, readily swell, and provide soft, seamless mechanical matching with tissue. At the same time, their swelling and mixed conduction allows for enhanced ionic-electronic coupling for transduction of biosignals. Such properties stress the importance of bulk transport processes, and serve to enable new capabilities, device concepts, and form factors relevant for, for example, electroactive scaffolds and bioactive constructs to modulate tissue state and/or cell fate. In this talk, I will demonstrate how molecular design and processing can be leveraged to achieve soft, conductive composites that are amenable to 3D printing, for example by micro-scale continuous liquid interface processes. Particle-based active materials can be readily tuned, integrated into process flows, and post-processed to achieve scalable soft, flexible, and stretchable electronics. New materials design will continue to fill critical need gaps for challenging problems in bio-electronic interfacing, regenerative engineering, and soft robotics.

4:00 PM EL18.08.06
Adhesive Semiconducting Polymers and Electrochemical Transistors for Conformable Biointerfacing Nan Li and Sihong Wang; University of Chicago, United States

Integrating bioelectronics with living biological tissues to interrogate and improve health status represents an important avenue for realizing human-machine interfaces. Semiconducting polymers-based transistors (e.g., organic electrochemical transistors (OECTs)) as an advanced sensing device, are highly desired for direct electrical biointerfacing due to their low operation voltage, high sensitivity and signal-to-noise ratio. We previously demonstrated a universal and facile approach for imparting conjugated polymers with a range of functional properties including direct photopatterning and biochemical sensing. To interface with wet and dynamically moving tissues, for example, heart, brain, or sciatic nerve, conventional suturing causes tissue/device damage and cannot achieve good conformability; having the adhesive property will ease the attachment process and help achieve a conformable contact and high spatial sensing resolution. However, the use of a separate adhesive layer between the semiconducting channel and tissue can cause increased interfacial impedance. Thus, developing an intrinsically adhesive active interfacing layer will significantly improve the devices' conformability on tissue surfaces and signal acquisition sensitivity. So far, however, to the best of our knowledge, none of the existing high-performance p/n-type semiconducting polymers are adhesive owing to a number of challenges, which pose significant challenges for using OECTs to achieve conformable electrical interfacing with wet and dynamically moving biotissues.

In this talk, I will present the development of an intrinsically adhesive semiconducting polymer by creating a rationally designed polymer network with interpenetrating semiconducting polymers and adhesive brush polymers to realize both high normalized maximum transconductance (~100 siemens per centimeter) and good adhesion on wet biotissues (interfacial toughness ~35 joules per square centimeter). Benefiting from the brush polymer design, the semiconducting polymer network possesses soft and viscoelastic mechanical properties (Young's modulus ~10 kilopascal) similar to biotissues, moderate water absorption (30 %), controllable swelling (<10 %), and abundant tissue-reactive groups (-COOH and -NHS), which synergically contribute to the adhesion on wet tissue surfaces. In addition, the semiconducting material shows abrasion-resistance and high stretchability above 100 % strain, which lead to the robust electrical performance. Also, the material presents good biocompatibility owing to low mechanical strain. Furthermore, enabled by the compatibility of the adhesive polymer with solution processing and vacuum deposition procedures, we fabricated an intrinsically adhesive and stretchable OECT with the adhesive semiconducting polymer as the active channel and gate and demonstrated its use for monitoring electrophysiological signals consistently and reliably on wet heart surfaces under perturbation scenarios.

4:15 PM EL18.08.07
Beyond 10 MHz/V High Speed All-Vertical Electrochemical Transistor Jung Woo Moon, Dong Gue Roe, Soo Young Cho, Yonghyun A. Kwon, InCheol Kwak, Seonkwon Kim, Seonmi Eom and Jeong Ho Cho; Yonsei University, Korea (the Republic of)

Organic electrochemical transistors (OECTs) have emerged as promising candidates for next-generation biosensing device due to their remarkable transconductance, low threshold voltage and good bio-compatibility. However, OECTs had to have a slow driving speed due to its unique operating principle, which have been pointed out as a disadvantage of OECTs. We propose another approach for overcoming this obstacle. Moreover, since most OECTs perform electrolyte gating, gating with Ag/AgCl reference electrode is common, therefore scalability was often not good. An all-vertical OECT architecture enable outstanding fast operating speed, and also enables to expansion of large-area and high-density OECTs. Simple approach for implementing the patterned Ag/AgCl reference electrode could be an answer for the scalability. As a result, 14 MHz/V operation frequency was yielded, which is the highest value for OECTs reported to date.

4:30 PM EL18.08.08
3D-printed OECT for Flexible Complementary Circuits Matteo Massetti; Linkoping University, Sweden

Silicon-based (Si) complementary metal-oxide-semiconductor (CMOS) field-effect transistors have been one of the main components in the field of the integrated circuit (IC) since the 1980s, mostly due to their low power consumption. For this reason, Si-based CMOS devices have been researched for Internet of Things (IoT) applications, acting as low-power sensors (e.g., motion, light, temperature). In the last decades, there have been a growing interest in developing flexible and soft IoT modules, capable of conforming to different shapes and eventually even placed on skin/inside the body, acting as smart biological sensors.
For this kind of applications, the perfect candidate is represented by organic electrochemical transistors (OECT). Indeed, OETCs typically operate with < 1 V and possess high transconductance, exploiting a mixed ionic-electronic semiconducting polymer as an active material and a highly ionically conducting electrolyte.
Here, we report the development of functional inks for 3D printing a flexible complementary OECT-based circuit. The electrical connections are 3D printed using carbon/silver-based flexible blends. The channel area is defined using 3D-printable green alcohol-based formulations of a n/p-type organic semiconducting materials. Finally, we print a PDMS formulation to insulate the electrical connections and define the channel area. These printed OECTs show excellent electrical and mechanical properties. In addition, we demonstrate the possibility of exploring alternative geometries to improve the circuit integration into smaller footprints as well as demonstrating low power consumption and operational voltage.
These fully 3D-printed inverters thus represent an interesting step towards the development of conformable, and wearable devices for IoT applications. In addition, the low operation voltage (<1V) offers the possibility of having self-powered devices (e.g. by light, heat, wireless power), thus paving the way to battery-free wearable electronics.

4:45 PM EL18.08.09
Self-Healable Printed Electronic Cryogels for Bioelectronics and Plant Monitoring Eloise Bihar[1], Elliot Strand[1], Megan N. Renny[1], Catherine Crichton[1], Ignacy Bonter[2], Jim Haseloff[2], Robert Mcleod[1] and Gregory L. Whiting[1]; [1]University of Colorado-Boulder, United States; [2]University of Cambridge, United Kingdom

Biocompatible cryogel scaffolds are of great interest in the field of biomedical research and translational medicine. Cryogels are traditionally used for the encapsulation of therapeutic or biological agents such as small molecule drugs, proteins, or biomolecules. Amongst them, Poly(vinyl alcohol) (PVA) is a good candidate for a novel gelling agent due to its self-healing properties, mechanical tunability, and biocompatibility. In this work, we present a novel method for integrating printed electronic materials with biocompatible PVA-based cryogels to form hydrogel bioelectronic devices. The electronic gels can be customized to offer various functionalities, including supercapacitors, electrodes, and Organic Electrochemical Transistors (OECT). These highly stretchable cryogel-based devices exhibit high conductivity (up to 350 S cm^{-1}), high transconductance (in the mS range), and high capacitance (up to 4.2 mF g^{-1}), as well as high stretchability (up to 330% strain), and self-healing properties. The biocompatible functionalized gel-based electrodes and transistors were successfully implanted in plant tissue. Data recording the ionic activity was collected for over two months with minimal scar tissue in tomato stems. These cryogel-based electronics are excellent candidates for tissue engineering scaffolds, biosensing, and drug-eluting systems.

SESSION EL18.09: Poster Session II
Session Chairs: Ho-Hsiu Chou, Francisco Molina-Lopez and Sihong Wang
Wednesday Afternoon, April 12, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM EL18.09.01
Photosensitisation of Inkjet-Printed Graphene with Stable All-Inorganic Perovskite Nanocrystals Jonathan S. Austin[1], Nathan D. Cotttam[1], Jonathan H. Gosling[1,1], Chengxi Zhang[2], Feiran Wang[1], Tyler James[1], Peter Beton[1], Yundong Zhou[3], Gustavo F. Trindade[3], Christopher Tuck[1], Richard Hague[1], Oleg Makarovsky[1] and Lyudmila Turyanska[1]; [1]The University of Nottingham, United Kingdom; [2]Shanghai University, China; [3]National Physical Laboratory, United Kingdom

Photodetectors based on low-dimensional materials are promising candidates for next generation optoelectronic devices and over the past decade the photoresponsivity of these devices has improved drastically due to material innovations [1]. All-inorganic perovskite nanocrystals (NCs) have been of particular interest owing to their high absorption cross-sections, long carrier diffusion lengths, tunable optical properties, and improved stability compared to other perovskite materials [2,3]. This stability enables the use of new manufacturing methods, specifically inkjet printing, which offers a promising route for scalable fabrication of devices with a high degree of design freedom and opportunities for device fabrication on flexible substrates [3-5].

Here we report a novel formulation of all-inorganic $CsPbBr_3$ and $CsPb(Br/I)_3$ NC inks for inkjet printing thin films over large areas and demonstrate high precision fabrication of complex photoluminescent patterns on rigid and flexible substrates. These films are used to photosensitise chemical vapour deposition (CVD) grown graphene transistors increasing their photoresponsivity to 10^7 A/W in the VIS-UV range [6], which is greater than that of any other inkjet-printed device recorded in the literature ($R = 10^4$ A/W [7]). We also fabricated fully printed photodetectors by incorporating inkjet-printed graphene (iGr) and printed Au electrodes. The fully printed $CsPb(Br/I)_3$/iGr photodetector displayed a maximum responsivity of 10 A/W [6], which to our knowledge is the largest responsivity reported for this type of device ($R = 10^{-1}$ A/W [8]). The performance of these devices is analysed and explained using modelling of charge transport through functionalised graphene and graphene networks [5] and explained by slow carrier dynamics governed by complex charging processes [9]. For reduced manufacturing complexity, we formulated and printed a hybrid ink containing both iGr and $CsPbX_3$ NCs (iGr-$CsPbX_3$) to produce photodetectors in a single deposition step on rigid and flexible substrates. In these detectors a single hybrid iGr-$CsPbX_3$ film acts as both photosensitive and conductive layer and achieved a maximum responsivity of 10^{-2} A/W, with negligible change in conductivity up to 200 bending cycles [6]. This work demonstrates successful integration of low-dimensional materials with additive manufacturing technologies and highlights its potential for scalable and customisable production of optoelectronic devices on rigid and flexible substrates.

Contact Resistance of Low-Voltage n-Channel Organic Thin-Film Transistors Based on Three Different Organic Semiconductors Sabrina Steffens[1], Tobias Wollandt[1], James Borchert[2], Ute Zschieschang[1], Benjamin A. Günther[3], Lutz A. Gade[3], Bettina V. Lotsch[1] and Hagen Klauk[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]Universität Göttingen, Germany; [3]Universität Heidelberg, Germany

Transistors based on organic semiconductors provide the possibility of fabricating electronic circuits and systems on flexible polymeric substrates, owing to the low process temperature of organic semiconductors. For mobile systems that can be used in wearable electronics and in diagnostic devices directly attached to the human body, an extremely low power consumption is a critical requirement. From a circuit-design perspective, the most effective approach to minimize the power consumption of digital electronic circuits is to combine p-channel and n-channel field-effect transistors in a complementary circuit design.

While the performance and stability of p-channel organic thin-film transistors (TFTs) are already sufficient for certain applications, the performance and stability of n-channel organic TFTs are still comparatively poor. This is partially due to the fact that in n-channel organic transistors, charge transport takes place in the lowest unoccupied molecular orbital (LUMO), whose energy must fall within a relatively narrow region between approximately -4.0 to -4.5 eV to allow efficient charge exchange with the source/drain contacts while providing sufficient stability. Organic semiconductors that fulfill this requirement include π-conjugated systems with strong electron-withdrawing substituents either attached to or incorporated into the molecular backbone.

Here, we compare the performance of low-voltage n-channel organic TFTs based on three promising small-molecule semiconductors having LUMO energies between approximately -4.0 to -4.5 eV, namely N,N'-bis(2,2,3,3,4,4,4-fluorobutyl)-(1,7 & 1,6)-dicyano-perylene-tetracarboxylic diimide (ActivInk N1100; Angew. Chem. Int. Ed. 43, 6363, 2004), 2,9-bis(heptafluoropropyl)-4,7,11,14-tetrabromo-1,3,8,10-tetraazaperopyrene (TAPP-Br_4; Adv. Funct. Mater. 23, 3866, 2013) and diphenylethyl-3,4,9,10-benzo[de]isoquinolino[1,8-gh]quinolinetetracarboxylic diimide (PhC_2-BQQDI; Sci. Adv. 6, eaaz0632, 2020). The TFTs were fabricated on flexible polyethylene naphthalate (PEN) substrates or on silicon substrates using a hybrid gate dielectric composed of a thin, plasma-grown aluminum oxide layer and an *n*-tetradecylphosphonic acid self-assembled monolayer. TFTs were fabricated either in the inverted staggered (bottom-gate, top-contact) or the inverted coplanar (bottom-gate, bottom-contact) device architecture, using gold for the source and drain contacts. In the coplanar TFTs, the surface of the source and drain contacts was functionalized with a chemisorbed monolayer of one of four different thiols, namely 4-methylbenzenethiol (MeTP), 4-(methylsulfanyl)-thiophenol (MeSTP), 4-methoxythiophenol (MeOTP) and benzyl mercaptane (BM) to improve the charge exchange between the contacts and the semiconductor. The semiconductors were deposited by thermal sublimation in vacuum. All electrical measurements were performed in ambient air

For each of the three semiconductors, the TFTs fabricated in the coplanar device architecture were found to have a smaller contact resistance (measured using the transmission line method) than the staggered TFTs; this finding is consistent with results reported previously for low-voltage p-channel organic TFTs (Nature Commun. 10, 1119, 2019). Regardless of the semiconductor, the best TFT performance was obtained by functionalizing the contacts with MeSTP. In addition, PhC_2-BQQDI and N1100 were found to provide smaller contact resistance and larger effective carrier mobility than TAPP-Br_4. Flexible coplanar PhC_2-BQQDI TFTs with MeSTP-functionalized contacts have an intrinsic channel mobility up to 0.6 cm^2/Vs, an on/off current ratio up to 10^6, a subthreshold slope as small as 100 mV/decade, and a contact resistance as small as 90 Ohm-cm (a record for n-channel organic TFTs). These results are important in view of the realization of low-voltage organic complementary circuits for low-power flexible electronics applications.

Highly Efficient Ternary Near-Infrared Organic Photodetectors for Biometric Monitoring Chih-Ping Chen; Ming Chi University of Technology, Taiwan

Near-Infrared (NIR) small molecule acceptor with the absorption of up to wavelength of 1000nm attracted much attention for organic photodetectors (OPD) and the biometric application. We evaluate the IEICO-4F as third component for PffBT4T-2OD: $PC_{71}BM$ based OPD to having efficient NIR response and greatly suppressing leakage current at reverse bias. By variation of the blend ratios and thickness (250-600nm), we realized an NIR OPD with ultralow dark current density (J_D=9.43 nA cm^{-2}) with an ultrahigh detectivity (D^*= 2.7 $\times 10^{12}$ Jones (850 nm)). Furthermore, the OPD shows consistent response, good reproducibility, and stability with a frequency of 0.5 MHz (f_{-3dB}) and ultrafast rise/fall response (560ns and 230ns at –2 V) under 850nm LED light. We demonstrated highly sensitive devices with photoresponse covering from the ultraviolet to near-infrared regions. The inferior compatibility originating from the intermolecular interaction between PffBT4T-2OD and IEICO-4F allowed manipulate the degree of phase donor and acceptor separation for well-defined phase segregation, leading to efficient charge separation, transport, and collection in ternary blends. We demonstrated the transmissive pulse oximetry by integrated our OPD and the LED and precisely calculated and collected the pulse oximetry.

Direct Printing of Suspended Metal Oxides Nanowires on MEMS Chip as Gas Sensor Yu Liu[1,2], Hongjun Liu[2], Xiaoyi Zeng[2], Zijun Chen[2], Xing Cheng[2] and Ji Tae Kim[1]; [1]The University of Hong Kong, China; [2]Southern University of Science and Technology, China

Semiconducting metal oxides(MOs) are prevalently used in gas sensors thanks to its unique charge transport mechanism being sensitive to surrounding gas molecules. [1] To enhance the performance of the chemiresistor-type gas sensor, both the composition and structure of the sensing materials need to be optimized. [2] One-dimensional MOs nanowires(NWs), comparing to the conventional thick films, have exhibited outstanding gas sensing performance such as lower detection limit and shorter response time.[3] Currently, various synthesis methods of MOs NWs have been developed including hydrothermal, chemical vapor deposition, electrochemical deposition, and electrospinning, etc. However, the current existing methods fail to deliver precise point-to-point fabrication, which makes the integration of multiple gas sensing materials rather challenging. In addition, with the existing NWs synthesis technology, the fabrication of gas sensing NWs on a suspended heater membrane of the Micro-Electro-Mechanical System(MEMS) chip is complicated.[4]
Here, inspired by the printing electronics, we present an alternative approach to fabricating freeform MOs NWs directly on the MEMS heater chip. The method exploits a nano-pipette filled with the ink containing polymer binder and metal precursors to print a preliminary composite wire with hundreds of nanometers in diameter and suspended arch architecture on micrometer-scale MEMS electrode pairs via a precise displacement and positioning system. After calcination, polycrystalline metal oxide NWs are successfully obtained. By optimizing the type or quantity of metal precursors in the ink, or adding precursors of noble metals such as gold, silver, platinum, and palladium, abounding MOs-based composite NWs are fabricated for diverse gas sensing. In addition, through such a point-to-point direct printing technology, various semiconducting metal oxides NWs can be assembled in a micron-scale region with high integration density, excellent precision, and nano-scale characteristics, which largely reduces power consumption and improves sensing performance. Furthermore, it also offers us a promising and straightforward process for multi-oxides material-based “E-nose” device fabrication.

A Pen-on-Paper Graphene Oxide-Based Nanocomposite for Multitype Strain Sensing Zengsheng Weng and Fangxin Zou; The Hong Kong Polytechnic University, Hong Kong

Flexible strain sensors that exploit nanotechnologies to achieve superior performances have become increasingly indispensable in a number of high-value-added applications, such as human body monitoring, structural health monitoring and human-machine interaction. For real-world implementations, it is utterly important to fabricate sensors that, on one hand, possess high sensitivities, and on other hand, are customizable and convenient to install.

Recently, the pen-on-paper (PoP) approach – a fundamental printing technique that makes use of ubiquitous and portable raw materials – demonstrates the potential to meet the installation requirements of flexible strain sensors in real-world applications. Moreover, many modified graphene-based nanofillers have been shown to exhibit high sensitivities to microscopic deformations. Owing to their long-term stable dispersibility in solutions, modified graphene-based nanofillers are considered high suitable ingredients for PoP inks. On this basis, a PoP ink was prepared from graphene oxide (GO) in this work, and the ink was used to fabricate a flexible GO/paper strain sensor that can capture multiple types of deformations (i.e., in-plane tension, in-plane compression and out-of-plane pressure).

To prepare a GO ink, graphene was first oxidized by the Hummers’ method to a certain degree of oxidation and then put into an ordinary ink pen, together with polymer dispersants including phenolic resin and amphoteric polyacrylamide. GO/paper sensor specimens were fabricated by using the ink pen to mark on printing paper. The dimensions of the sensor specimens are fully customizable. The ink demonstrates an excellent writability even when a piece of paper is in bent state. Furthermore, even if an ink is left unused for several months, sensor specimens that are fabricated from it would exhibit a similar sensing capacity to those that are fabricated from a freshly prepare ink.

The sensitivities of the GO/paper sensor to in-plane tensile strain and in-plane compressive strain were evaluated by subjecting sensor specimens to bending. Within 1% strain, the gauge factors were found to be 121 (tension) and 103 (compression). Thanks to the 3D structure of GO, the GO/paper sensor is also able to capture out-of-plane pressure, exhibiting a sensitivity of 0.34 kPa^{-1} within pressure range of 2-7 kPa. To simulate real-world implementations, sensor specimens were attached onto aluminum alloy substrates to monitor the tensile strain, compressive strain and pressure applied onto the substrates. The real-world practicality of the GO/paper sensor was further demonstrated through a number of applications, including gesture recognition, eye movement and intraocular pressure monitoring, and aerodynamic pressure measurement.

Through the abovementioned experiments, it was observed that the sensitivity of the GO/paper sensor to tensile and compressive strain is inversely proportional to the degree of oxidation of the GO used. From material characterization results, it was found that as the degree of oxidation of the GO in a sensor specimen increases, the energy band gap and the distances between the GO particles would increase, while the number of layers and the size of the GO particles would decrease. The result of these changes would be the damaging of the conductive network in the sensor specimen and the weakening of the tunneling effect across the GO particles, leading to a reduction in sensitivity.

To summarize, this work introduces a flexible GO/paper strain sensor fabricated by the PoP approach. The sensor demonstrates high sensitivities to various types of real-world deformations, including in-plane tension, in-plane compression and out-of-plane pressure. Moreover, the GO ink prepared possesses an outstanding long-term stability. Last but not least, the inverse relationship between sensitivity and the degree of oxidation of GO was discussed.

5:00 PM EL18.09.06
Printed Memristors for Memory, Computing and Hardware Security Hongrong Hu[1], Alexander Scholz[1], Liang Yang[1], Gabriel Cadilha Marques[1], Florian Feist[1], Eva Blasco[2], Christopher Barner-Kowollik[3], Martin Wegener[1] and Jasmin Aghassi-Hagmann[1]; [1]Karlsruher Instituts für Technologie, Germany; [2]Universität Heidelberg, Germany; [3]Queensland University of Technology, Australia

Memristors are two-terminal electronic devices whose resistance can be changed upon the application of an electrical field. The device could be potentially used for non-volatile memory, novel computing paradigms, and hardware security. Currently, most of the reported memristors are fabricated by traditional thin film techniques such as vacuum deposition methods, photolithography, or CMOS-compatible processes. Additive manufacturing techniques like inkjet or laser printing have only recently been demonstrated to be feasible for memristor fabrication. This has the advantage of efficient material usage, cost-effectiveness, and rapid prototyping capability.

We demonstrate three types of memristors fabricated either by inkjet printing or laser printing. The first device is a fully inkjet-printed symmetric Ag/ZnO/Ag structure which shows digital resistive switching. Our utilized ZnO precursor ink is water-based and requires a post-deposition annealing step. The fully inkjet-printed memristor exhibits excellent parameters such as a high R_{off}/R_{on} ratio of 10^7, a long retention time of over 10^4 seconds, good endurance, and almost forming-free characteristics, which are advantageous for non-volatile memory applications. The second device is partially inkjet-printed and based on Ag/WO_{3-x}/Au. The device itself can be probed dynamically by applying a bias to exhibit digital resistive switching, caused by conductive filaments, or it can be operated as an analog resistive switching device without forming a conducting filament. The analog resistive switching properties are utilized to mimic the behavior of a biological synapse or neuron. This includes short-term plasticity, metaplasticity, and integration of several input signals. The third presented device is a fully laser-printed memristor formed by Ag and Pt as the electrodes and ZnO as the active layer. The semiconductor ZnO is converted from a novel precursor ink through local laser-induced hydrothermal synthesis. In addition, the memristors are integrated into a 6×6 fully-laser printed crossbar structure and successfully utilized for physical unclonable function (PUF) implementation.

In summary, we have demonstrated inkjet-printed and laser-printed memristors fabricated in a facile, rapid, and material-efficient approach. The introduced printed memristors show excellent device performance and are hence promising candidates for applications in non-volatile memory, neuromorphic computing, and hardware security.

Formation of NiSi by Pulsed Laser Annealing on Contact Resistance Reduction and its Applications on Flexible Inverter and 6T-SRAM Yu Chieh Hsu[1], Yan Yu Chen[1], Jia-Min Shieh[2], Wen-Hsien Huang[2], Chang-Hong Shen[2] and Yu-Lun Chueh[1]; [1]National Tsing Hua University, Taiwan; [2]Taiwan Semiconductor Research Institute, Taiwan

With the proper selection of metal silicide, contact resistance can be effectively reduced between the source/drain (S/D) and connected metal. The addition of metal silicide at any connection region can also raise the on/off ratio and improve the performance of electric devices. In this work, we applied the pulsed laser annealing (PLA) method to form nickel silicide (NiSi) between S/D metal and the top connecting metal. Three different kinds of laser wavelengths, including 355 nm (ultraviolet laser), 532 nm (green laser) and 1064 nm (infrared laser), were used to compare the results of NiSi formation in these laser annealing processes. NiSi phase with low sheet resistance was formed by an ultraviolet laser annealing process without damaging the polyimide (PI) substrate. After integrating the PLA NiSi onto the S/D region, the on/off ratio increased at least 3 times and the field effect mobility increased by 50%. The contact resistance was lowered from 21 kΩ to 8.5 kΩ after integration. Furthermore, the voltage gain of the CMOS inverter was also improved by 30%, making it have a faster switching speed. For the 6T-SRAM part, the static noise margin (SNM) of 6T-SRAM is elevated from 0.82V to 1V at V_{dd} = 4V. This work shows the achievability of using the PLA process to synthesize low thermal budget NiSi on the flexible substrate and the successful integration provides a new route to improve the performance of flexible 6T-SRAM devices. Better performance of the devices can ameliorate the application and function of wearable electronics, which will be an important part of the IoTs generation in the future.

5:00 PM EL18.09.08
Thiol-ene Chemistry in the Dielectric Layer Manipulating Polymer-based Devices from Transistors to Non-volatile Memory Devices Chang-Jing Liu and Wen-ya Lee; Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, Taiwan

Stretchable electronic materials with a high dielectric constant are promising for low-voltage-driven devices. This work demonstrates a stretchable dielectric layer using poly (acrylonitrile-co-butadiene) (NBR), a higher dielectric constant for the dielectric layer. The stretchable dielectric layer is cross-linked using the thiol-ene reaction between the double bond and the thiol functional groups. It has also been found that the chemical structure of thiol functional groups is capable of determining the device's memory characteristics. The CN triple bond in the NBR polymer structure is highly polarized, thus leading to a high capacitance. The highest capacitance can reach 60 nF/cm^2, and the dielectric constant can reach 14.6. Moreover, the mobility can approach 2.87 cm^{2}V^{-1}s^{-1}, the on-off ratio reaches 10^6, and the threshold voltage is 0 V. In addition, by observing the hysteresis characteristic of the device, it can be found that the memory windows of the crosslinked NBR dielectric showed a large window of 3.14 V under a voltage program voltage of -5 V. This results indicates that the crosslinking density can affect charge retention capability of the devices. The memory characteristics and synaptic behavior of devices have also been achieved using cross-linked NBR-based transistors. This work provides new insight into designing neuromorphic devices for the next generation of artificial intelligence.

Photocurable Stretchable Silver Nanocomposite Electrodes Pei-Tun Liao, Wan-Yi Lai and Wen-ya Lee; Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, Taiwan

Stretchable conductive electrodes are an essential component to transport electronic current without degradation, even under large deformation. To achieve reasonable electronic properties in soft electronics, it is necessary to transmit electronic signals through stretchable conductive materials to avoid loss of signal under strains. However, it is challenging to obtain stretchable electrodes with high stretchability (100%) and conductivity (>10^6 S/cm). Silver nanowire (AgNWs) is a great one-dimension candidate for a stretchable and conductive electrode due to their excellent electrical characteristics. The purpose of our research is to prepare a stretchable silver nanocomposite using AgNWs by modifying silver nanowires with polyisoprene via thiol-ene chemistry. The nanocomposite decreases the contact resistance to achieve high conductivity and low sheet resistance. Furthermore, Adding polyisoprene can effectively improve stretchability. The photo-cured stretchable electrodes show great solvent resistance under various organic solvents. The great solvent resistance makes the stretchable electrode patternable. Currently, our stretchable electrode patterning has been successfully developed to below 20 μm, and the sheet resistance can be controlled below 0.8 Ω sq^{-1} under 100% strain. This work successfully demonstrates photo-patternable stretchable electrodes with low resistance and high stretchability.

5:00 PM EL18.09.10
Morphological Investigation of High Performance Bulk Heterojunction Active Layer to Probe the Origin of Device Instability Haoyu Zhao, Nathaniel L. Prine, Guorong Ma, Andrew Bates and Xiaodan Gu; The University of Southern Mississippi, United States

The performance of conjugated polymer-based organic photovoltaic device relies on the bulk heterojunction morphology of the electron donor and acceptor blend. The morphology including the average domain size, crystallinity, and phase purity of donor/acceptor blend determines the device performance. Although the power conversion efficiency (PCE) is above 18%, the origin of the instable performance over longer times remains poorly understood. In this work, we conducted multiple characterization techniques to explore the dynamic, temperature-dependent morphology of a state-of-the-art donor polymer (PM6) blended with a non-fullerene small-molecule acceptor (Y6). Particularly, we focused on the thermal analysis of the donor and acceptor using fast scanning calorimetry (Flash DSC) to understand the crystallization kinetics. Combined with the assistance of atomic-force microscopy paired with infrared microscopy (AFM-IR) and X-ray scattering, we concluded the origin of PCE loss can be attributed to the severe phase separation caused by acceptor diffusional crystallization. The pure Y6 showed crystallization dominates the process at 110 °C. And the isothermal crystallization of donor further accelerated for Y6 in the blend. As the blend is maintained at elevated temperatures, the crystallization of the Y6 domains was observed to induce phase separation with donors, as evidenced by the AFM-IR characterizations. Finally, we systematically examined the impacts of operational conditions (temperature and time) on the blend film morphology, which could suggest a pathway to suppress the crystallization to improve the device stability in future.

5:00 PM EL18.09.11
Chemical Activation of Commodity Plastics for Patterned Deposition of Flexible Electronics Jessica Wagner[1], Jared Fletcher[1] and Stephen A. Morin[1,2,2]; [1]University of Nebraska - Lincoln, United States; [2]University of Nebraska–Lincoln, United States

A low-cost and scalable procedure for the deposition of electronic materials onto thin polymeric substrates would be useful to the fabrication of flexible circuits. Traditional fabrication methods such as photolithography and laser-direct structuring are expensive, require long processing steps, and are not readily scalable to 3-dimensional components or flexible polymeric substrates. While electroless deposition is an ideal method for bridging the gap from 2D to 3D fabrication, metal delamination of the deposited films remains a significant problem. We have developed a general approach to increase the adhesion of metal films to commodity plastic substrates using a metal-chelating polymer, polyethyleneimine, in conjunction with patterned electroless deposition. When combined with flexible microfluidic reactors for deposition of different metals and materials (conducting, semi-conducting, etc.), a procedure (microfluidic-directed material deposition or mDMD) for entirely solution-based manufacturing of flexible and non-planar electronics can be realized. We demonstrated the durability of these traces using adhesion tests and mechanical deformations and illustrated the functionality of these metals in simple electronic circuits and electrochemical devices. The ability to deposit different types of materials following the reported procedure allows for the fabrication of flexible circuits with a diversity of functionalities (e.g., optoelectronic, potentiometric, etc). mDMD is compatible with a diverse array of plastics (e.g., PC, PET, PP), metals (e.g., copper, nickel, silver, and gold), and, through the use of chemical bath deposition procedures, semiconductors (e.g., metal chalcogenides and oxides) with properties applicable to flexible electronics, sensors, and electrochemical devices.

5:00 PM EL18.09.12
Flexible Adhesive-based Multilayer Antenna Using Press Patterning at Room Temperature for Electronic Applications Min-Seok Jeon[1], Jae-Hoon Lee[1], Jeong-Ryul Kim[2] and Duk-Hee Kim[3]; [1]Korea Testing Laboratory, Korea (the Republic of); [2]ICH Co., Ltd., Korea (the Republic of); [3]APC Co., Ltd., Korea (the Republic of)

Flexible electronics have attracted significant research attention due to their distinct features and emerging applications in numerous fields such as, flexible displays, implantable sensors, wearable medical devices, and energy storage systems, among other applications. One of the current and future challenges in electronics is to develop suitable multifunctional materials which can address simultaneously several parameters such as flexibility, lightweight, conductivity, environmental impact, and production cost. Adhesive polymer electronics (multiply patterned laminates without lithography and etching process) forms a new and high-potential technological field, which may pave a way for many novel electronic applications and products. In this presentation, a new distinct fabrication method was applied to make flexible and adhesive patterned multilayer antenna using just press patterning at room temperature. This process needs no etching steps and gives no environmental wastes. In addition, several process steps can be reduced and, therefore, cost competitiveness can be improved very much. Overall structure is composed of multi polyimide film, metal film, adhesive and liner film. The patterned structure can be made only pressing at room temperature. Dielectric properties of the antenna were measured in the range of 6 to 10GHz. Precise cross-sectional structures, interfaces, and defects were analyzed by SEM, EDX, and ion beam polishing. Mechanical and thermal durability tests were performed to demonstrate possibility to several fields of wearable electronic applications. Failure analysis was compared between test antenna with different structures on the basis of physics-of-failure. Overall reliability of the antennas was evaluated by the results of durability test and failure analysis.

Direct Metal Printing of 3D Electronic Components and Circuits Using MetalJet Negar Gilani, Nesma Aboulkhair, Marco Simonelli, Mark East and Richard Hague; University of Nottingham, United Kingdom

Printed electronics have been the focus of increasing attention in the past decade due to their wide range of diverse applications, including soft robotics, actuators, wearable electronics, biomedical applications, and human-machine interfaces. Considerable research has been devoted to nanoparticle-based inkjet printing as a large-scale fabrication method of such devices, and tremendous advances have been obtained. However, there are still process-related challenges to be addressed, including nozzle clogging, ink formulation, nanoparticle synthesis, drying, and sintering of the nanoparticles. Furthermore, higher electrical resistivity than the corresponding bulk metal, poor adhesion of printed traces to the substrate, and the coffee ring effect are common quality-related challenges associated with the process.

Drop-on-demand Metal Jetting (DoD-MJ is an emerging Additive Manufacturing technology that has the potential to fabricate 3D electronic components and flexible electronics whilst overcoming the challenges mentioned above. The metal jetting approach consists of dispensing and depositing individually-controlled droplets of molten metal onto a substrate at precise locations. DoD-MJ processes are classified based on the droplet generation actuation method. MagnetoHydroDynamic (MHD) actuators are the most advanced devices to date that have overcome the challenges of producing high-temperature droplets at high rates. One of the main advantages of DoD-MJ over inkjet printing is its simplified fabrication approach. This simplicity is granted by a wide availability of potential feedstock material, no residual impurities, and the elimination of the need for pre-processing and post-print processing.

MetalJet, the MHD-based system used in this study, has the capacity to produce molten micro-droplets (60–90 µm) at temperatures up to 2000 °C to form single and multi-material objects at frequencies up to 2 kHz. The work presented here reports that interface formation at the droplet substrate during the deposition of molten droplets embeds them into the substrate to obtain an acceptable level of adhesion. Moreover, strong metallurgical droplet-droplet bonding was obtained through remelting the interfaces. Consequently, the electrical resistivity of printed structures was comparable to that of the corresponding bulk metal. Overall, the work paves the way for the fabrication of next-generation electronics.

5:00 PM EL18.09.14
A Generalized Model for Thin Film Transistors on a Substrate of Arbitrary Geometry Shirsopratim Chattopadhyay[1] and John Labram[2]; [1]Oregon State University, United States; [2]University College London, United Kingdom

Flexible electronics is an emerging and rapidly blossoming technology that makes cheap, compact, light-weight devices with exotic form factors realizable. It's expected to usher in a paradigm shift in diverse real-world applications of paramount importance, from medical technology to robotics to industrial Internet of Things (IoT).
While a lot of research has been done on developing novel materials and manufacturing techniques for these devices, a comprehensive mathematical model to describe their behavior remains elusive. With the traditional Gradual Channel Approximation used for linear, flat thin film transistors (TFTs) still being the standard approach. This approximation will be invalid when the curvature of these devices becomes comparable to device dimensions. It's vital to develop the mathematics that encapsulates this behavior before flexible electronics becomes fully commercial, as it forms the building block for further integrated circuit (IC) design with flexible TFTs.
While there have been works on modelling the effect of physical stress due to deformation, such as those arising from bending and shear, on the electrical characteristics of TFTs, the effect of geometry itself is something seldom considered. In this work, we borrow on ideas from Differential Geometry and Point Set Topology to analytically develop a mathematical model that would predict electrical characteristics given the device geometry. We show that our model accurately predicts the expected behavior for a traditional linear TFT, as well as those on the surface of a cylinder and a sphere. It's expected that the proposed model will guide future design and fabrication of ultrathin film chips and circuits. For flexible electronics to be commercially viable, it must be predictable under all circumstances.

Extraordinary Mechanical Properties of Inorganic Double Helical van der Waals Crystal Nan Wang, Jiangbin Wu, Hefei Liu, Xinghao Huang, Hung-Yu Chen, Jiahui Ma, Hangbo Zhao and Han Wang; University of Southern California, United States

Tin indium phosphate (SnIP) is a quasi-one-dimensional inorganic double helical van der Waals semiconductor consisting of two atomic helical chains twining around each other along the axis of the helix at the atomic scale. Here, we experimentally discovered the extraordinary mechanical properties of SnIP. Confirmed through both nanomechanical bending measurements and the Brillouin scattering spectroscopy, this unique double helical structure possesses the smallest Young's modulus (~13.6 GPa) among any known stable inorganic materials and is even comparable with many polymers. Furthermore, the relatively easy slippage between neighboring double helices coupled through van der Waals interactions resulted in a surprisingly large elastic (>27%) and plastic (>60%) bending strain, conferring SnIP the highest flexibility and deformability among all known semiconducting materials. This discovery represents a major breakthrough in materials science that not only sets new records for key mechanical properties of inorganic materials, but also advances the understanding of this unique class of double helical van der Waals crystals with application potentials in a broad range of nanomechanics and nanoelectronics disciplines.

5:00 PM EL18.09.16
Iontronic Pressure Sensor Based on Modulation of Electrical-Double-Layer Kota Inoue[1], Kazumoto Miwa[2], Sunao Shimizu[2], Shimpei Ono[2] and Hiroki Ota[1]; [1]Yokohama National University, Japan; [2]Central Research Institute of Electric Power Industry, Japan

An iontronic pressure sensor that uses modulation of electrical charges in the electrical-double-layer(EDL) due to pressure was demonstrated in this study. In recent years, tactile sensors using various pressure-sensitive materials such as piezoresistive, capacitive, piezoelectric, and friction types have been developed to detect a wide range of pressures for applications in artificial joints, robots, and wearable devices. Among pressure sensors, the capacitive type is being commercialized at the product level as touch screens and biometric authentication in smartphones and PCs, taking advantage of its features such as high sensitivity, low power consumption, and fast response time. In particular, capacitive pressure sensors using EDLs of iontronic thin films are capable of excellent sensing over a wide range and with high resolution. Ionic liquids (ILs), which are commonly used as materials for iontronic thin films, have high electrical conductivity, electrochemical stability, and thermal stability. Gelation of ILs in the liquid state to form ionotropic thin films provides structural stability and reduces the risk of ILs leakage. The principle of conventional iontronics based pressure sensors is that the capacitance of the EDL is directly proportional to the contact area between electrodes and surfaces of the iontronic thin film. In other words, it is necessary for external pressure to cause mechanical deformation of the iontronic thin film in order for sensing. Therefore, to use iontronic thin films as pressure sensitive materials, microfabrication and fine patterning processes are required. Even as a pressure sensor, having a fine pattern remains a challenge in terms of structural stability.
In this study, we confirm that EDLs at the interface between iontronic thin films composed of ionic liquids and polymers and metal electrodes are modulated by the physical addition of pressure. This phenomenon is not due to mechanical deformation of the ionic liquid thin film, but to an increase in the charge of the EDL due to the application of pressure. Using this mechanism, IL-based iontronic thin films can function as deformation-independent pressure sensors. In this study, IL gel thin films fabricated without patterning were used as iontronic thin films. In addition, the signal was amplified by an electrical-double-layer transistor (EDLT). Iontronic thin film was applied as the gate insulating layer of the EDLT and the EDL modulation due to pressure was output as modulation of current value. Organic semiconductor material was selected as the channel material of the EDLT, and at low voltage the channel can be controlled by EDLs generated by IL gels. The use of a transistor as a signal amplifier also facilitated the use of a pressure sensor matrix. The pressure sensor matrix is important for pressure mapping, and this device is useful for applications in artificial joints, robots, and wearable devices. This research uses the new concept of ion modulation in EDLs, which expands the possibilities of devices using EDLs.

5:00 PM EL18.09.18
Lubricant-Infused Gravure Printing Plate for Conductive Pattern Printing Hsuan-Chin Lu and Ying-Chih Liao; National Taiwan University, Taiwan

The development of printing technologies to fabricate conductive patterns on flexible and stretchable substrates has gained much attention in recent years due to the pursuit of high-performance healthcare and communication applications. Among various printing methods, gravure printing is a high-speed, low-cost printing method capable of fabricating high-resolution patterns on the scale of microns. The successful printing of high-quality features depends heavily on the ink transfer ratio from the printing plate to the target substrate. In our previous study, the mechanisms of liquid transfer were investigated and we demonstrated that a lubricant-infused surface can provide fast contact line slippage to enable total liquid transfer between flat plates. In this study, PDMS-based gravure printing plates with porous microstructures are fabricated, which can help retain lubricating oils and improve the longevity of the lubricating layer by oil effusion to the surface. Different methods are utilized to fabricate the porous microstructures, and the effects of pore size, porosity and morphology on the transfer ratio are investigated. The mechanical properties and durability of the printing plates are also investigated to prove the applicability of using this method for practical applications. Finally, modified conductive ink is used to print conductive patterns onto a polymer substrate to demonstrate the potential for creating flexible or stretchable electronics.

Generation of Additional Logic States in Molecular-Switch Embedded Anti-Ambipolar Transistor for Realizing Multi-Valued Logic System Chan So, Dae Sung Chung, Seong Hoon Yu and Syed Zahid Hassan; Postech, Korea (the Republic of)

Developing logic circuit systems that have high data throughput levels and mechanical flexibility is becoming more and more important with expanding market of AI and autonomous driving. It is known that the organic thin film transistor can meet the above conditions. However, organic thin film transistors have weaknesses in high-temperature processes and fine patterning. Therefore, there is a limit to increasing the speed of data process by improving the degree of integration. As an alternative to solving this problem, a logic (MVL) system has been proposed. The traditional logic inverter system can perform 2^n processing operations, but the triangular logic inverter system can process 3^n processing operations, which is about 160% more efficient than the traditional logic inverter.

The mechanism of multi-valued logic system is described below. If n-type semiconductor and p-type semiconductor are in lateral contact, the current graph will show the effects like 'union' in the sets. On the other hand, if two semiconductors contact in vertical way, the current graph will show the effects of 'intersection'. Interestingly, in the case of one semiconductor gets over the other at lateral contact to create both lateral and vertical contacts, both effects happen and an additional middle logic state could be generated. This heterojunction, which is called anti-ambipolar, changes the sign of the slope of the drain electrode current value in a specific voltage range. However, as we are planning to make higher level of base, you need a very complex structure. Therefore, a new strategy is needed to implement a high-base logic system. Accordingly, we tried to introduce molecular switch to develop MVL circuits.

As a result, diarylethene, a molecular switch that can change its structure by light, was able to successfully decrease the current level of embedded organic polymer. In the electric field condition, charge carriers move from one electrode to the other. When UV light is irradiated to DAE, the HOMO level of DAE rises as the molecule becomes closed form. Then UV irradiation causes them to be trapped in the HOMO of DAE, which leads to the reduction of overall current level and make additional middle logic state. The reduced current and the shift of NTC range allow us to distinguish different states.

In this work, We demonstrated anti-ambipolar transistor(AAT) and MVL system that used it. Most of DAEs were successfully co-deposited with organic semi-conductor(DNTT). It is believed that molecular switch that has less sterically hindered characteristics obtained better drain current and mobility due to securing free volume for molecular switching.

5:00 PM EL18.09.20
Strain Insensitive Pressure Sensor Integrated on Selectively Photo-crosslinkable Substrate Hyon-Gyu Park, Hayeong Park, Minsung Kim and Joon Hak Oh; Seoul National University, Korea (the Republic of)

Soft, stretchable, and wearable electronic devices have been studied for their potential use in various applications that cannot be achieved with conventional rigid devices. Stretchable electronics, as an advanced technology for flexible devices, have great potential to be used in various wearable devices and sensors, regarding human skins or tissue's stretchable property. However, it is still insufficient for commercial use due to lack of durability and performance.
A common method of manufacturing stretchable electronic devices is to design all constituent materials to be stretchable. Another approach is to design the substrate so that the strain is concentrated on the interconnects and strain-free or limited strain on the unit area. The former approach can provide high integration, but there is a limit to making all elements of a device stretchable. While stretchable substrates (SEBS or PDMS) can be stretched up to 100%, it is very challenging for other elements such as electrodes and active layers to be stretched along the substrate. Even an organic semiconductor that can be significantly stretchable than an inorganic material, it is not easy to withstand deformation of more than tens of %. The latter approach, "rigid island" structure allows the integration of existing rigid electronic components with-out deformation. In particular, the development of stretchable printed interconnects has made it possible to successfully integrate active electronic devices located on rigid polymer islands into stretchable devices.
Herein, we introduce a simple method to fabricate a photo-crosslinkable, transparent elastomer substrate for stretchable electronics and its application to physical sensors. Acrylate based substrate was formed with copolymers. With photo-initiator, acrylate functional group can be crosslinked by UV irradiation and by adjusting the amount of crosslinker, we could control its crosslinking density and modulus. The modulus of substrate increased to 8900%. Additional crosslinking provided 38000% higher modulus than that prior to UV irradiation. The substrate can be selectively crosslinked by exposure to UV light in order to form a rigid region using a patterned mask. Rigid island pattern shape and size can be designed without restraint owing to its simple crosslinking mechanism. 20 mm pattern of rigid/soft area pattern was stretched 100% to confirm its stretching property, rigid region was only stretched 30% while soft area was stretched 210%.
Rigid island structures with repetitive rigid-soft-rigid systems can facilitate the development of capacitive strain/pressure sensor by forming electrodes only on the rigid islands. Rigid island can work as a dielectric layer of the capacitor, sensor sensitivity to strain and pressure are dependent to modulus of the rigid island. We designed pressure insensitive strain sensor (PISS) and strain insensitive pressure sensor (SIPS) by this system. For SIPS, electrospun dielectric layer was introduced to increase pressure sensitivity while maintaining low strain sensitivity.

5:00 PM EL18.09.23
Solution Deposition and Photonic Curing of Hybrid Transparent Conducting Electrodes Robert T. Piper, Gary G. Turner, Justin C. Bonner, Weijie Xu and Julia Hsu; The University of Texas at Dallas, United States

Development is still needed to improve flexible transparent conductive electrodes (TCE), the starting point for many optoelectronic devices, such as LEDs, photovoltaics, and touch-sensitive screens, which are the backbones of many modern technologies. PET/ITO is a common TCE but is made with slow vacuum deposition and thermal annealing processes, which are not compatible with high-speed roll-to-roll (R2R) manufacturing. Because of the limited thermal budget, ITO films must be thicker on PET than on glass substrates to maintain similar sheet resistance (R_{sh}), resulting in lower ITO transmittance. Many solution deposition techniques can already achieve high R2R web speeds > 10 m/min. However, post-deposition thermal annealing of sol-gel TCE precursors requires high temperature (> 300°C) for a long time (> 30 min), leading to either a reduction in R2R web speed or implementation of long, high-energy-consuming ovens. In addition, plastics have higher coefficients of thermal expansion than oxides, resulting in mechanical failures when thermally annealed at high temperatures. A promising alternative to thermal annealing that is R2R compatible is photonic curing. Photonic curing is a photoirradiation process during which a xenon flash lamp emits high-intensity, broadband (200 – 1000 nm) light upon a sample in discreet pulses lasting micro or milliseconds. Light impinging on the sample is absorbed by the film and converted into heat depending on its optical absorption, which drives material transformations: crystallization, phase change, or sol-gel conversion. Because photonic curing uses high-intensity, low-energy light to anneal materials, high-temperature processing can be performed on plastic substrates, which do not absorb a significant amount of light, without damaging them. Photonic curing requires simultaneous optimization of multiple parameters, which will be explored in this work: pulse voltage, pulse length, number of micro-pulses, duty cycle, number of pulses, repetition rate, and radiant exposure.

In this work, a hybrid TCE material is solution deposited and photonic cured on PET substrates. The hybrid TCE consists of a transparent conducting oxide made from sol-gel precursors and a metal network—silver nanowires (AgNW), metal grid traces (MG), or a combination of both. The metal network enhances electrical conductivity without sacrificing optical transmittance. AgNWs and MGs significantly affect the photonic curing process because they absorb light which leads to heating within the material stack. This additional light absorption may enhance the sol-gel oxide conversion during photonic curing. The conversion of the sol-gel metal oxide was tested using a weak acid etch. To evaluate the hybrid TCE performance, we measure sheet resistance (R_{sh}) and average optical transmittance from 400 to 700 nm (T_{avg}) to calculate the figure of merit (FOM) [1]. The preliminary results on spin-coated films show the best-performing hybrid TCE made by photonic curing AgNW and IZO composite films achieves $R_{sh} = 16 \pm 4$ Ω/sq, $T_{avg} = 78 \pm 2\%$, with a FOM

= 90 ± 14. This TCE already outperforms some commercially available PET/ITO products, which have FOM ranging from 24 to 110. To transition to R2R processing, we employ blade-coating to deposit the hybrid TCE materials. The blade-coating and photonic curing processes will be optimized together to produce high FOM hybrid TCE films. Finally, perovskite solar cell devices will be fabricated on these hybrid TCEs and compared to devices made on commercially available PET/ITO.

Low-Temperature Heat Treatment Schemes for Particle-Free Reactive Silver Inks Steven DiGregorio, Subbarao Raikar and Owen Hildreth; Colorado School of Mines, United States

Printed electronics afford greater flexibility, fewer processing steps, and less material waste over other electronic manufacturing techniques. Printed electronics often rely on particle-based metal inks that have the downside of high processing temperatures. Even low-temperature silver pastes require temperatures above 200 °C, making them incompatible with some polymers used in flexible electronics. Reactive inks are particle-free conductive inks that can achieve highly conductive metal layers at temperatures as low as 60 °C. Reactive inks contain metal complexes that reduce to metallic films upon printing. The underlying reduction mechanisms are crucial for designing high-performance inks but are not well understood for reactive inks with self-reducing functions. This work investigates the interplay between thermal and evaporative reduction mechanisms in self-reducing reactive silver inks to understand their impact on film morphology and electrical resistivity. We also investigate the bending durability of films with different morphologies to demonstrate the applicability of reactive inks for flexible electronics.

Mold-Free Fabrication of Highly Sensitive Pressure Sensors Using oCVD PEDOT and 3D Printed Microstructured Substrates Jinwook Baek, Mitesh Mylvaganan, Yujie Shan, Huachao Mao and Sunghwan Lee; Purdue University, United States

Recent advances in 3D printing have demonstrated splendid promises in next-generation high performance sensor applications due to freedom of design, cost-effectiveness, and rapid prototyping. In this work, we showcase a new manufacturing paradigm to exclude conventional mold-dependent manufacturing of pressure sensors, which requires a series of complex and expensive patterning processes such as mask aligning, photolithography, and etching. Our mold-free fabrication leverages high resolution 3D printed multiscale microstructures as substrate and a gas-phase conformal polymer coating technique to complete the mold-free sensing platform. Micropatterning through a cutting-edge 3D printer enables one to fabricate a non-trivial structure with complex geometry and customized shapes. The array of dome and spike structures with a controlled spike density was applied for a substrate, ensuring a high surface area. For uniform coating on the microstructured surface, oxidative chemical vapor deposition (oCVD) is leveraged to deposit a highly conformal and conductive electrode, poly(3,4-ethylenedioxythiophene) (PEDOT) at low temperature (< 120 °C). The fabricated pressure sensor reacts sensitively to various ranges of pressures depending on the density of the spike and shows high response ($I/I_0 > 10^4$) even pressures under 1 kPa. The mechanism of the high performance achieved was verified through the finite element analysis, which allowed us to identify a correlation between surface structure and sensor characteristics. Our unique findings are expected to be of significant relevance to the technology that requires higher sensing capability, scalability, and facile adjustment of sensor geometry in a cost-effective manufacturing manner.

5:00 PM EL18.09.27
Engineering Soft, Elastic and Conductive Polymers for Stretchable Electronics Using Ionic Compatibilization My Linh Le, Intanon Lapkriengkri, Cassidy Tran, Phong H. Nguyen, Rachel A. Segalman, Christopher M. Bates and Michael L. Chabinyc; University of California, Santa Barbara, United States

Designing a material that is soft, elastic and conductive for stretchable electronics has remained a major challenge due to the tradeoff between conductivity and mechanical flexibility caused by the high stiffness of conventional conductive materials. In this study, we show that ionic interactions provide an effective pathway to obtain materials with appreciable conductivity and flexibility, while also eliminating many synthetic and processing complications in commonly employed strategies. In particular, a conjugated polyelectrolyte (CPE) was blended with a bottlebrush polymeric ionic liquid (BPIL) whose side chains are oppositely charged. In this design, the CPE provides electrical conductivity, while the BPIL offers a super-soft elastomer matrix for mechanical flexibility. Due to the strong electrostatic attraction between the oppositely charged pendant side chains of the CPE and the BPIL, phase separation was effectively suppressed and the polymers formed a homogeneous blend. The resulting material has a Young's modulus of 100 kPa, lying well within the range of soft tissues moduli (25 kPa to 140MPa), and is highly stretchable with a tensile strain to break of 400% and an ultimate tensile strength of 800 kPa. Once electronically doped with a strong acid, this polymer blend has an electronic conductivity that was ~ 0.1 S/cm, a comparable value to that of as-cast commercial PEDOT:PSS. Lastly, the ionic interactions physically crosslinked the polymers, forming a network that strained elastically up to 40% strain without any added crosslinkers.

5:00 PM EL18.09.29
Flexible Hydrogen Sensors Based on Pd-decorated Graphene Microchannels with Low Power Consumption Yeonhoo Kim[1], Taehoon Kim[2], Tae Hyung Lee[2], Yong Seok Choi[2], Seungwoo Song[1], Ansoon Kim[1], Byung Hee Hong[2] and Ho Won Jang[2]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Hydrogen is a promising future energy source since it is clean, non-toxic, and renewable but explosive over a wide range, from 4 to 74 percent in ambient air. For this reason, the detection of hydrogen gas at an early stage is of great importance in varied research fields such as hydrogen storage systems, fuel cells, and water splitting. Although semiconducting metal oxides have been extensively explored for sensing applications, metal oxides are not suitable for flexible electronics. On the contrary, two-dimensional(2D) materials including graphene are promising alternatives to conventional sensing materials since they are entirely flexible and transparent. To modify the sensing characteristics of pristine 2D materials, various methods such as functionalization, composites, and noble metal decoration have been studied. Among the methods, noble metal decoration is one of the most facile methods to tune the sensing properties of 2D materials.

In this work, we decorated palladium nanoparticles on graphene microchannels with electron beam evaporation to enhance the hydrogen sensitivity of the graphene layers. As the graphene layers are patterned with microchannels, the self-heating effect is induced by current crowding in the narrow electrical path. The self-heating effect enables to detect hydrogen gas at room temperature, which lowers power consumption by not using external heaters. The apparent temperature of the microchannel is characterized by an infrared camera. The hydrogen sensors exhibit good linearity, high sensitivity, and selectivity in a wide range of hydrogen gas concentrations from 1 to 50 ppm. The theoretical detection limit is calculated to be ~241 ppb. Moreover, the flexible sensors show stable sensing performance under mechanical bending strain. The ultralow detection limit and stability of the sensors broaden the potential use of Pd-decorated graphene microchannels for next-generation flexible/wearable applications.

5:00 PM EL18.09.30

Mechanically Stable Flexible Organic Photovoltaics with Silver Nanomesh for Indoor Applications Jae Won Kim[1], Sung-il Chung[2] and Jin Young Kim[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Korea Electrotechnology Research Institute, Korea (the Republic of)

Improved performance of flexible organic solar cells (FOSCs) was achieved by developing the performance of organic solar cells (OSCs). OSCs are promising candidates as energy sources for low-power supply systems such as the Internet of Things (IoT) under indoor lighting environments. To apply FOSCs to flexible or wearable applications, they must be mechanically stable. In this study, we fabricated FOSCs with silver nanomesh (AgNM) as the bottom transparent conductive electrode (TCE). Instead of ITO, AgNMs were prepared using three pitches of 25, 50, and 100 µm with a square pattern, using a polyethylene terephthalate (PET) substrate. Notably, the device using AgNMs with a pitch of 25 µm exhibited a power conversion efficiency (PCE) of 14.93% under 1 sun illumination and 17.91% under 1000 lux of LED light conditions. Flexible devices using AgNMs maintained over 92% of their initial PCE under 1 sun illumination (PCE decreased to 12.98% from 14.04%) and over 92% when tested under 1000 lux of LED light illumination (PCE decreased to 16.57% from 17.91%) after 1000 instances of bending. These results demonstrate the advantages of using AgNMs as an alternative TCE under both 1 sun and indoor lightning environments and are promising candidates for flexible applications.

5:00 PM EL18.09.31
Flexible Device Applicable High Mobility InGaZnO/polyimide Thin Film Transistor at Low Temperature Using Interfacial Defect Control Min Jung Kim[1], Hyunmin Hong[1], Shin Dong Yeob[2], Dong-Joon Yi[2], Na Young Choi[2], Si yeon Choi[2], Kwangsik Jeong[2] and Kwun-bum Chung[2]; [1]Dongguk university, Korea (the Republic of); [2]Dongguk University, Korea (the Republic of)

Polyimide (PI) is currently used in various fields, such as substrate, passivation, gate insulator (GI), because PI can be fabricated in the condition of low temperature (~ Room temperature), low cost, large area deposition. Many research have reported PI which has high dielectric (≥ 2) constant and withstand high temperatures (~ 300 °C). In the case of a device using a soft insulating film such as PI, the fabrication method is limited according to the characteristics of PI. In the case of organic thin film transistor (OTFT), in which PI is mainly used as a gate insulator, the carrier mobility of organic semiconductor films is strongly influenced by the crystallinity, molecular packing structures of the organic thin films and charge traps at the gate dielectric/semiconductor interface. Even if certain molecular organic semiconductors can form various molecular packing structures by changing film formation process, the OTFT fabrication has very low reproducibility. It is difficult to analyze and control the composition and defect states in the semiconductor/GI interface of OTFT compared to inorganic device, because polymer materials are mainly used. The operation of the TFT device is affected by a channel formation in the active/GI interface. The analysis of the grain boundary, crystallinity, and defect states in the interface must be supported to adjust the device characteristics according to the purpose. In this study, we suggest a low-temperature ($\leq$100 °C) fabrication method of high mobility (> 10 cm^2/Vs) oxide thin film transistors using 6FDA-MDA as a gate insulator with Al_2O_3 buffer layer and analysis of the qualitative/quantitative defect sites in the interface between PI and IGZO layer. Spectroscopic ellipsometry (SE) and x-ray photoelectron spectroscopy (XPS) are used to the analyze qualitative physical properties of the interface, for example fermi level in the band gap, thickness, composition. Quantitative defect state analysis according to the defect activation energy of the IGZO channel region was conducted by photo induced current transient spectroscopy (PICTS). The improvement of device reliability, especially for PBS seems to be due to the decrease in the deep level defect states in the interface, which is related to the trend of change in composition in the interface due to the application of buffer layer. We applied the optimum fabrication condition to the flexible device with parylene/PET substrate and conducted a bending test to confirm the stability of the device over 1000 times.

5:00 PM EL18.09.32
Fully Spray-Coated Triboelectric Devices for Ubiquitous Smart Objects Shujia Xu[1,1] and Wenzhuo Wu[1,1,2]; [1]Purdue University, United States; [2]Regenstrief Center for Healthcare Engineering, United States

Triboelectric nanogenerator (TENG) has been widely explored for self-powered wearable sensors. Progresses in novel material for high-output TENG have attracted tremendous attention. However, simultaneous consideration of materials system design and manufacturing process receive limited attention. Manufacture and encapsulation techniques feasible for large-scale fabrication in combination with functional materials systems need to be co-developed. Spray coating is an attractive method for large-scale deposition of ink-based materials. Here, we demonstrate fully sprayed TENG on ubiquitous surfaces using ink-based functional materials. Several functional inks compatible with spray coating are formulated to fabricate flexible TENGs for applications such as human pulse monitoring, human-machine interaction, and energy harvesting. Such flexible sensors could also be sprayed and integrated on arbitrary surfaces (e.g., living plants) for deriving ubiquitous smart objects.

5:00 PM EL18.09.33
Novel High-k Fluorocarbon Ultrathin Films for Passivation of Two-Dimensional Nanomaterials Anh V. Hoang, Viet Dongquoc, Phan Thi Kim Uyen, Jeong-A Jo and Eui-Tae Kim; Chungnam National University, Korea (the Republic of)

Two-dimensional (2D) layered materials, such as graphene and transition metal dichalcogenides, have been extensively studied beyond their applications of bulk Si and compound semiconductor technologies as potential semiconductor platforms. However, their excellent electrical performance, including the carrier mobility, are significantly degraded by molecular adsorption from the environment. High-k oxide dielectric capping layers, such as Al_2O_3 and HfO_2, have been applied to suppress Coulomb scattering by shielding the surface from ambient molecules and phonon dispersion, thereby, significantly enhancing the mobility of 2D field-effect transistors (FETs). However, the oxide films not only more often introduce interface trapping defects at the dielectric/2D interface, but also are brittle, so that they cannot be applicable in flexible devices. In this presentation, we report passivation effects of amorphous high-k fluorocarbon (FC) films on graphene FETs. The organic based FC films were deposited on metal-catalytic Si/SiO_2 substrates by using inductively coupled plasma chemical vapor deposition and were subsequently transferred on graphene FETs. Amorphous FC films with high k values more than 30 significantly improved the mobility of graphene FETs, surpassing the corresponding graphene FETs passivated by atomic- layer-deposited Al_2O_3 film. We will further discuss passivation effects of FC films, including long-term stability and density functional theory calculations.

3D Printed Triboelectric Smart Skin Mo Lv, Shujia Xu and Wenzhuo Wu; Purdue University, United States

This research presents a novel electrical sensor device, namely 3D printed triboelectric smart skin. The mechanical energy harvesting device and sensor is demonstrated to be stretchable and wearable. Tribo-negative material Polydimethylsiloxane (PDMS) matrix is selected as the dielectric layer with embedded fluidic electrode carbon grease. Triboelectrication and electrical induction are exploited for sensing subtle movements such as heart pulse and large joint movements from human bodies. The device has been investigated through design optimization process with an enhanced mechanical performance. This work demonstrates the device's capability to monitor the human's health status by detecting the heart pulse from the wrist and neck respectively, as well as identifying speech patterns through detecting the vibrations from human voice cord.

5:00 PM EL18.09.36
Morphology Reversal of a Non-Fullerene Acceptor Via Surface Controlled Decal-Printing Technique for Efficient Photo-Conversion and Detection in Organic Optoelectronic Device Minsoo Kim, Dong Hwan Wang and Woongsik Jang; Chung-Ang Univ, Korea (the Republic of)

Recently, the dry film transfer process using polymer mold has been attracted by advanced technology to overcome the limitation of the conventional wet coating process such as spin or dip coating. To demonstrate the transfer process, the soft polymer mold as process mediator is key factor. Polydimethylsiloxane (PDMS) is widely introduced to transfer the thin films previously, but it is difficult to adopt in the organic solvent filed due to the poor chemical resistance. To alternate this, polyurethane acrylate (PUA) material is introduced having proper physical and chemical property to the organic solvent such as chlorobenzene (CB) which is extensively used in organic optoelectronic devices. In this study, a novel thin film transfer technique is highlighted, named decal-printing process, using the surface controlled PUA mediator by introduced hydrophilic 2-hydroxyethyl methacrylate (2-HEMA) as reactive diluent.[2] By controlling the adhesion of the mediator based-on wetting coefficient theory, the decal-printing process is successfully demonstrated by transferring the organic photoactive layer composed of the polymer donor, poly[4,8-bis(5-(2-ethylhexyl)thiophen-2-yl)benzo[1,2-b;4,5-b′]dithiophene-2,6-diyl-alt-(4-(2-ethylhexyl)-3-fluorothieno[3,4-b]thiophene-)-2-carboxylate-2-6-diyl)] (PTB7-Th) and narrow bandgap non-fullerene acceptor (NFA), 2,2′-[[4,4,9,9-tetrakis(4-hexylphenyl)-4,9-dihydro-s-indaceno[1,2-b:5,6-b′]dithiophene-2,7-diyl]bis[[4-[(2-ethylhexyl)oxy]-5,2-thiophenediyl]methylidyne(5,6-difluoro-3-oxo-1H-indene-2,1(3H)-diylidene)]]bis[propanedinitrile] (IEICO-4F).[3] This process induces a sharp morphology of the thin film, prevents damage to the underlying layer by suppressing the solvent penetration because of this technique enable to dry-transfer process. Both photovoltaic cells and photodetectors prepared by the decal-printed photoactive layers containing fluorinated NFAs showed higher performance (power conversion efficiency = 10.69% and specific detectivity = 1.27×10^{12} A cm Hz$^{1/2}$ W^{-1}, respectively) than those of devices prepared by the conventional spin-coating process owing to morphology reversal and smoother interface that led to suppressed internal resistance and enhanced charge flow in normal structure. Thus, the reproducible decal-printing process using a customized elastomeric polymer mediator is an important thin film fomration technique for efficient next-generation organic optoelectronic materials.[4]

5:00 PM EL18.09.37
Low Effective Modulus Buckled Crack-Based Sensor for Human Respiration Monitoring Gunhee Lee[1], Jingoo Lee[2], Taewi Kim[2], Inyong Park[1], Sang Bok Kim[1], Dae Hoon Park[1] and Bangwoo Han[1]; [1]Korea Institute of Machinery and Materials, Korea (the Republic of); [2]Ajou University, Korea (the Republic of)

Among the various wearable devices for monitoring various human bio-signals (e.g., human motion monitoring, health care monitoring) being developed, the strain sensor is one of the representatives means for measuring mechanical bio-signals. In order to effectively utilize the strain sensor as a wearable monitoring device, it should satisfy high sensitivity, long-term durability, fast response characteristics, and high flexibility. However, it remains a challenge to accurately detect deformations caused by small stresses with high sensitivity due to the stiffness of the sensor itself. In general, the strain sensor expresses the sensitivity as the magnitude of the signal change with respect to the strain. In the case of soft objects such as human skin, even if an ultra-sensitive strain sensor is used, it cannot detect the deformation properly because the deformation of the skin cannot deform the sensor if the sensor itself is too stiff. To solve this problem, strain sensors made of low-modulus materials can be used, but these generally have low sensitivity and high hysteresis, making accurate measurements difficult. Herein, we proposed a buckled crack-based sensor consisting of thin metal films and polymer-based substrates to deal with these abovementioned problems. The crack-based sensor with a buckling structure sensitively responds to skin deformation and has a strain range of up to 80%. The buckled crack-based sensor possesses high sensitivity (gauge factor (GF) ≈ 250), long-term stability (>10,000 cycles), and low mechanical stiffness during stretching. As the human health monitoring system application, the buckled crack-based sensor successfully demonstrated to measure human respiration rate and depth, as well as the volume of inhalation and exhalation.

Breathable Pixelated Stretchable Sensor for Profiling Respiration Air Flow Jaehyun Kim, Yebin Park, Wonjeong Suh, Dongbeom Kim and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

Due to the air pollution and the pandemic outbreak, the need of quantitative pulmonary monitoring has been greatly increasing. Although a large number of deformable sensors have been developed for wearable healthcare, deformable sensors for monitoring the respiratory patterns have rarely been investigated. Herein, we introduce an air-permeable stretchable pixelated thin film pressure sensor that can be integrated on a commercial face mask. The sensor can provide 2D profiles of the air flow and pressure distribution during inhaling and exhaling. This study presents that a CNT-polymer coating layer deposited on the electrospun microfiber is viscoplastic. The localized viscoplastic piezoresistive patterns enable the strain-independent pressure sensing performance so that respiratory pressure distribution on the pixelated sensor can be quantitatively obtained without being affected by deformation of the sensor. The wearable sensor is expected to monitor temporary breathing disorders and help prediction of pulmonary diseases.

Oxygen Vacancy Concentration Controlled Sol-gel Processed Y_2O_3 Resistive Random Access Memory by Al Doping Process HaeIn Kim and Jaewon Jang; Kyungpook National University, Korea (the Republic of)

In this work, we investigated the effect of Al doping on the switching behavior of sol-gel processed Ag/Y_2O_3/ITO RRAM devices. High-quality pure metal oxide layers can be simply deposited via sol-gel process. Their chemical, structural, and electrical properties can be easily tuned by adjusting the precursor component ratio. Moreover, the liquid phase precursor solution can be used for large-area applications, such as in dip-coating, printing techniques, and spin-coating.
Too much oxygen vacancies in the insulating layers of RRAM devices may degrade nonvolatile memory characteristics and increase the leakage current, thereby reducing HRS/LRS ratio. To overcome this issue, we doped Y_2O_3 layer with Al and observed the change of memory characteristics while adjusting Al doping concentration. Undoped RRAM devices exhibited relatively poor endurance characteristics of approximately 30 switching cycles with a small resistive window (~10). But, 50 % Al-doped RRAM devices showed more than 200 switching cycles with a decent resistive window (>10^2). In addition, it was confirmed that as the doping concentration of Al increased, the oxygen vacancy ratio decreased and the lattice oxygen ratio increased in the XPS measurement. These results confirm that appropriate concentration of Al doping can reduce excessive oxygen vacancies and thus improve the nonvolatile memory characteristics of Y_2O_3-based RRAM devices.

Crosslinking Organic–Inorganic Hybrid Dielectric with Azide-functionalized Ligand for High-Performance Solution-Processed Oxide Thin Film Transistors Juhyeok Lee, Syed Zahid Hassan, Sangjun Lee, Hye Ryun Sim and Dae Sung Chung; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Owing to the global development in IoT technology, interest in metal-oxide semiconductor-based circuits with low standby power consumption, particularly in thin-film transistor (TFT) materials capable of low-cost solution processing, has been rapidly increasing. Notably, most of the high electron mobility oxide TFTs were based on high-*k* inorganic gate dielectrics. Compared with conventional SiO_2, high-*k* oxides such as HfO_2, ZrO_2, and Al_2O_3 are ideal candidates for realizing a high-capacitance dielectric layer capable of low-voltage driving and high density of charge accumulation. However, these high-k inorganic dielectric layers are hindered by 1) expensive deposition equipment and high process temperature for vacuum deposition, and 2) imperfect inorganic purity and porous morphology for solution deposition. Therefore, the development of a solution-processed high-*k* dielectric layer with a high dielectric strength is urgently required. A possible strategy to strengthen the dielectric properties of solution-processed high-*k* oxides is to realize an organic-inorganic hybrid dielectric layer, which typically comprises nanocomposites of polymer and high-*k* oxide nanoparticles (NPs) combining high permittivity of the inorganic NPs and high breakdown strength, mechanical flexibility, and easy processability of the polymer dielectrics. However, existing hybrid dielectric layers have not shown this synergistic effect and yielded only marginal performances, particularly for oxide TFTs.
The aforementioned synergetic effects can be achieved only when the complementary organic and inorganic constituents are well mixed. In reality, owing to the different surface energies of organic and inorganic inclusions, the thin-film morphology of hybrid dielectrics often has the limitations of air voids and low thin-film density, thereby resulting in a high leakage current and consequently a low on/off ratio of the resulting TFT. Furthermore, owing to the thermodynamic instability of the mixed binary phase, the hybrid dielectric layer can lack long-term operational stability. Therefore, it is challenging to simultaneously realize a high-*k* and high dielectric strength from a hybrid dielectric layer.
In this study, we attempted to achieve an organic–inorganic hybrid dielectric layer with a covalently networked morphology between organic and inorganic inclusions for high-performance solution-processed oxide TFTs. We propose a method for chemically crosslinking zirconia NPs and PMMA with functionalized azide ligands, which show higher crosslinking efficiency with a minimized amount. However, simply mixing azide molecules with ZrO_2 NPs and PMMA cannot guarantee crosslinking between inorganic and organic phases; nitrene generated from azide can react with alkyl CH or π-conjugated aromatic groups; therefore, crosslinking is limited only between PMMAs and not between the ZrO_2 NPs and PMMA. Therefore, we newly synthesized azide-functionalized acetylacetonate, functioning as a 1) ligand of ZrO_2 NP in post sol-gel synthesis and 2) crosslinking agent between ZrO_2 NP and PMMA. From the optimized processing conditions, we obtained an excellent dielectric strength of over 4.0 MV cm^{-1}, a high-*k* of ~14, and a low surface energy of 38 mN m^{-1}. We demonstrated the fabrication of exceptionally high-performance, hysteresis-free n-type solution-processed oxide TFTs comprising an In_2O_3/ZnO double layer as an active channel with an electron mobility of over 50 $cm^2\ V^{-1}\ s^{-1}$, on/off ratio of ~10^7, subthreshold swing of 108 mV dec^{-1}, and outstanding bias stability. From temperature-dependent *I–V* analyses combined with charge transport mechanism analyses, we demonstrated that the proposed hybrid dielectric layer provides percolation-limited charge transport for the In_2O_3/ZnO double layer under field-effect conditions.

5:00 PM EL18.09.42
The Effect of Thickness and Oxygen Vacancies on the Performance of Sol-Gel Based Y_2O_3 RRAM Kyoungdu Kim and Jaewon Jang; School of Electronics and Electrical Engineering, Korea (the Republic of)

It is widely known that the admirably pure materials such as metal oxide can be easily obtained by solution-gelation (sol-gel) method. Also, it is remarkable that we are readily able to manufacture the metal oxide-based devices and measure their characteristics simply using several steps. Moreover, using water-based metal-oxide precursors such as an ink is beneficial for mass-production desired in the industry due to the high throughput, low-cost manufacturing, and simple process. Also, these inks can be used for a number of techniques such as direct writing printing (non-contact), transfer printing (direct-contact), inkjet printing, and aerosol-jet and spray printing.
In this experiment, a solution-gelation (sol-gel) processed Y_2O_3 resistive random-access memory (RRAM) devices which showed bipolar characteristics were fabricated. The chemical, structural, and electrical characteristics of the sol-gel based RRAM devices were studied as the liquid-based precursor concentration (0.05 M, 0.2 M, 0.6 M) changed. The Y_2O_3 thickness grow thicker proportionally as the concentration increased. Furthermore, the proportion of oxygen vacancies in Y_2O_3 oxide escalated. The devices which contained minimum oxygen vacancy concentration did not showed bipolar RRAM electrical characteristic. Moreover, the devices with the thickest Y_2O_3 layer exhibited weak resistive switching performance. Among them, the 37 nm thickness of Y_2O_3 layer was an optimal in terms of resistive random access memory properties with low SET voltage (less than 1.5 V) and RESET voltage (-15.0 V). Additionally, the devices presented the longest retention (over 10^3 s), endurance (over 10^2 cycles), and highest ON/OFF ratio (over 10^4).

5:00 PM EL18.09.43
Improved Positive Bias Illumination Stability of Sol-gel Processed SnO_2 Thin-Film Transistor by Depositing Ultra-thin Al Layers Taehun Lee and Jaewon Jang; Kyungpook National University, Korea (the Republic of)

We demonstrate an ultra-thin aluminum layer deposited sol-gel processed SnO_2 thin-film transistors (TFTs) showing high stability performance under bias stress condition. The sol-gel process, one of the printing techniques, is a useful method for depositing metal oxide materials having a high film quality and purity. The properties of deposited film can be simply controlled by adjusting the concentration or other variables of precursor. The advantages of this process allows fabricating metal-oxide layer in large-area applications. Metal Oxide TFTs have gradually alternated silicon based TFTs due to their high field effect electron mobility, simple fabrication process and transparency. Metal Oxide TFTs, Unfortunately, contain electrical instability problems because of oxygen vacancies and defects that are the origin of trap formation. To solve this problem, we deposited an ultra-thin aluminum layer on the active layer of SnO_2 TFTs. In this experiment, we first fabricated pure SnO_2 TFTs via sol-gel process. Then aluminum was thermally evaporated on the prepared device followed by an annealing process at 300°C for 20 minutes. Under the positive bias illumination stress, pure SnO_2 TFTs have a mobility change from 6.27 cm^2/Vs to 5.91 cm^2/Vs and +6.51 V threshold voltage shift. Meanwhile, SnO_2 TFTs with Al deposited layer show the mobility change from 6.03 cm^2/Vs to 5.51 cm^2/Vs and +1.47 V threshold voltage difference. The results reveal that the deposited aluminum layer clearly advanced the positive bias illumination stability. We expect that the ultra-thin aluminum layered SnO_2 TFTs are an excellent candidate for high stability application in transparent electronics.

5:00 PM EL18.09.44
Effect of Photoinitiator Types and Concentrations on the Photocrossliking Density in Acrylate-based UV-curable Inks Bo-Young Kim[1], Subin Jo[1], Jihoon Kim[2], Seong Dae Park[1], Myong Jae Yoo[1] and Hyunseung Yang[1]; [1]Korea Electronics Technology Institute, Korea (the Republic of); [2]Kongju National University, Korea (the Republic of)

The acrylic resin has excellent mechanical and optical properties because it is simple to control the optical properties due to the molecular structure and forms 3-dimensional network structures after photocuring. In addition, the photocuring process has advantages of reducing process time because the curing time is shorter than thermal curing. Recently, the direct printing method using acrylate inks has been applied to manufacturing the printed circuit board for electric devices. [K1] After the manufacturing of circuit using acrylic ink, the chemical process such as etching is performed; for this reason, adhesion properties between ink layer and substrate become a very important factor in manufacturing the printed circuit board. In the case of acrylate inks, the crosslinking density is determined by the type and amount the photoinitiators, the contents of the monomer and oligomer, the UV irradiation time and intensity. In this study, acrylate inks are prepared by varying the type and amount of the photoinitiators, the photo curing behavior and the adhesion properties of acrylate inks[K2] . We confirmed that the photocrosslinking density of the acrylic ink increased as the photoinitiator content increased, also increased the adhesion to the substrate. Finally, acrylic inks with excellent adhesion and etching and stripping was prepared.

5:00 PM EL18.09.45
Intrinsically Stretchable Semiconductor Metallization via Physical Vapor Deposition Method for Skin-Like Electronics MinWoo Jeong[1], Minhyouk Kim[1], Jun Su Kim[1], Tae Uk Nam[1], Ngoc Thanh Phuong Vo[1], Lihua Jin[2], Tae Il Lee[3] and Jin Young Oh[1]; [1]Kyung Hee University, Korea (the Republic of); [2]University of California, Los Angeles, United States; [3]Gachon University, Korea (the Republic of)

Despite the recent application of metallization for stretchable organic thin-film transistor (OTFT), it is challenging in terms of crack-based, limited material and excessive deformation of target materials. Herein, we report a mechanically robust and intrinsically stretchable metallization on an stretchable semiconductor film based on metal-semiconductor intermixing. We deposited noble metals (Ag, Au and Cu) on stretchable semiconductor film and found that vaporized silver forms most continuous intermixing layer during thermal evaporation among three noble metals because of its high diffusivity. The Ag metallized film has a high conductivity (>10^4 S/cm) even under 100% strain stretching and durability that maintains its conductivity without delamination even after 10,000 stretching cycles at 100% strain and several adhesive-tape tests. Furthermore, a native silver oxide (Ag_xO) layer was formed on the interface between stretchable semiconductor film and metallized silver layer to facilitate efficient hole injection and transport, which transcends previously reported stretchable electrodes for OTFTs.

5:00 PM EL18.09.46
Fabrication of Inkjet Printed Tunable BST/P(VDF-TrFE) Dielectrics for Flexible Varactors Tim P. Mach and Joachim R. Binder; Karlsruhe Institute of Technology, Germany

Printed electronics are gaining more attention due to their ability to produce electrical components. For wireless communication, the high-frequency range plays an important role, which makes flexible components such as varactors interesting. Here, the ceramic or polymer dielectric is responsible for the dielectric properties. However, as both come with their own drawbacks, ceramic-polymer composites can be used to combine the excellent dielectric characteristics of ceramics and the easy processibility and flexibility of polymers. Furthermore, to obtain flexible varactors, inkjet printing offers a well-established method for the preparation in a fast and precise manner.
In previous works, an inkjet printed capacitor system consisting of (Ba,Sr)TiO3)/PMMA has already been successfully implemented. However, for varactors, tunability can be achieved in a BST/P(VDF-TrFE) system with the introduction of ferroelectric PVDF based polymers. Herein, printable inks were developed with varying ratio between BST and P(VDF-TrFE) to achieve high tunability and low dielectric losses. Through rheological property and drying temperature adjustments, the so-called coffee stain effect can be prevented. Therefore, thin layers can be realized and characterized on their dielectric properties.

5:00 PM EL18.09.48
Ultrafast, Autonomous Self-healable Electronic Skin with Mechanosensitive Ion Dynamics Elvis K. Boahen[1], Baohai Pan[2], Hyukmin Kweon[1], Joo Sung Kim[1], Hanbin Choi[1], Zhengyang Kong[1], Dong Jun Kim[1], Jin Zhu[3], Wu Bin Ying[1,3], Kyung-Jin Lee[2] and Do Hwan Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Chungnam National University, Korea (the Republic of); [3]Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China

The self-healing properties and mechanosensing capabilities of the human skin has inspired the designs of various self-healing iontronic sensors that respond to pressure, strain, and torsion. Electronic skins based on iontronic materials can be utilized in wide range of applications including wearable technologies, human–machine interfaces, prosthetics, and soft robotics owing to their high noise immunity, exceptional spatial resolution, and excellent response to both static and dynamic stimuli. Conventionally, due to the intrinsic softness of such iontronic materials, they are vulnerable to unexpected mechanical damage, which leads to broken functionalities and limited device longevity. Moreover, the iontronic sensing mechanism most often generates a high initial capacitance due to the limited control of mobile ion dynamics, which results in poor sensitivity. To enhance the control of ion dynamics, previous studies have employed inorganic–based heterogeneous systems to realize ion confinement effect, which resulted in tremendously enhanced device sensitivity. However, the design of such heterogeneous systems can hardly achieve autonomously superior self-healing properties owing to the restricted mobility of polymer chains caused by the slow–moving nanomaterials attached to the polymer. Therefore, designing iontronic systems with simultaneous superior self-healing properties and effective control of ion dynamics, is extremely challenging.
Here, we develop a Cl-functionalized iontronic pressure sensitive material (CLiPS) via the introduction of Cl-functionalized groups (Cl groups) into a polyurethane (PU) matrix, which exhibits not only excellent autonomous self-healing properties but also mechanosensitive ion trap and release mechanism. The design concept involves strategic selection of high chain mobility isophorone diisocyanate and dynamic disulfide bonds to construct the backbone of the PU structure, which are key factors in achieving autonomous self-healing properties of both active matrix and electrodes at room temperature. In addition, with the inclusion of the ionic liquid, a trap and release mechanism is established owing to the ion-dipole interactions between the Cl groups and the ion pairs. On the basis of this unique design approach, we achieved an ultrafast self-healing speed (4.3 µm/min at 25 °C), a high self-healing efficiency (91% within 60 min), and an excellent pressure sensitivity (7.36 kPa^{-1}). Our CLiPS-based device functioned as a pressure-induced tactile sensor to modulate LED brightness, which validates its capability for applications in next-generation wearable technologies and smarter human-machine interfaces.

5:00 PM EL18.09.49
Eco-friendly Transparent Flexible Heater with Metal Mesh Structures Yoonkap Kim and Han-Jung Kim; Gumi Electronics & Information Technology Research Institute, Korea (the Republic of)

Transparent heaters (THs) have been researched with indium tin oxide (ITO) and fluorine-doped tin oxide (FTO) for defrosting and defogging windows, outdoor display panels, and self-heated sensors. However, there is limitation with the ITO and FTO to adapt to flexible and wearable heaters due to their brittleness. Hence, in this study, we proposed a transparent flexible heater (TFH) with copper (Cu) mesh structures fabricated onto poly(vinyl alcohol) (PVA) substrate, which can be dissolved in water, with transfer printing method. The transparent flexible heater exhibited an optical transmittance of ~86% at 550 nm, and reached to ~110 °C with applied voltage of 3V DC. In addition, the thermal response time of the TFH accelerated with a decrease in the thickness of the PVA substrate. In this case, the Cu mesh/PVA-based TFH with a thickness of approximately 75 µm showed fast and effective Joule heating characteristics at a low input voltage (3V DC). Therefore, we expect that the transparent electrode on the PVA substrates considered suitable to develop eco-friendly next-generation electronic devices such as flexible printed circuit boards (PCB) and heater-sensor platforms, flexible actuators and so on.

5:00 PM EL18.09.51

Deformable Tactile Sensor Arrays Integrated with a Frictionless Sensor Interface Enabling Complementary Slip Profiling Yebin Park, Dongbeom Kim, Jaehyun Kim, Wonjeong Suh and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

To successfully replicate complex human tasks, a robotic hand capable of dexterous object manipulation such as grasping, object reorientation, texture perception, and slip detection is urgently demanded. Among various object manipulation performances, slip detection is the key performance that a dexterous robotic hand should acquire to achieve successful interaction between the object and the robotic hand. In the past decade, numerous artificial tactile sensors for robotic hands have shown vast progress in slip detection and grasping. However, slip detection of these sensors mainly relies on the normal force at the contact position without considering tangential force, which only provides limited slip information. In this work, the deformable ion gel strain sensor array and the piezoresistive pressure sensor array are integrated into a single device to obtain spatial distributions of the tangential shear strain and the normal force at the contact area. The tangential shear strain profile from the ion gel strain sensor array provides a visual representation of various slip occasions, such as translational and rotational slip, through changes in the shape and size of the strain fields. Additionally, the normal force profile from the piezoresistive pressure sensor array allows tracking of contact position and normal force distribution. Moreover, a frictionless interface between sensor arrays was achieved through the use of talc particles. The strain sensor array can accommodate deformation from slip more freely through the frictionless interface, which is crucial for a more accurate shear strain profile. Furthermore, the deformable tactile sensor arrays were attached to the robot gripper to demonstrate effective contact analysis on both translational and rotational slip occasions.

5:00 PM EL18.09.52
Large-Area Vacuum-Filtrated 2D MXene ($Ti_3C_2T_x$) Contacts for Flexible Monolayer Organic Field-Effect Transistors Yifan Guo[1], Keqiao Li[2], Yang Li[2], Baoling Huang[2] and Paddy K. L. Chan[1,3]; [1]The University of Hong Kong, Hong Kong; [2]The Hong Kong University of Science and Technology, Hong Kong; [3]Advanced Biomedical Instrumentation Centre, Hong Kong

High-quality monolayer-based organic field-effect transistors (OFETs) have shown great progress to serve as the building blocks of next-generation flexible electronics. Traditional metal evaporation could cause thermal damage on the organic active layer, thus limiting their electrical performance. MXene ($Ti_3C_2T_x$), a two-dimensional transition metal carbides and nitrides, have high conductivity and compatibility with low-cost solution-processed electrode deposition without inducing thermal damage. By vacuum-filtrated assistance, MXene can achieve lower electrical resistivity due to a tighter layer-by-layer structure compared with other deposition methods. The MXene layer can be patterned by a conformal mask that attached to the printing stamp directly and form a high-resolution electrodes array by direct transfer without a lift-off process. The patterning, deposition of MXene, and subsequent electrodes-transfer are all chemical-free processes, which avoid the chemical damage of the organic active layer and make them extremely suitable for the large-area mass production.

In this work, Meniscus-guided coating is used to grow 2,9-didecyldinaphtho[2,3-b:2′,3′-f]thieno[3,2-b]thiophene (C_{10}-DNTT) organic semiconductor monolayer on gate dielectric as the active channel, then transferred vacuum-filtrated MXene electrodes (15 µm channel length, which cannot be achieved without photolithography-patterning in previous study) to form the bottom-gate top-contact structure. The $Ti_3C_2T_x$ nanoflakes alignment was improved during the transfer process from cross-sectional SEM and XRD characterization. A subthreshold swing of ~72 mV/decade and field-effect mobility of ~4.2 $cm^2/V/s$ were achieved on high-κ dielectric HfO_2 by decent contact of HfO_2/C_{10}-DNTT/MXene interface, and the I_{ON}/I_{OFF} ratio reached ~10^8. We further fabricated OFETs on an ultra-thin conformal flexible substrate and realized uniform electrical performance. Compared with other MXene contacts, our current work shows comparable mobility with the shortest channel length, which expanded the application range of low-dimensional conductors as the patterning electrodes. We believe this processing approach of the 2D carbon-based MXene is extremely suitable for the layer-by-layer assembly of the next-generation large-area flexible electronics.

5:00 PM EL18.09.54
ZnO Nanorod Decorated Polyvinylidene-MXene Composite Nanofiber for High Electromagnetic Interference Shieling Effectiveness Sol Lee, Minje Kim, Chang geun kim, Viet Anh Cao and Junghyo Nah; Chungnam National University, Korea (the Republic of)

Electromagnetic waves emitted from different wireless devices may adversely affect electronic devices and cause communication faults. To cope with EM pollution, development of high-performance electromagnetic interference shielding materials with lightweight and flexibility is urgently needed. In this study, we developed ZnO nanorod decorated PVDF-MXene composite nanofiber for EMI shielding. To achieve maximum flexibility, polymer nanofiber is used as matrix polymer, and MXene nanoflakes exhibiting excelling EMI SE was incorporated inside the PVDF nanofiber,, forming the composite nanofiber. Additionally, surfactant-coated ZnO nanoparticles (NPs) were mixed in PVDF-MXene composite solution, which was then electrospun to form ZnO NP loaded PVDF-MXene composite nanofiber. During subsequent hydrothermal growth process, ZnO NPs inside the nanofiber are transported toward the surface of the nanofiber, so ZnO NRs start to grow on the outer surface of the nanofiber. Therefore, EMI shielding material developed in this work provides excellent flexibility, superior absorption SE, and increased multiple reflection and scatterings, resulting in high EMI SE (61 dB) and absolute EMI SE (21830 $dB.cm^2/g$). In addition, the oxidation of MXene nanoflakes can be effectively prevented by the encapsulating PVDF nanofiber, maintaining high EMI SE for a long period time. Therefore, the ZnO-decorated PVDF-MXene composite nanofiber introduced in this work has demonstrated high EMI SE, excellent flexibility, and long-term stability.

5:00 PM EL18.09.56
Effect of Gel Electrolyte Mass Fraction on Dye-Sensitized Solar Cell Using Carbon Nanotube Composite-Papers Yi Kou and Takahide Oya; Yokohama National University, Japan

In recent years with the gradual focus on environmental issues, renewable energy sources have gained more and more attention, among which solar energy has gained widespread attention for its wide range and cleanliness, etc. This study investigates the new type of dye sensitized solar cells (DSSC), which are produced by the redox reaction of dyes. The aim of this study is to achieve unique dye sensitized solar cells by using carbon nanotube (CNT) composite papers (CNTCPs) which this study is developing.

Since the CNTs contained in the CNTCP have metallic or semiconducting property, the use of the CNTCP as the cathode and anode of the DSSC has enabled the realization of a paper-DSSC with low cost and reduced environmental pollution. However, in our previous research, the paper-DSSC evaporated and leaked the contained electrolyte after about twenty minutes of operation when using a liquid electrolyte. To extend the life of the paper-DSSC, in this study, the safety and durability of the electrolyte is tried to improve by introducing a gel electrolyte, as follows:

Firstly to make our CNTCPs, we add 48 mg of single-walled CNT and 70 mg of dispersant (Sodium Dodecyl Sulfate) in 36 ml of pure water. Next, this mixed solution is ultrasonically dispersed for 1 hour by using an ultrasonic homogenizer to prepare a CNT dispersion. 1 g of pulp is then blended in 1000 ml of pure water for 1 hour in a blender to obtain the pulp dispersion. The resulting metallic CNT dispersion is mixed with the pulp dispersion and the CNTCP is produced by the modified Japanese washi papermaking method. In the same way, 4 mg of semiconducting CNTs and 36mg of purple sweet potato color are dispersed in 18ml of water. The paper is then mixed with the pulp dispersion to produce a semiconducting CNTCP. The paper is then dried and shaped by heat pressing.

Here, the gel electrolyte is made, the same as the liquid electrolyte used last time, this time still using iodine and potassium iodide as the main materials to carry out the redox reaction. 38.2 mg of iodine and 200 mg of potassium iodide are first dissolved in 20 mg of acetonitrile by heating in a water bath at 60 degrees centigrade, after it is completely dissolved, polyethylene glycol (PEG) was added, after it is dissolved again, the temperature is adjusted to 80 degrees centigrade and PolyVinylidene DiFluoride (PVDF), after all dissolved, the dispersion is placed in an oven at 70 degrees centigrade for 15 to 20 hours, when most of the acetonitrile has evaporated, the electrolyte at this point takes on a viscous liquid form.

The electrolyte is dropped between the two laminated papers just made and when the remainder has evaporated, the electrolyte takes on a gel-like appearance. In our current study, this paper-DSSC was successfully made to generate electricity and extended its lifetime to more than 2 hours by using 1 g PEG and 1 g PVDF, obtaining fill-factor (FF; performance evaluation index) of 0.22 and a photovoltaic conversion efficiency of 6.9×10^{-5}%.

In order to obtain higher photovoltaic conversion efficiency, the concentration ratio of PEG and PVDF is tried to be adjusted this time to compare the effect of this electrolyte on the photovoltaic conversion efficiency of paper-DSSCs at different ratios. Without changing condition for semiconductor electrodes, gel electrolytes with PEG: PVDF of 5:5, 6:4 and 4:6 are added into the paper-DSSCs as trial. As results, we found that changing the ratio of PEG and PVDF tended to affect the photovoltaic conversion efficiency. We are now trying to find the suitable condition for the ratio.

We believe that desired paper-DSSCs with high photovoltaic conversion efficiency and lifetime can be obtained by using carbon nanotube composite paper and our approaches.

5:00 PM EL18.09.57

Recent Progress in X-Ray Scattering Characterizations for Organic Optoelectronic Devices Yu-Wei Su; Feng Chia University, Taiwan

Recent progress in X-ray scattering have provides unique insights into the characterization of polymers in energy applications of photovoltaics and photodiodes. We presented using grazing incidence wide-/small angle X-ray scattering (GIWAXS/GISAXS) to study the bulk-heterojunction morphology of active layers in high-efficient organic photovoltaics (PCE >10%) and photodiodes. The active layer is mainly composed of donor–acceptor type conjugated polymer and n-type fullerene (or non-fullerene) small molecules. The GIWAXS is sensitive to the polymer's crystalline and can determine the crystal structure and the orientation of the crystalline regions. By using GISAXS, the aggregation cluster of conjugated polymer/small molecules can be detected to a length scale range from nanometers to several hundred nanometers.

5:00 PM EL18.09.59

Origin of Layered Herringbone Packing in Polyacenes as Investigated by Stepwise Crystal Structure Optimization Ryota Ono, Kanata Koyama, Satoru Inoue, Seiji Tsuzuki and Tatsuo Hasegawa; The University of Tokyo, Japan

Layered organic semiconductors (OSCs) are useful and suitable for manufacturing thin-film transistor (TFT) device structures. The carrier transport properties in these OSCs are primarily determined by molecular arrangement or crystal structure. It is thus expected that the development of high-performance OSC materials could be highly accelerated, if crystal structure of molecules designed on the desk is known prior to the actual synthesis of the molecules. To achieve this goal, it is essential to understand the origin of structural order found in the known crystals.

Here we investigate the origin of crystal structures for a series of polyacenes, from naphthalene (ring number 2) to hexane (ring number 6), through stepwise quantum chemical optimization approach as to intermolecular arrangements. We simplify and classify intermolecular arrangement parameters by focusing on both layered molecular packing and high crystal symmetry, as is typically observed in layered OSCs. The method allows to achieve highly accurate structure optimization in a short time by utilizing dispersion-corrected density functional theory (DFT) calculations as a technique used for calculating lattice energy. We found that adequate treatments of the variable parameters at each optimization steps lead to reproducing the experimental crystal structures of the compounds. Furthermore, the study revealed that origin of ring number dependence of crystal symmetry and layered crystal structures in polyacenes. We used Gaussian 16 for calculating lattice energy as the sum of intermolecular interaction with B3LYP functional and Grimme's D3 dispersion correction [1]. We first model a simple molecular dimer at an arbitrary relative position that assumes glide reflection symmetry with parallel and unslipped molecular long axes; the dimer is utilized as a fundamental unit for architecting monomolecular layers. First-step lattice energy minimization for the intralayer molecular arrangements allows to obtain regular layered herringbone packing through optimizing the intermolecular dihedral (or herringbone) angle. Then we take slipping or twisting structure into account and search for locally stable layered structure. Finally, we calculate interlayer interaction and search for stable layer arrangement. Through these steps, we can optimize intralayer and interlayer arrangement and gain probable and physically reasonable crystal structure. We optimized molecular arrangement of a series of polyacene molecules by this method, and successfully reproduced the structures of the respective compounds, including their polymorphs. Based on the results, we discuss the origin of the variation in these molecular packing structures in terms of the change of intermolecular twisting structure resulting from the increase of the number of benzene rings.

Liquid Metal Incorporated Devices Toward Multifunctional Soft and Stretchable Electronics Priyanuj Bhuyan, Yuwen Wei and Sungjune Park; Jeonbuk National University, Korea (the Republic of)

In the past decade, liquid metals, especially gallium and its alloys, have surfaced as rapidly emerging cutting-edge functional materials with a view to revolutionize the field of soft and stretchable devices. This special class of materials possesses a handful of fascinating properties. As "liquid" they have low viscosities almost similar to water, along with higher surface tension, negligible vapor pressure and low toxicity; and as "metal" they possess high electrical and thermal conductivity, and transition from their liquid phase to solid phase and vice versa is easily attainable through nucleation and low temperature melting. Effective tuning of these properties and their inclusions in elastomeric materials in various forms via several unconventional techniques can lead to elastomeric metamaterials displaying interesting properties. Herein, we present a compilation of our research works which focuses on liquid metal inclusion in several forms in elastomeric substrates. We shed light on the use of liquid metal in three forms: as bulk injectable electrode material into elastomeric fibers and films, as rheologically modified ink for electrode printing and as micro fillers in elastomeric substrates to amplify electrical properties. Whereas presence of bulk liquid metal as core in 1D fibers and 2D films can render shape memory properties through phase change along with electrical conductivity, solidified gallium wires can be assembled into 3D structures through "room temperature welding" which can be subsequently included in elastomers to realize a 3D fluidic network. The rheology of liquid metal can be tuned to obtain an ink suitable for electrode printing on polymeric films in order to fabricate flexible, ultrasoft and ultrastretchable electronics systems with unhindered electrical and mechanical functionalities. The fluidic nature and low viscosity of liquid metals facilitates their inclusion in elastomeric matrix in the form of micro particles via high shear mixing in order to tune electrical and thermal properties through liquid metal particle inclusions. In short, our compilation provides an insight into conjugating liquid metals in various forms into elastomeric substrates of various physical shapes and mechanical properties via which we were able to design several soft and stretchable systems with specific properties: stretchable 1D fibers and 2D films with shape memory and electrical conductivity, elastomers with 3D fluidic electrode inclusions, flexible, ultrasoft and ultrastretchable sensos with fluidic electrodes and soft devices capable of functioning as healable/reconfigurable waste energy harvesters.

GaAs Photovoltaic Arrays Integrated on an Ultrathin Polymer Film Substrate for High Flexibility and a Lightweight Design Sungbum Cho, Dongwuk Jung and Jongho Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

Ultrathin and lightweight photovoltaics with high efficiency and reliability serve as a convenient untethered power source for new types of electronic devices, such as attachable or implantable electronics, small-scale robots, and many others. However, the extreme mechanical properties of high-performance solar cells and ultrathin films present challenges when handling and processing them to realize ultrathin solar cell arrays. In this paper, we present a highly efficient GaAs photovoltaic array integrated on an ultrathin polymer film (1.4 µm thick). Full processes, including framing, cold-welding, epitaxial lift-off (ELO), and microfabrication, are used realize ultra-flexible and lightweight GaAs photovoltaic arrays. The mechanical characteristics were analyzed via numerical and experimental methods along with demonstrations with electrically functional devices. The power-to-weight ratio (specific power: 5.44 W g^{-1}) is in the highest range, even with single-junction solar cells.

5:00 PM EL18.09.63
Cu_2O Thin-Film Transistor for CMOS Logic Circuit Through the Chemical Reaction During Annealing in N_2 Atmosphere Jae Hak Lee and Youn Sang Kim; Seoul National University, Korea (the Republic of)

Metal oxide semiconductors have been emerging as a semiconductor material for next-generation electronic devices such as switching devices in displays, thin film diodes, solar cells, and Dynamic Random-Access Memory (DRAM) due to several advantages such as low cost, various deposition methods, low processing temperature, and processability on large-area glass substrate. However, it is difficult to construct a low power logic circuit based on Complementary Metal-Oxide-Semiconductor (CMOS) with only n-type metal oxide TFTs, so p-type metal oxide TFTs with good electrical performance is required. Cuprous oxide (Cu_2O) is a potentially promising p-type semiconductor due to the intrinsically good electrical properties such as high hole mobility over 100 cm^2/Vs and the possibility to fabricate devices using conventional semiconductor processes. Despite an intrinsic high hole mobility, Cu_2O TFT has still shown poor electrical performances. Several studies proposed dissociative Cu defects and CuO impurities as the cause of the poor electrical properties of Cu_2O TFTs. First, dissociative Cu (interstitial Cu) defects create a donor-like sub-gap states in the band gap of p-type Cu_2O, causing high off-current. Second, the other considering point is CuO impurities in the Cu_2O thin film, which induce sub-gap states that serve as a hole trapping site above the VBM of Cu_2O because the bandgap of CuO (1.4 eV) is smaller than that of Cu_2O (2.17 eV). Thus, dissociative Cu (interstitial Cu) defects and CuO impurities play a critically detrimental role in the quality of Cu_2O thin film. Dissociative Cu defects cause high off-current and CuO impurities cause low field effect mobility. Therefore, it is essential to reduce dissociative Cu and CuO impurities in order to improve the electrical performance of Cu_2O TFTs.
Here, we demonstrated Cu_2O TFTs with high field effect mobility and low off-current through reduction of CuO impurities and dissociative Cu defects by simply controlling the fabrication conditions without inducing any additional layers or chemical treatments. In the Radio Frequency (RF) sputtering deposition process, a Cu_xO thin film with a high CuO ratio was fabricated by using a mixed gas of Ar and O_2 as working gas. Then, post annealing was performed while flowing N_2 gas. Oxygen added to the working gas during deposition increases the CuO ratio in the copper oxide thin film and consequently reduces dissociative Cu defects. Also, the N_2 atmosphere in annealing plays an important role in reducing Cu_xO to Cu_2O and prevents oxidation to CuO phase. During post annealing, when CuO - CuO transformed to Cu_2O, oxygen is generated, and the generated oxygen oxidized dissociative Cu defects to CuO. The formed CuO also combined with another CuO and transited to Cu_2O. These chemical reactions occur repeatedly and continuously during the annealing process, creating a chain reaction. By XRD and XPS analysis, we confirmed that the fabrication method of Cu_2O thin film combined with controlled deposition and anneal effectively reduces CuO impurities and dissociative Cu defects, the ratio of dissociative Cu defects decreased from 11.3% to 3.1%, which are responsible for the degradation of the electrical properties of Cu_2O TFTs. The fabricated Cu_2O TFTs were showed the field effect mobility of 1.19 ± 0.06 cm^2/Vs, the on/off current ratio of $1.09 \pm 0.06 \times 10^5$. And the Cu_2O TFT device exhibited a Vth shift of 3.31 V under negative bias stress (Vds = -10V, Vgs = -20V, 4000s). As a practical application, we demonstrated CMOS inverter with n-type IGZO TFT and p-type Cu_2O TFT and this device achieved a gain of 14 at V_{DD} = 20 V. Our new fabrication route showed that it was possible to simply fabricate a high-quality Cu_2O thin film, effectively improve the electrical properties of Cu_2O TFTs, and make low-power CMOS logic circuits based on metal oxide semiconductors.

5:00 PM EL18.09.64
Inorganic Nanopillar Arrays Significantly Enhance Optoelectronic Functions, Environmental Stability and Mechanic Robustness of Flexible Perovskite Optoelectronic Devices Zhifeng Huang; The Chinese University of Hong Kong, Hong Kong

One-dimensional (1D) nanostructure arrays can reduce light reflection loss, suppress recombination dynamics, guide charge carrier transport, and relax stress and strain in flexible optoelectronic devices, to improve optoelectronic functions and stability under aging and mechanical bending. However, *in-situ* fabrication of 1D nano-arrays on polymer-based flexible electrodes is challenging, mainly due to degradation of polymer-based electrodes at high temperature of *in-situ* growth.
Here, nanopillar arrays (NaPAs) made of diverse inorganic materials, such as Ti, TiO_2, SnO_x (functioning as electron transporting layers) and NiO_x (serving as hole transporting layers), are deposited onto a flexible electrode by glancing angle deposition (GLAD), to create perovskite solar cells (PSCs) and photodetectors. As-grown NaPAs enhance light transmittance, facilitate light harvesting in perovskite, promote charge carrier transport and collection, and facilitate the formation of large perovskite grains. All these features lead to high efficiency of >20% and >17% for the rigid and flexible PSCs, respectively. No obvious crack nucleation is formed on the NaPAs after 500 bending, resulting in good mechanic robustness and environmental stability of photovoltaic performance. Large-area (1 cm^2) flexible PSCs containing the SnO_2 NaPAs show the champion power conversion efficiency (PCE) of 14.9%, which undergoes only 10% degradation for approximately 800 h storage and 20% degradation by manual bending for around 400 times. Furthermore, compared to the conventional mesoporous counterparts, metallic oxide NaPAs enable the perovskite photodetectors to comprehensively enhance the detection speed, responsivity, and detectivity, and to extend the linear dynamic range.
We devise an advanced technique of low-substrate-temperature GLAD generally adapted to *in-situ* deposition of charge carrier transporting layers made of inorganic NaPAs on flexible electrodes, to significantly enhance optoelectronic performance, mechanic robustness, and environmental stability of flexible optoelectronic devices.

5:00 PM EL18.09.66
In-Depth Study on Molecular Structure-Property Relation for Y6-Based Nonfullerene Acceptors in Organic Photovoltaics Chang Woo Koh[1], Shuran Xu[1], Min Hun Jee[1], Dohun Yuk[2], Jin Young Kim[2], Han Young Woo[1] and Sungnam Park[1]; [1]Korea University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Organic photovoltaics (OPVs) have drawn much attention as the next-generation of renewable energy harvesters due to their significant advantages of solution processability, lightweight, mechanical flexibility, semi-transparency, and indoor applicability. Recently, power conversion efficiencies (PCEs) have recently increased to over 20% in tandem devices and over 19% in single cells due to the development of high-performance nonfullerene acceptors (NFAs). Among the NFAs, Y6 is unquestionably a representative benchmark structure with several distinct characteristics, including dominant face-on orientation, high electron mobility, and low energy loss. Y6 has an acceptor-donor-acceptor (A-D-A)-type structure consisting of a

dithieno[2″,3″:4′,5′]thieno[2′,3′:4,5]pyrrolo[3,2-e:2′,3′-g] [2,1,3]benzothiadiazole (BTP) core and two electron-accepting 2-(5,6-difluoro-3-oxo-2,3-dihydro-1H-inden-1-ylidene)malononitrile (INCN-2F) terminal moieties. In particular, an undecyl side chain is substituted at the β-position of the thienothiophene (TTh) moiety (in the Y6 core) to impart solution processibility. However, owing to the complicated synthetic procedure of alkyl-substituted core, further optimizing the molecular structures and industrial scale-up of Y6-based materials are required. Moreover, the bulky side chains on the core of Y6 obstruct core-core intermolecular packing interactions, influencing electronic coupling and charge transport properties.
In this study, three new Y6 derivatives (YBO-2O/-FO/-2F) were synthesized and characterized as an acceptor in OPVs. Compared with Y6, the YBO series have no alkyl chains in the core, and it has been shown that the intermolecular packing properties in the solution processed thin films are significantly improved because of the absence of core alkyl chains. Tighter π-π stacking was confirmed by grazing incidence wide angle X-ray scattering (GIWAXS) and higher electron mobility were also measured by the space charge limited current (SCLC) method with the YBO-2O, YBO-FO, and YBO-2F films compared to Y6 films. From molecular dynamics (MD) simulations, the YBO series were found to preferentially form core-core and terminal-terminal (CC-TT) interactions rather than terminal-terminal (TT) interactions in Y6, which induced dense intermolecular packing for efficient charge transport. The mechanism for dimer formations in solution state is found to be different for YBO series compared to Y6. In the case of YBO series, two molecules initially formed TT dimers as an intermediate state and were subsequently converted into more stable CC-TT dimers. However, in the case of Y6, TT dimers were readily formed and kinetically trapped due to the alkyl chains in the core, and thermodynamically stable CC-TT dimers were relatively slowly formed. Our newly designed YBO series are excellent NFAs in terms of better intermolecular packing, higher electron mobility, and kinetically more favorable aggregation.

5:00 PM EL18.09.68
Effect of Electric Field on Metal Capping Layer of Thin-Film Transistor (TFT) and Its Potential Seo D. Hyo, Sang Yeol Lee and Yoon HongJoon; EMADE.LAB, Korea (the Republic of)

Thin film transistor research has been studied with high mobility and stability to implement high-definition displays and thin film transistor-based electronics, such as neuromorphic devices, multi-value devices and 3D integrated circuits. A metal capping(MC) TFT is a device that meets these needs of the times. The improvement of electrical properties and mobility of TFT will be studied using MC layers on channel layers. It can increase the mobility of TFT by adopting the metal layer on the channel material because the MC material has a relatively lower resistance than that of the channel materials. MC-layer is attributed to form strongly compacted ω-shape current-path by tunneling effect as a result of effective control of the surface potential by low resistance of MC-layer in channel region. In addition, the proposed device structure contributes to the changes in transistor performance when electric field is applied to the MC layer step by step. This could suggest the possibility of the application for contact sensors with high response due to high mobility of MC TFTs.

5:00 PM EL18.09.69
Highly Conductive p-type Transparent Conducting Electrode with Sulfur-Doped Copper Iodide Gahye Kim and Myung-Gil Kim; Sungkyunkwan University, Korea (the Republic of)

Although n-type transparent conductors have been commercialized with high optical transmittance and electrical conductivity, the realization of their p-type counterparts has been a challenging problem. Here, we report the synthesis of a highly conductive transparent p-type sulfur-doped CuI (CuI:S) thin film using a liquid-iodination method with a thiol additive. The CuI:S film shows a remarkably high electrical conductivity of 511 S cm^{-1} with an optical transmittance of greater than 80%. Furthermore, additional hole doping of CuI:S with H_2O_2 treatment improves the electrical conductivity to 596 S cm^{-1}. Consequently, CuI:S exhibits a record-high figure of merit (FOM) value of 63,000 M Ω^{-1} (73,000 M Ω^{-1} with H_2O_2 treatment), which is ~ 370% (~430% with H_2O_2 treatment) higher than the previously reported record-high FOM value. The highly conducting CuI:S electrode is successfully applied as transparent conducting electrodes of the organic light-emitting diode and transparent p-type thin film transistor. The liquid-iodination chemical method with unconventional control of the reaction parameters can be generalized to produce high-quality metal halide thin films, allowing them to be applicable for transparent electronics and optoelectronics.

5:00 PM EL18.09.70
Buckling Instability Control of 1D Nanowire Networks for a Large-Area Stretchable and Transparent Electrode Byoung Soo Kim[1,2], Jeong Gon Son[2] and Sang-Soo Lee[2]; [1]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

A commonly used strategy to impose deformability on conductive materials is the prestrain method, in which conductive materials are placed on prestretched elastic substrates and relaxed to create wavy or wrinkled structures. However, 1D metallic nanowire (NW) networks typically result in out-of-plane buckling defects and NW fractures, due to their rigid and brittle nature and nonuniform load transfer to specific points of NW. To resolve these problems, an alternative method is proposed to control the elastic modulus of 1D NW networks through contact with various solvents during compressive strain. Through solvent contact, the interface interactions between the NWs and between the NW and substrate can be controlled, and it is shown that the surface instability of the 1D random network is formed differently from a uniform bilayer film, which also can vary with the modulus of the network. For modulus values lower than the critical point, slippage and rearrangement of NW strands mainly occur and individual strands in the network show an in-plane wavy configuration, which is ideal for structural stretchability. Based on the solvent-assisted prestrain method, letter-sized, large-area stretchable, and transparent electrodes with high transparency and conductivity are achieved, and stretchable and transparent alternating current electroluminescent devices for stretchable display applications are also realized.

Direct Writing of Elastic Conductors for Three-Dimensional Stretchable Electronics Seungjun Chung; Korea Institute of Science and Technology, Korea (the Republic of)

Skin electronics augment the capability of shareable signals from personal and metabolic activities over communication networks by blurring the physical discontinuity between electronic devices and human skin. With their unique mechanical characteristics, such as lightweight design, softness, and stretchability, skin electronics can be functionalized on various body parts in the form of biosensors, processors, and displays. For high-fidelity operation under these challenging circumstances, the design of skin electronics needs to be tailored elaborately to individuals. However, traditional mask-based lithography primarily optimized for the mass production of standardized, uniform electronics cannot effectively deal with the morphological diversity of the human bodies. Moreover, existing manufacturing processes still lack strategies to implement three-dimensional (3D) structures with soft functional materials such as vertical interconnect accesses (VIAs) and multilayer circuitries that are crucial to the realization of high-performance, multifunctional applications.

Printing technologies have attracted tremendous attention in the realization of customized soft electronics due to their advantages, such as non-vacuum, low-temperature, and non-contact processability. However, most conventional 3D printing processes still deposit one layer at a time, which is unsuitable for complex, filamentary, and omnidirectional wirings (including a z-directional component). In this regard, omnidirectional direct ink writing for self-supporting 3D wirings with elastomer composites has attracted much attention, but the complex composition of their inks that meets apposite rheological properties is a critical bottleneck, resulting in structural collapse and nozzle clogging during extrusion simultaneously. In this presentation, I would like to present our recent results of printing Intrinsically stretchable solid-state elastic conductors into self-supporting 3D geometries. These results promise the design diversity of soft electronics, enabling complex, multifunctional, and tailored human-machine interfaces. Our omnidirectional printing strategies achieve superior viscoelastic properties that provide the structural integrity of printed features, and pseudoplastic and lubrication behaviors that allow great printing stability simultaneously. Freestanding, filamentary, and out-of-plane 3D geometries of intrinsically stretchable conductors are directly written, achieving a minimum feature size <100 µm and excellent stretchability >150%. Particularly, the evaporation of the continuous phase in the emulsion results in microstructured, surface-localized conductive networks, significantly improving their electrical conductivity. To illustrate the feasibility of our approach, we demonstrate skin-mountable electronics that visualize temperature on a matrix-type stretchable display based on omnidirectionally printed elastic interconnects.

9:00 AM EL18.10.04

Universally Applicable Three-Dimensional Photo-Crosslinkers for All-Photopatterned Electronics BongSoo Kim[1], Myeongjae Lee[2], Min Je Kim[3] and Jeong Ho Cho[3]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Yonsei University, Korea (the Republic of)

Fabrication of electronic components at high resolution remains a challenging task for organic electronic devices fabricated entirely through a series of solution processes. We report the all-solution processing of highly integrated arrays of organic thin-film transistors (OTFTs) and logic gates. This processing is performed using newly developed multi-bridge photo-crosslinkers containing 4 or 6 photo-crosslinkable units. Under UV, photo-crosslinkers mixed within solution-processable electronic materials generate a three-dimensional (3D) network of the given host electronic materials. We note that our photo-crosslinkers can produce the 3D network state efficiently even at an unprecedentedly small loading (only 1 or lower wt%), which, in turn, enables preservation of the intrinsic electrical properties of the photo-crosslinked material. Moreover, the crosslinking of electronic component layers allows not only micropatterning of the layers at high resolution (< 5 µm) but also stacking of a given electronic component layer on top of the other layers.[1,2] Furthermore, our efficient photo-crosslinkers enable to produce an ultrathin polymer gate dielectric, the application of which results in excellent hole and electron mobilities of 12.4 and 10.1 $cm^2 V^{-1}s^{-1}$, respectively, from *p*- and *n*-type OTFTs operated at < 3 V.[3] These works demonstrate that the use of photo-crosslinkers paves a new avenue to fabricate future electronic devices.

An N-Type, Stable Electrolyte Gated Organic Transistor Based on a Printed Polymer Fabrizio A. Viola[1,2] and Mario Caironi[2]; [1]Università degli Studi di Cagliari, Italy; [2]Italian Institute of Technology, Italy

Electrolyte-gated organic transistors (EGOTs) have been proven to be one of the most attractive platforms for next-generation biosensors [1], neuromorphic systems [2] and low-voltage electronics [3]. They are particularly indicated for applications where stable operation in aqueous environment and cost-effective manufacturing are required. However, despite a large number of solution processable EGOTs have been reported in literature so far, only few are based on printed semiconductors, with no examples of digitally printed, i.e. inkjet printed, n-type devices, which would easily enable complementary architectures [4].

Therefore, a current challenge is the fabrication of stable n-type EGOTs through large-area, scalable and additive printing techniques for the deposition of the organic semiconductor, facilitating future scale-up and cost-effective process flows. Indeed, through printing techniques such as inkjet, the materials can be deposited in an controllable way over both rigid or flexible substrates with a small production of waste. Moreover, enabling reliable printed n-type EGOT could pave the way for the development of robust complementary electrolyte-gated electronic circuits, which are highly advantageous especially for bioelectronics, for instance as signal amplifiers of weak biopotentials, thanks to their high gain with a very low-power consumption and low-voltage operation.

In this work we propose the first example of a n-type electrolyte gated organic transistor based on an inkjet printed polymer [5].

The proposed device shows a high stability when operated in water and requires only 3 hour of conditioning to produce a stable response, a much faster dynamic than in the case of printed polymers currently tested for p-type EGOTs. The electrical characterization demonstrated a good reproducibility of the device performance, especially in terms of maximum output current, the on/off ratio is above 10^4 and the transconductance is equal to 370 ± 40 uS – when the devices are measured with a Ag/AgCl gate electrode and 0.1 M NaCl as gate electrolyte. Furthermore, as a proof-of-concept, we successfully integrated the proposed printed n-type EGOT with a printed p-type device in an inverter gate able to operate in water for more than 15 hours with a proper inverting behavior and a substantially stable gain. Overall, besides providing a valid and cost-effective technological solution for the fabrication of EGOTs, based on ink-jet printing technique that make possible the integration of n-type and p-type devices, the proposed approach can be a candidate for a plethora of possible use ranging from biosensing, for healthcare or biomedical applications, to complementary circuitry, where reproducibility, high operating stability and low-voltage operation are required.

Flexible Capacitive Pressure Sensors with 3D Printed Lattice Dielectric Layers Arielle E. Berman, Kaiwen Hsiao, Chengyi Xu, Emily Stein, Khuyen Nguyen, Joseph M. DeSimone and Zhenan Bao; Stanford University, United States

Dexterous robotic manipulation and perception requires the sensing of multidirectional forces and combined loadings. With integrated sensor types and a wide variety of possible applications, fabrication techniques can quickly increase in complexity. Additionally, they lack reproducibility and precise control over the microstructure. By utilizing an additive manufacturing process called Continuous Liquid Interface Production (CLIP), three-dimensional lattice elastomeric polyurethane dielectric layers for capacitive sensors can be reliably produced. These different, intricately architectured lattices, called Voronoi, Rhombic, Tetrahedral, and Kagome, cannot be generated with conventional fabrication techniques. The first step towards designing sophisticated capacitive sensors was to characterize the performance of different lattice forms under normal pressure when laminated onto interdigitated electrodes. The impact of altering lattice design parameters, such as volume fraction, strut width, and dielectric thickness, on sensitivity and capacitive response will be discussed in this talk. MicroCT will also be utilized to elucidate the influence of lattice design on the deformation mechanisms and initial capacitance. With this information, rationally designed multifunctional sensors with combined lattice types for anisotropic mechanical properties can be easily printed. CLIP enables simple printing of complex and flexible dielectric layers for fabrication of customizable dielectric layers for capacitive sensors responsive to various external loadings.

9:45 AM EL18.10.07
Biomimetic, Programmable, and Part-by-part Maneuverable Single-body Shape Morphing Film Yongrok Jeong[1,2], Junseong Ahn[1], Ji-Hwan Ha[1,2], Jiwoo Ko[1], Soon-Hyoung Hwang[2], Sohee Jeon[2], Munjeong Bok[2], Jun-Ho Jeong[2] and Inkyu Park[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Machinery and Materials, Korea (the Republic of)

Recently, shape morphing films (SMFs) have been actively researched owing to their diverse applications such as soft robotics, soft gripper, and healthcare/wearable devices. Recent research about SMF concentrates on improving the morphing complexity, possibly widening the applicable area of the SMF. Their morphing complexity has been achieved by assembling multiple actuation elements in a single system. However, most of them are manually assembled, leading to unreliability in the assembled result, and are unsuitable for complex movements such as the gripping motion of the *Drosera Capensis,* which needs elaborate morphology and a highly ordered structure with multipTon order to resolve this problem, this study proposes a biomimetic, programmable, and part-by-part maneuverable single-body SMF, which may replace the conventional assembly methods.

An electrothermal actuator is adopted as the fundamental principle: multiple layers with diverse coefficients of thermal expansion (CTE) cause bending, originating from the difference in volume change induced by Joule heating. A strain-restricting layer and a strain-inducing layer were required, therefor polyimide and SU-8 with low CTE as the strain-restricting layer, and PDMS with high CTE as the strain-inducing layer, were adopted. Equivalently function to the assembled system, programmability and part-by-part maneuverability should be realized either. Programmability was achieved by a similar mechanism with *Bauhinia variegates*, which morphs by the hygroscopic volume change of overall tissue with restriction by the cellulose fibril structure. Similarly, the temperature-induced volume changes and anisotropy in elastic modulus by SU-8 microwall cause the bending of film in the intended direction. In the case of part-by-part maneuvering, it is achieved by controlling the voltage distribution of the underlying electrothermal heater.

The SU-8 wall pattern was optimized to maximize the bending sensitivity. Four variables (width (w), pitch/width ratio (p/w), height ($t_{\text{SU-8}}$) of the SU-8 micro-wall, and the relative thickness of PDMS concerning that of SU-8 ($t_{\text{PDMS}}/t_{\text{SU-8}}$)) are optimized to maximize the curvature (k) between the initial and heated states. Resultantly, $w = 25$ µm, $p/w = 2$, $t_{\text{SU-8}} = 75$ µm, and $t_{\text{PDMS}}/t_{\text{SU-8}} = 1.5$ was selected. Based on the simulated result, over the NiCr nano-mesh-embedded PI film used as the electrothermal heater, the SU-8 wall with morphology that follows the optimization ($w = 25.1$ µm, $p/w = 1.99$, $t_{\text{SU-8}} = 80$ µm, and $t_{\text{PDMS}}/t_{\text{SU-8}} = 1.28$) was fabricated as SMF.

For characterization, two samples of sizes 1x1 and 5x5 mm^2 were analyzed. The first experiment investigated the change in depends on power density ($P' =$ applied power/area of SMF). The results show a linear relationship between P' and κ for both samples, with a sensitivity ($S = \triangle P'/\triangle\kappa$) of 7.83 cm/W for the 1x1 SMF, and $S = 6.26$ cm/W for the 5x5 SMF. In the second experiment, 10–90% rise time (τ_R) and 90–10% fall time (τ_F) were measured for $P' = 0.6$ W/cm^2. As a result, $\tau_R = 4.08$ s, $\tau_F = 4.09$ s for the SMF, and $\tau_R = 4.91$ s, $\tau_F = 11.11$ s for the SMF were measured. Finally, 1000 cycles of heating/cooling were performed with the 5x5 SMF, and no noticeable irregularity was observed.

Complex movements were demonstrated for two biomimetic applications: artificial inchworm (crawler) and artificial *Drosera capensis* (gripper). In the case of the artificial inchworm, five different motions were demonstrated (pose stabilization: front-to-back flip and back-to-front flip; basic movements: crawl, left turn, and right turn). In the case of the artificial *Drosera capensis*, the insect-gripping motion via hierarchical morphology was demonstrated. The proposed method for the fabrication of a biomimetic, programmable, and part-by-part maneuverable single-body SMF can successfully replace the conventional assembly process and achieve advanced SMF technology by enabling various complex movements toward practical applications.

Tuning Polymer-Acceptor Backbone Coplanarity and Conformational Rigidity to Achieve High-Performance Printed All-Polymer Solar Cells with Reduced Charge Recombination Yilei Wu and Zhenan Bao; Stanford University, United States

Compared with small-molecule acceptors (SMAs) based polymer solar cells, all-polymer solar cells (all-PSCs) comprising both polymer donor and polymer acceptor offer superior morphological and mechanical stability as well as a broader processing window. However, current performances of all-PSCs are still inferior to those of SMA systems, mainly because of the scarcity of high performing polymer acceptors relative to the diverse SMAs. Herein, we report a high-performance polymer acceptor incorporating intramolecular noncovalent interlocking effect that leads to a more coplanar and rigid molecular conformation compared to the polymer acceptors based on commonly used thiophene-based linkers. As a result, this new polymer shows a better backbone conjugation and tighter interchain π-stacking, leading to all-PSCs with higher charge-transport mobility and reduced energetic disorder. Furthermore, detailed morphology and photophysical investigations reveal that such blend exhibits a good balance between polymer miscibility and domain purity, thus leading to a more suppressed charge recombination and higher current density and fill factor. Overall, a significantly higher efficiency of 15.6% is achieved respect to control system (9.8%). Moreover, a remarkable efficiency of 14% is demonstrated for the solution-sheared All-PSCs under ambient conditions, which is a record-high value for devices made under conditions relevant to the real-life printing technologies. This study reveals the potential of noncovalent interlocking effect to construct polymer acceptors with more coplanar and rigid chain conformation, which are desirable properties to achieve superior All-PSCs.

Inkjet Printing Organic Photovoltaics for Contact Lens Applications Tsu-Yu Chou, Tanmay Sinha and Francisco Molina-Lopez; KU Leuven, Belgium

Smart contact lenses (SCL) are considered as a noninvasive platform for health monitoring and diagnosing. We can use SCL to measure eye movements, blood oxygen, or even detect the concentration of glucose for some diabetes patients. However, the space limitation in SCL makes it challenging to power them since current performing batteries are too bulky to be integrated on the lens. We propose inkjet printing (IJP) organic photovoltaic (OPV) cells as an alternative complementary (to small batteries) power supply for SCL. OPVs are good candidates in this application because they involve non-toxic materials that can be processed from solution using green solvents. Moreover, the absorption spectrum of the organic semiconductors used in OPVs matches well the one of indoor lighting, leading to cells with higher power conversion efficiencies (PCEs) than traditional Si solar cells for indoor conditions. The use of IJP is justified because contrary to typical applications of solar cells, the integration of OPVs on SCL does not require high-throughput or large-area deposition. Instead, free patterning with good resolution is a main aspect to pursuit. In our work, we focus on the relation process-morphology-performance of the inkjet-printed active layer. By choosing proper solvents, which takes into consideration the boiling point, surface tension, viscosity and density, we succeed in reducing the coffee-ring effect and in making uniform films. Those improved films will ultimately lead to higher PCE.

Printed and Flexible Carbon Nanotube Based Thermoelectrics Mariano Campoy-Quiles; ICMAB-CSIC, Spain

The conversion of waste heat into electricity using solid state devices, namely thermoelectrics, based on carbon materials has experienced renewed interest in the last decade as these materials are particularly suited for large area and low-temperature operation applications since they are abundant, typically show low-toxicity and are easy to process [1].
In this contribution we will focus on our recent attempts to further extend the sustainability, scalability and range of applications of CNT based thermoelectrics. First, we will describe the use bacteria in environmentally friendly aqueous media to grow large area bacterial nanocellulose (BC) films with an embedded highly dispersed CNT network [2]. The thick films are fully bendable, can conformally wrap around heat sources and are stable above 500 K. The resulting composite films exhibit comparable thermoelectric properties to buckypapers while saving more than 90% of the carbon nanotubes. Interestingly, BC can be enzymatically decomposed, thus completely reclaiming the embedded CNTs once the generator has reached the end of its lifetime. Second, we will show our recent studies on the stability and scalability of CNT based thermoelectrics, starting from CNT salts, [3] and give some examples of potential uses, such as solar thermoelectrics [4].

All-Aerosol-Jet-Printed Highly Sensitive and Selective Polyaniline-Based Ammonia Sensors Tolga Aytug[1], Christine Fisher[2,1], Pooran Joshi[1], Lydia Skoolrood[3,1] and Bruce Warmack[1]; [1]Oak Ridge National Laboratory, United States; [2]The City University of New York, United States; [3]North Carolina State University, United States

Early detection of refrigerant gas leaks, in particular ammonia (NH_3), is crucial to avoid significant economic loss and prevent harmful effects to human health and environment. We report design and scalable fabrication of a low-cost and low-power polyaniline-based NH3 gas sensor on flexible polyimide (PI) substrates using additive manufacturing techniques. The silver interdigitated electrode arrays and conducting polymer films are printed onto PI using a direct-write technology of aerosol-jet printing (AJP). The gas sensing performance of the fabricated devices is evaluated in the analytical early leak detection range of 5–1000 ppm NH_3 in air as a function of both thermal and relative humidity exposures. The sensor exhibits sensitivity down to 5 ppm NH_3 with a sub-ppm detection limit and good repeatability. Application of AJP to print other ink formulations on technological viable platforms will also be discussed.

11:45 AM EL18.10.12
A Transient Printed Soil Decomposition Sensor based on a Biopolymer Composite Conductor Gregory L. Whiting[1], Madhur Atreya[1], Stacie DeSousa[1], John-Baptist Kauzya[1], Evan Williams[1], Austin Hayes[1], Karan Dikshit[1], Jenna Nielson[1], Sara Khorchidian[1], Abigail Palmgren[1], Shangshi Liu[2], Anupam Gopalakrishnan[1], Eloise Bihar[1], Carson Bruns[1], Richard Bardgett[2], John Quinton[3] and Jason C. Neff[1]; [1]University of Colorado Boulder, United States; [2]The University of Manchester, United Kingdom; [3]Lancaster University, United Kingdom

Soil health is one of the key factors in determining the sustainability of global agricultural systems and the stability of natural ecosystems. Microbial decomposition activity plays an important role in soil health; and gaining spatiotemporal insights into this attribute is critical for understanding soil function as well as for managing soils to ensure agricultural supply, stem biodiversity loss, and mitigate climate change. Here, we present a novel approach to monitiroing microbial activity by demonstrating an in-situ electronic soil decomposition sensor that relies on the degradation of a screen-printed conductive composite trace utilizing the biopolymer poly(3-hydroxybutyrate-co-3-hydroxyvalerate) as a binder. This material responds selectively to microbe-active environments with a continuously varying resistive signal that can be readily instrumented with low-cost electronics to enable wide spatial distribution. In soil, a correlation between sensor response and intensity of microbial decomposition activity is observed and quantified by comparison with respiration rates over 14 days, showing that devices respond predictably to both static conditions and perturbations in general microbial decomposition activity.

Assessing Edible Semiconductors for Future Edible Electronics Mario Caironi, Alessandro Luzio, Alberto Davide Scaccabarozzi and Elena Feltri; Istituto Italiano di Tecnologia, Italy

Edible Electronics [1] is an emerging field targeting devices and sensors that can be safely ingested without need of supervision nor recollection, and are degraded within the body after performing their function. Final applications are both in the healthcare, in forms of smart pills which are not simply ingestible but are also digestible, and in the food sector, offering safe direct tagging of food. For future edible electronic systems, active circuits will be required, both for logic and control. To this end, one of the main challenges is the development of transistors based on edible semiconductors with sufficient performance to be adopted in such systems. Here we report on our recent progress on reassessing carotenoids semiconductors, mainly beta-carotene, for thin films in transistors. By careful processing and microstructuring of films, a maximum field-effect mobility exceeding 10^{-2} cm^2/Vs was achieved, with reasonable stability in dark-conditions. At the same time, we report on the integration of commonly ingested organic dyes in fully edible transistors architectures. Such results indicate that options for edible semiconductors are available and can be exploited towards first integrated edible logic circuits.

Predictive Design of A Conjugated Polymer's Mechanical Property from its Dynamics Xiaodan Gu; University of Southern Mississippi, United States

Organic semiconducting polymers are promising candidates for stretchable electronics for their mechanical compliance. Donor-Acceptor-type conjugated polymers have been the key driver for the recent boost in device performance. To date, the effect of the conjugated backbone building block on the thermomechanical property of conjugated polymers has not been well understood, despite much work on their influence on the electronic property. In this talk, I will discuss our work on the structure and dynamics study of thin-film thermomechanical property relationship for donor-acceptor polymers with systematically varied donor units on the conjugated polymer. From our previous study, we realized the importance of the Tg on the mechanical property, here, I will discuss our effort to develop a machine-learning model to predict the glass transition temperature and modulus of the polymer. In the end, I will provide some perspective about the accessible range of the modulus and stretchability we can reach.

2:00 PM EL18.11.03
Control of Surface Wrinkling through Compliant Nanostructured Interfaces Kuo-Kang Hung and Ioannis Chasiotis; University of Illinois at Urbana-Champaign, United States

A novel approach for independent control of the wrinkle wavelength and amplitude, with the additional capability for anisotropic wrinkling without the need for multiaxial loading, is presented for applications in flexible electronics. Surface wrinkling occurs due to the mechanical instability induced by the stiffness mismatch between a soft substrate and a stiff film. In a two-layer system comprised of a thick compliant substrate and a thin stiff film, the wrinkle pattern, as described by the wrinkle wavelength, amplitude and orientation, is limited by the material properties and thickness of the two layers. In this work, an interface layer of nanostructures fabricated by Glancing Angle Deposition (GLAD) is introduced to modify the surface wrinkling of polydimethylsiloxane (PDMS) due to a Cu film, thus enabling further control of wrinkling in an otherwise constrained material system. Isotropic (nanospring) and orthotropic (nanochevron) Cu interfaces were GLAD-deposited with different geometric parameters to control the in-plane stiffness of the interface. The isotropic nanospring films provided a novel means to control the scale of wrinkle patterns, namely both the wavelength and the amplitude of surface wrinkles, while maintaining the amplitude-to-wavelength aspect ratio. The anisotropic nanochevron films resulted in anisotropy ratio of ~10 which provided a unique means to modify the wrinkle direction independently of the direction of applied load. The predictions by an experimentally-calibrated analytical model for anisotropic wrinkling were in very good agreement with experiments.

Sustainable Future Wearable Devices Through Entirely Recyclable Organic Electronics Kyoseung Sim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

The organic electronic waste produced during the synthesis and disposal of organic electronics is becoming an unavoidable problem for the environment, as a result of the growing interest and efforts being put into developing organic electronics for future technologies such as wearable electronics. Although organic e-waste may pose a risk of genotoxicity and cytotoxicity to both the natural environment and humans, most efforts to reduce the amount of e-waste have concentrated on recycling metallic components. In this study, we present a recyclable organic flexible (ROF) electronic device that may be constructed without the need for spin-coating by employing selective dissolution and closed-loop recycling of the whole process of material recapturing and reusing. Both the ROF electrode and the electronic device maintained their reliable electrical characteristics after being subjected to mechanical bending and having been recycled five times. In addition, ROF transistors and logic gates were manufactured with organic semiconductors and dielectrics, and recycled devices exhibited no significant degradation in performance. In the end, we were successful in creating a sustainable device cycle by rebuilding a variety of ROF electronics solely utilizing components recycled from a variety of working devices. In this work, ROF electronics reveal a potentially fruitful technique for a sustainable system for the future development of wearable electrons.

3:30 PM EL18.12.01
High-Speed Fabrication of Intrinsically Stretchable Perovskite Optoelectronic Devices on Ubiquitous Substrates (Elastomer, Paper, Textiles, *etc.*) Using Printing and Handwriting Junyi Zhao[1], Zhibin Yu[2] and Chuan Wang[1]; [1]Washington University in St. Louis, United States; [2]Florida State

University, United States

Stretchable optoelectronic devices built on thin elastomer substrates may find a wide range of applications in wearable health monitoring devices, soft robots, deformable displays, and many more. Although considerable efforts and progress have been made to explore the potential of using halide perovskites in high-performance light-emitting diodes (LEDs), existing fabrication techniques based on the rigid substrate cannot meet the growing demand from large-area flexible or stretchable displays. In this work, we report the high-speed fabrication of intrinsically stretchable perovskite LEDs (PeLEDs) printed directly on elastomer thin films, in which every single layer in the device from bottom anode to top cathode is patterned solely using the highly scalable inkjet printing approach. In addition to the elastomer, paper and textiles commonly used in our daily lives also hold great potential as platforms for next-generation flexible and wearable electronics. We have developed a highly versatile, scalable, and eco-friendly handwriting approach that enables multicolor PeLEDs (covering the entire visible spectrum) and perovskite photodetectors (PePDs) (both vertical-photodiode configuration and planar-photoconductor configuration) to be directly drawn onto various unconventional substrates (paper, textiles, plastic, rubber, metal, and three-dimensional objects) in an ultrafast and mask-free manner. This is achieved by daily used ballpoint pens filled with our uniquely formulated inks of conductive polymers, metal nanowires, and perovskite/polymer composite for photoactive layers. One of the greatest challenges associated with implementing optoelectronic devices on paper and textiles is the rough surface morphology of the yarn and fiber networks, which could result in nonuniform printed film thickness and leakage current. To tackle this issue, the ionic polymer was blended into inks to establish localized self-planarization as well as strengthen the composite stretchability. Just like drawing with multicolor pens, by writing the above functional inks layer-by-layer, high-performance perovskite optoelectronic devices can be customized on almost any target substrate within minutes even by untrained individuals. Noted that the entire manufacturing was conducted in ambient conditions without any specific moisture and temperature control. Our simplified device architecture and fabrication strategy dramatically reduce the fabrication time compared to the hours or days required by conventional microfabrication processes. The handwritten PeLEDs exhibit a brightness as high as 15,225 cd/m^2, a current efficiency of 6.65 cd/A, and a turn-on voltage of 2.4 V. The PePDs exhibit an on/off ratio over 10^4, a responsivity of up to 132 mA/W, and a response time of less than 15 ms. Owing to the extraordinary flexibility of each functional layer, the handwritten LEDs on the paper substrate could be bent to a 1 mm extreme curvature radius for over 5000 cycles without decay in performance. This work opens the avenue for perovskite optoelectronics in extremely low-cost and large-area application scenarios such as E-textile, E-paper, smart packaging, and other disposable electronics and wearables.

3:45 PM EL18.12.02

Growth of Transition Metal Oxides and Sulfides on Liquid Metal Core-Shell Particles for Optically Responsive Soft Electronics Wilson Kong[1], Rebecca Chai[2] and Christopher E. Tabor[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Ga-based liquid metals (LM) are gaining significant noteriety as functional soft materials utilized as stretchable conductors, catalytic substrates, and a platform for materials development. Rapid formation of a surface oxide enables core-shell micro or nanoscale particle structures for LMs, further increasing their functional capabilities. However, the utility of these particles are often governed by the properties of the native gallium oxide shell which hinders their potential application space. In particular, the optical properties of eutectic Ga-In alloys (eGaIn) is limited to the UV absorption spectrum[1] compared to other noble metal nanoparticles which absorb light in the IR-Vis range. Transition metal oxides or sulfides are commonly employed as optically responsive materials for flexible electronics and sensing devices[2-4], with absorption frequencies that extend into IR-Vis. Recent research investigated the synthesis of such materials on a LM substrate due to its electron-rich surface[5], opening new opportunities for materials development. Having a synergistic combination of optically responsive coatings, with a soft conductive core can potentially lead to new hybrid materials for the next generation of optically tunable, stretchable electronics and sensors. In this work, we investigate a solution-based method to directly synthesize tungsten oxide/sulfide coatings on eGaIn surface during particle processing. The reactive surface of eGaIn drives the reduction and deposition of these materials from a single precursor, which can be tuned by multiple processing parameters. Specifically, we elucidate factors such as precursor concentration, reactive ion species, and solvent selection that can influence the favorability of tungsten sulfide or oxide growth on eGaIn particles. Additionally, we characterize the compositional and optical properties of these core-shell structures to gain better insight into their structure-property relationships. This method yields a simple and generalizable pathway for producing functional LM particles with tunable optical behavior that show potential usage in soft optoelectronic applications.

4:00 PM EL18.12.03

Strain Dependency of Charge Transport of Stretchable Conjugated Polymers Kilwon Cho, Seung Hyun Kim and Sein Chung; Pohang University of Science and Technology, Korea (the Republic of)

Semiconducting conjugated polymers (CPs) have attracted considerable interests due to their great potential for application in flexible and stretchable electronics. However, there still remains challenging work to control the strain-induced thin-film properties, such as crystallinity, morphology, and charge transport properties of CPs. We investigated how straining of CP films affect microstructures and electrical properties of organic semiconductor films. Results on photocrosslinking of CPs by a length-modulated azide crosslinker will be discussed. Azide crosslinking selectively controls the microstructure of the amorphous domain to improve stretchability and retain the charge transport properties of CP films. Next, the influence of the backbone rigidity of CPs on thin film's stretchability and charge transport properties will be discussed. Strain-induced alignment and conformational change of polymer chains provide favorable transport pathways for charge carriers in organic thin films.

4:15 PM EL18.12.04

Intrinsically Stretchable and Highly Conductive Self-Doped Polymer Thin Films Tokihiko Shimura[1,2], Minoru Ashizawa[3], Stephen O'Neill[4], Taizo Tominaga[1,2] and Naoji Matsuhisa[2,1]; [1]Keio University, Japan; [2]The University of Tokyo, Japan; [3]Tokyo Institute of Technology, Japan; [4]University of Cambridge, United Kingdom

Soft conducting polymers, which have been prepared mainly with Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS), show high conductivity, stretchability, biocompatibility, and transparency, which enables applications in electronic skins of robots and high-quality biological sensing. Although pristine PEDOT:PSS is brittle, additives can significantly enhance the stretchability.[1,2] However, insulating additives can ultimately limit the conductivity or stability under various environments, including high humidity. We hypothesized that self-doped PEDOT (S-PEDOT), which has shown

high conductivity in a recent study,[3] is an ideal system to achieve both high conductivity and stretchability with a single component.
Here, we demonstrate the high stretchability and conductivity of S-PEDOT thin films without any additives. The S-PEDOT thin film on thermoplastic polyurethane (TPU) showed a high stretchability of over 200%, which is significantly better than that of PEDOT:PSS. Our S-PEDOT showed a high conductivity of 100 S/cm alone, as well as an enhanced conductivity of 500 S/cm by the addition of sulfuric acid to the solution. The increased molecular weight through controlling the polymerization condition enabled high conductivity and stretchability. Further details regarding the processing conditions for high conductivity and stretchability will be discussed in the talk. Additionally, the S-PEDOT thin film can be patterned in a high resolution (~tens of micrometer) by nanosecond UV laser ablation. Therefore, the S-PEDOT thin film has sufficient performance to realize various stretchable electronic devices.

4:30 PM EL18.12.06
Beyond Stretchability: Increasing the Strength, Hardness, and Survivability of Semiconducting Polymers by Crosslinking Alexander Chen[1], Jeremy Hilgar[1], Anton Samoylov[2], Silpa Pazhankave[3], Jordan Bunch[1], Kartik Choudhary[1], Guillermo Esparza[1], Allison Lim[1], Xuyi Luo[4], Hu Chen[5], Rory Runser[1], Iain McCulloch[6], Jianguo Mei[4], Christian Hoover[3], Adam Printz[2], Nathan Romero[1] and Darren J. Lipomi[1]; [1]University of California, San Diego, United States; [2]The University of Arizona, United States; [3]Arizona State University, United States; [4]Purdue University, United States; [5]King Abdullah University of Science and Technology, Saudi Arabia; [6]University of Oxford, United Kingdom

Essentially all research done on the mechanical properties of polymeric semiconductors for organic photovoltaics has had the underlying goal of increasing the "stretchability": that is, the deformability and softness. However, softness is the wrong figure of merit for many applications envisioned for organic semiconductors, including distributed sources of solar energy subject to damage by indentation, scratching, and abrasion. A focus on modulus and fracture strain at the expense of strength, toughness, and elastic range – i.e., properties characteristic of hardness and resilience – leaves many potentially lucrative applications on the table. For example, in organic photovoltaics, applications in which materials can be integrated onto surfaces already modified by human artifacts (e.g., rooftops, roads, and painted surfaces) comprise an enormous potential source of renewable energy. Additionally, the predominant focus on tensile properties fail to account for other forms of mechanical injury these devices will face (e.g., compressive forces). For photovoltaic applications that require high mechanical robustness, the mechanical properties of semiconducting polymers must be optimized to improve their strength, toughness, resilience, and hardness while maintaining their stretchability. Crosslinking is a well-understood technique for tuning the mechanical properties of conventional polymers. In this talk, we discuss our progress in increasing the mechanical robustness of semiconducting polymer films by using a four-armed azide-based crosslinker ("4Bx"). We show that low loadings of 4Bx can be used to improve the strength, toughness, and hardness of semiconducting polymer films, while maintaining their stretchability (i.e., fracture strain). Additionally, low loadings of 4Bx can be used to increase the mechanical robustness of the bulk heterojunction in organic solar cells, resulting in devices with increased survivability and stability (i.e., abrasion resistance, thermal ageing, solvent resistance).

EMI Sheilding Film Design, Fabrication and Characterization Mingxuan Li, Mohammad Mehdi Zarei and Paul Leu; University of Pittsburgh, United States

With the increasing use and complexity of electronic devices and systems, new types of electromagnetic interference (EMI) shielding are needed. The purpose of EMI shielding is to reduce the coupling of electronic components to surrounding radiation, which could reduce the functionality or accuracy of electronic devices or shorten their lifetimes.
In many optoelectronic applications, electromagnetic interference shielding (EMI) is required to protect electronic devices from surrounding radiation while allowing high levels of visible light transmission. Literature has yet to report structures with high transmission (over 92.5%), high EMI shielding efficiency (over 30 dB). We optimize nanophotonic structures for high EMI shielding efficiency (SE) and high visible light transmission using Bayesian optimization. We demonstrate the ability to achieve structures with 41.2 dB SE and 90.8% visible transmission and 35.6 dB SE and 95.1% visible transmission. The results of our work also provide some insight into how to design better optical surfaces.
In addition, we are developing next generation EMI shielding materials. We demonstrate the incorporation of reactive silver inks into PET and textiles. Silver thin films on PET demonstrate 82.6 dB SE in the X band (8 – 12 GHz) and 85.3 dB SE in the Ku band (12-18 GHz). Furthermore, these films maintain performance after repeated bending. Furthermore, we have incorporated these silver inks into knitted textiles and demonstrated 74.8 dB SE in the X band (8-12 GHz) and 76.6 dB SE in the X band (8 – 12 GHz). As prepared silver films do not degrade after 1,000 stretching cycles at 50% strain and maintain EMI SE higher than 70 dB after 300 min washing. This work demonstrates reactive silver ink coated films on different materials for efficient EMI shielding protection that may be used for smart wearable devices, personal medical electronics, and next generation communications.
Microgrid is another structure we explored for transparent EMI shielding. It has the advantage of controllable, scalable and flexible.

5:00 PM EL18.13.02
Achieving High-Mobility Pentacene Thin-Film Transistors by Reducing the Trapping Density Between Insulators and Organic Semiconductors Yunseok Jang, Jeongdai Jo and Seung-Hyun Lee; Korea Institute of Machinery & Materials, Korea (the Republic of)

Organic thin-film transistors (OTFTs) continue to attract much attention as a key driving component of commercial wearable devices such as glasses, watches, wristbands and belts. Wearable devices are also being studied in the direction of electronic skin (e-skin) by fusing various sensors.[1-2] Because e-skin requires effective communication between biological and electrical signals, OTFTs are frequently used to detect target biomolecules and biological signals. For this, it is necessary to develop a high-performance OTFTs, and many studies are in progress.[3]

It is well known that interface control is very important in the fabrication of high-performance OTFTs. Many studies show the importance of treating the dielectric surface to impart improved molecular ordering such as good morphology and molecular alignment. [4] Although these findings are important, we consider that carrier trapping in the channel region formed between the insulator and the organic semiconductor will also be an important parameter. Holes are carriers in p-type organic semiconductors such as pentacene, and this study was conducted considering that holes may be easily captured by hydroxyl groups on the surface of the insulator. Hydroxyl groups may be present due to incomplete crosslinking, as residual hydroxyl groups from the solvent due to incomplete baking after solution-based film formation, or from absorbed water molecules due to exposure to ambient air. [5,6]
To clearly understand these effects, the surface roughness and surface energy of the insulator and the crystal structure were uniformly controlled. In addition, hundreds of nanometers of cured poly(4-vinyl phenol) (PVP) and tens of nanometers of additional layers were used to maintain the same insulating properties and to control the carrier density by adjusting the content of hydroxyl groups. As a result, the charge mobility was increased by 400% by controlling the carrier trapping density. This result shows that control of the carrier density is an important factor in the fabrication of high-performance OTFTs. [7]

This research was supported by the National Research Council of Science & Technology (No. CAP22081-300/2020M3H4A3106319/NK236B/NB1520/MO5970/2015K000217/10052802).

Piezoelectric Anisotropy-Induced PVDF Cube Switch with Multiple Responses Hyeongjin Jo, Yujun Song and Ji-Hyeon Song; Dankook University, Korea (the Republic of)

Smart materials, which suggest a way to overcome the limitations of conventional ones, have led researchers and scientists beyond the possibility now. Among those, piezoelectric materials have advantageous properties such as being light-weight and self-powered. This innovative material opened a new chapter of trend in electronics: flexible electronics. Remarkably, PVDF film has been spotlighted among the piezoelectric materials by the scientist due to its flexibility, and biocompatibility. Owing to its properties, it has great potential to be applied in a diversity of fields. Piezoelectric materials have another distinctive characteristic: anisotropy. Due to the anisotropy of the materials, they generate an independent electrical signal in accordance with their own piezo element axis.

In this study, we conceptualize a multi-responsive cube switch by utilizing anisotropy of PVDF film with a structural approach. Since the cube switch is in a 3D structure, the cube exhibits multiple responses simultaneously from its sides with a single stimulus. By diversifying cube planar figures, the amount of electrical potential value from the cube side can be adjusted. When the cube planar figure is in the 2D plane, each section generates an identical voltage as a response to vertical pressure. However, when this cube planar figure is folded and assembled into a 3D structured cube, each side of the cube starts to get individual coordinates in terms of the piezo axis. This dimensional change (from 2D to 3D) and anisotropy of PVDF film allow the cube switch to respond with multiple voltage waveforms with a single force.

As an extended method, we suggest cutting angle variation of planar figures as a method to diversify response from the device. Responses from the vertical sides of the cube are closely related to the cutting angle. The external force which aligns with the piezo definition eventually triggers piezoelectric materials to generate voltage. When the cutting angle starts to deviate from its original direction, the angle between the force direction and piezo definition also departs. Ultimately, the deviation of the force direction from the corresponding piezo axis makes the device generate a different electrical signal. By combining the two methods above (cube planar figure designs and cutting angle variation), we variegate possible cases of response from the device. The design stage and fabrication process of the cube switch is relatively simple and cost-effective than other piezoelectric material-based devices. Simply cutting and folding is enough to make this smart responsive device.

The PVDF cube switch has the potential to be applied to a system where diversity of response is needed, such as a security system. The security system with a lack of cases in passcode patterns is fatal to users. This cube-type switch can compensate for possible problems of the conventional security system. The multi-responsive security system will be highly user-dependent and inimitable by the third party. Also, users may easily designate and variegate the passcodes by adjusting pressing displacements, cube planar designs, and the number of switches in the system.

Active-Matrix Electrochemical Display Based on Stable Crosslinked-Silver Nanowires InCheol Kwak, Dong Gue Roe, Soo Young Cho, Yonghyun A. Kwon, Seonkwon Kim, Jung Woo Moon, Seonmi Eom and Jeong Ho Cho; Yonsei University, Korea (the Republic of)

In recent years, advances in technology for flexible optoelectronics have attracted considerable attention. According to the industrial demands, numerous types of research have been devoted to improving the performance of these devices. The transparent electrodes, which are an essential component in flexible optoelectronics, must satisfy the optimum compromise between optical transparency, electrical conductivity, and mechanical flexibility. Silver nanowires (AgNWs) based on percolating networks have been considered the most promising transparent electrodes; because they yield a low sheet resistance at high optical transmittance and high mechanical flexibility with their physical properties attributed to a high-aspect ratio. Moreover, AgNWs have also several advantages of low-cost processing and compatibility with large-area deposition owing to the simple solution process.
Although AgNWs networks possess these outstanding characteristics, it is still a great challenge to utilize AgNWs adequately in integrated electronic devices due to the inherent characteristics of high surface roughness, low work function, instability in the air, and poor adhesion to plastic substrates. Additionally, high-resolution patterning of AgNWs with desired line width and line spacing must be developed to extend the application of complicated optoelectronics. Herein, we report a simple processing method for fabricating high-resolution AgNWs patterns using a solution-processable crosslinking agent. A crosslinker referred to as 2Bx_4EO, which can be dissolved in alcohol solvents is applicable to various materials containing alkyl chains. In this study, patterned AgNWs were obtained by crosslinking polyvinylpyrrolidone from nanowires synthesized by the polyol process. Moreover, the strategy of selective wetting of conductive polymer only onto AgNWs patterns was employed for complementing the inherent characteristics of AgNWs. Furthermore, we demonstrate the application of AgNWs/polymer hybrid conductive films to fabricate organic electrochemical transistors and electrochromic cells.

Structural Control of Organic Solar Cells by Photo-Crosslinking Reactions Ryo Suzuki[1,2], Makoto Miyasaka[1], Kyohei Nakano[2], Yuto Ochiai[2], Yumiko Kaji[2] and Keisuke Tajima[2]; [1]Tokyo Denki University, Japan; [2]Riken, Japan

Current organic thin-film solar cells have problems in the precise controls of the nanostructures in thin films which are stable and suitable for the efficient charge generation. In this study, we aim at constructing the ideal mixed donor/acceptor structures with high stability by immobilization of organic semiconductors through photo-crosslinking. Several azide- and diazirine-based crosslinkers with one to four reaction points were synthesized and used as photo-crosslinkers. It has been reported that these photo-crosslinkers do not change the electrical properties of the semiconductor polymers by crosslinking because the photo-generated singlet active species (i.e., nitrene or carbene) insert mainly into the alkyl side chains but do not react with the aromatic rings. We first investigated the immobilization of mixed bulk heterojunction (BHJ) structures by photo-crosslinking. PM6:Y6 was selected as the donor/acceptor materials, and the mixed thin film with 1 wt% crosslinker was irradiated with corresponding UV light for a designated time. The physical properties and the structure of the resulting thin films and their solar cell properties were evaluated. After the light irradiation, the BHJ thin films were washed with chloroform and the absorption spectra of the films were measured. As the result, about 30-90 % of visible light absorption remained relative to the film without irradiation, depending on the irradiation time. These results suggest that the photo-crosslinking reaction insolubilizes PM6 and immobilizes its structure in the BHJ thin films. We evaluated the properties of the organic solar cells with the crosslinked films. It was found that the addition of crosslinkers alone did not change the solar cell performance with the power conversion efficiency of about 14% under the simulated solar light, but photo-crosslinking of the BHJ films resulted in degradation of the photovoltaic properties. We also apply the crosslinkers to the sequentially deposited films of Y6 and PM6 to see the effects of the crosslinking of each layer on the performance. Interestingly, in contrast to the mixed films, the organic solar cells prepared by the sequential depositions in which only the PM6 layer was photo-crosslinked showed no degradation in the photovoltaic performance (PCE 13.8%) that is comparable to those of the BHJ devices. These results give important insight into the morphological control in organic solar cells by using the singlet photo-crosslinkers.

Cu-Metal Assisted Chemical Etching that can Fabricate Auxetic Microstructures of Thin Flexible Si Wafer Eunsol Lee, Changsoon Kim and In-Suk Choi; Seoul National University, Korea (the Republic of)

Metal assisted chemical etching (MACE) has attracted considerable attention as an anisotropic Si etching process due to its simplicity and versatility. In this presentation, we introduce copper-based MACE that can substitute for conventional noble metal (Au, Ag, Pt, etc.)-based MACE processes. By systematically controlling the etching parameters, we develop the Cu-MACE process for the first time to tailor the size and depth of anisotropic Si microstructures. Consequently, this led to a cost-effective and simple etching process to fabricate auxetic structured Si membranes that can be used as flexible and deformable substrates for wearable devices.

5:00 PM EL18.13.08

Dry Adhesives Capable of Selective Adhesion Control based on Shape Memory Polymer Han Jun Park, Minsu Kim, Dokyung Kyeong, Ga-in Lee and Moon Kyu Kwak; Kyungpook National University, Korea (the Republic of)

As substrates used in display and semiconductor manufacturing processes become thinner and larger, the demand for ‘transfer printing’ systems for transferring objects with various surface profiles is increasing significantly. High efficiency of this system, carried out with pick-and-place method, requires strong adhesion for ‘pick-up’ and weak adhesion for ‘place’. The so-called 'adhesion switching' is an essential mechanism in the transfer printing systems. Traditionally, this adhesive conversion process used a friction, a vacuum chuck system or interlocking system, and a chemical-based wet adhesive system. However, while these proposed methods can be 'picked up' efficiently and reliably, their use is limited because they require complex equipment and mechanical elements, and the adhesion is not weak enough to 'place'. Various studies have shown that, away from friction, vacuum systems or adhesion by chemicals, 'dry adhesives' provide new pickup possibilities based on Van der Waals interaction. Dry adhesives are rapidly being commercialized in the transfer printing field, attracting attention for their low cost and mechanical durability. In particular, gecko-inspired dry adhesives succeeded in exerting a strong adhesion of more than 20 N/cm^2, developing a massive production system for the manufacture of biomimetic dry adhesives. However, despite their excellent performance, there are some limitations due to the problem of implementing an adhesive removal mechanism for stable detachment when switching adhesion of artificial dry adhesives. Although various attempts have been made to solve these problems, the proposed methods are mainly applied to limited surface roughness such as smooth surfaces. In addition, there is an inefficient cost problem because additional equipment such as a vibration jig or gripper is required.

Shape memory polymers are smart materials with the ability to remember ‘permanent shape’ through ‘shape memory effect’ and to be fixed as ‘temporary shape’ in certain stimuli. Many methods have been suggested to implement a transfer printing system as a mechanism to achieve pick-up by adapting the surface shape to the substrate using SMP's ‘shape memory effect’ and return to its initial shape to remove adhesion. However, it still remains a time-consuming manufacturing process, such as the need to combine multiple materials and a long thermosetting time.

In this work, we report the design of SMP Dry adhesive for a highly reversible thermally active adhesive switch systems using NOA63, a material with a programmable glass transition temperature based on curing conditions. Overcoming the limitations of fabrication time of adhesives introduced previously, we developed an adhesion switch system that can be manufactured very quickly and simply through UV irradiation. The ‘adhesion on mode’ of the fabricated SMP Dry adhesive showed a pull-off strength of about 24 N/cm^2 and could be adapted to various surface topologies. It was also confirmed that the substrate was safely detached by effectively removing the pull-off strength to 1.5 N/cm^2 or less in the 'adhesion-off mode' by the micro-lens pattern formed on the surface. These characteristics of SMP Dry adhesive show strong potential to pick-and-place not only fragile substrates such as wafers and glass, but also various substrates such as micro/nano-scaled semiconductor devices, metals, and plastics. Therefore, it is expected to be applied to an efficient transfer system in a wide range of fields such as display, semiconductor, and robot industries.

5:00 PM EL18.13.09

Sensitive SARS-CoV-2 spike Protein Nano-sensor (CovPNs) based on Gold-nanoparticles Decorated Micropatterned Poly(3,4-Ethylenedioxythiophene) Nanorods and Immobilized with Natural Receptor Angiotensin-Converting Enzyme-2 Syed Atif Ali[1,2,3] and Hsiao-hua Yu[1]; [1]Institute of Chemistry, Academia Sinica, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan; [3]Taiwan International Graduate Program-Sustainable Chemical Science and Technology, Taiwan

The Carboxyl-functionalized poly(3,4-ethylenedioxythiophene) (EDOTAc) Nanorods were designed into sensitive SARS-CoV-2 Nano-sensor surface (CovPNs) decorated with electrodeposited gold nanoparticles (AuNPs) was found to be highly sensitive. The developed CoVPNs based on electrochemical signals which is good alternative to replace the tests which require lot of time. The structures made into hybrid nanomaterial has shown excellent electrochemical properties. The sensor surface was characterized by electrochemical techniques, SEM, Fluorescence microscopy and XPS. Moreover, morphology of the nanomaterial was characterized by scanning electron microscopy. The results show a linear response for the diluted spike protein of SARS-CoV-2. DPV technique was used for sensing the spike protein on CoVPNs sensor surface which shows that in future the developed surface has potential to be integrated in flexible or wearable immunosensors and transistors for the detection of SARS-CoV-2 spike protein in a short time.

5:00 PM EL18.13.10
Ion Doping Induced Threshold Voltage Control in Electrolyte Gated Transistors Kyung Gook Cho[1], Minsu Kim[1], Kihyon Hong[2] and Keun Hyung Lee[1]; [1]Inha University, Korea (the Republic of); [2]Chungnam National University, Korea (the Republic of)

Ion doping and dedoping phenomena in organic/polymer semiconductors are important for improving the device performance of electrolyte-gated transistors (EGTs) in various iontronic applications including neuromorphic devices, nonvolatile memories, and chemical/bio sensors. In this study, the effects of component ions and their mixtures on the electrical characteristics of the EGTs were systematically investigated utilizing ionic liquid-based solid electrolytes (known as ionogels) as a high capacitance gate dielectric. Electrochemical impedance measurement, secondary ion mass spectrometry (SIMS), and optical absorbance spectroscopy confirmed that anions in the ionogels determined the carrier accumulation in organic *p*-type semiconductors. Accordingly, transistor characteristics such as threshold voltage, subthreshold swing, and charge carrier mobility were dominated by the type of anions because the positive holes are the majority charge carriers. More importantly, a new concept for fine tuning threshold voltage, which is crucial for the determination of power consumption and operational characteristics of logic circuits, was suggested by controlling the molar fractions of binary anions. This new and simple strategy successfully controlled the inversion characteristics of ion-gated inverters. Thus, this study proposes a useful route for tuning the electrical characteristics of EGT-based logic circuits as well as provides an important guideline for material selection in high-performance iontronic thin-film devices.

5:00 PM EL18.13.11
3D Printable Double-Network Solid Polymer Electrolytes for Accurate Motion Monitoring Chae Yoon Lee, Jeong Mu Heo and Keun Hyung Lee; Inha University, Korea (the Republic of)

Solid polymer electrolytes based on ionic liquids, also known as ion gels, have gained significant research interest due to their great features including mechanical robustness, high stretchability, non-volatility, thermal/electrochemical stability, and high ionic conductivity. To increase the durability and reliability of stretchable strain sensors, sensing elements can sustain a wide range of mechanical variation with sufficient mechanical strength. To achieve this, we employed two different polymer networks, or double networks (DN), by using chemically and physically crosslinkable polymer hosts in ionic liquids. The chemically crosslinked network in the DN ionogel provided sufficient adhesiveness between a substrate and the ionogel by incorporating chemical bonds. The physically crosslinked network in the gel offered adequate viscosity for 3D printing. In terms of sensing capability, improving the sensitivity of stretchable sensors is essential for accurate conversion of mechanical deformation. To improve the sensitivity, we designed and fabricated delicate and unique structures by using 3D printing. We designed and patterned gaps in the sensing element that can apart as the sensor stretched, and close as it contracted, which leaded to a large variation in the relative resistance and thus high sensitivity upon deformation. The resulting stretchable strain sensors can precisely detect various motions and convert them into electrical signals.

5:00 PM EL18.13.12
Thermally Stable n-Type Electrolyte Gated Transistors Using High Capacitance Ionogel Dielectrics Su Jung Kim, Dong Hyun Park and Keun Hyung Lee; Inha University, Korea (the Republic of)

Organic electrolyte gated transistors (OEGTs) have gained increasing interest as the principle building unit for printed logic circuits, bioelectronics, and artificial neural networks owing to their outstanding features including low-voltage operation and high transconductance. While OEGTs based on p-type polymer/organic semiconductors are well developed, n-type counterparts still suffer from low performance, thus, precluding the development of all-printed large-area OEGT-based complementary circuits. Most of the recently reports on n-type OEGTs focus on the design and synthesis of high-performance semiconductors and less attention has been made in the electrolyte dielectrics. In these studies, a liquid-state NaCl solution was employed as the dielectric. However, in the case of NaCl solution electrolyte, evaporation of the volatile water prevents long-term stability of the devices even at ambient conditions. In this present study, we fabricated n-type OEGTs using nonvolatile high-capacitance ionogel dielectrics consisting of ionic liquid solidified with 3D polymer networks. Resulting devices operated at low voltages (< 2 V) and exhibited high on/off current ratios (~10^5), which are similar to those of p-type OEGTs. Carrier accumulation and ion doping phenomena in the semiconductor channel were systematically investigated by using impedance spectroscopy, optical absorbance spectroscopy, current relaxation, and cyclic voltammetry. In addition, owing to the non-volatile property of the ionogels, OEGTs maintained their electrical performance even after high temperature annealing as well as long-term operation in ambient conditions. Furthermore, we demonstrated flexible all organic complementary logic circuits by connecting n- and p-type OEGTs.

5:00 PM EL18.13.15
Entangled Hydrogel Staking Layers: Universal Adhesive Material for Soft Electronics Yejin Jo, Yurim Lee and Jungmok Seo; Yonsei University, Korea (the Republic of)

The rapid growth of bioelectronics has stimulated research into soft electronics that integrate electronic devices to human bodies. Soft electronics are commonly composed of rigid electronics interconnected with soft electrode materials having flexibility, elasticity, and Young's modulus similar to that of native tissues to ensure conformal contact with the tissues. Although many materials for interconnecting soft materials to rigid electronics have been reported, there are only a few universal biocompatible bonding techniques have been studied.

Here, we developed a universal adhesive for soft electronics by utilizing layer-by-layer (LbL) stacking of poly(vinyl alcohol) (PVA) and tannic acid (TA) hydrogels. The sub-micron PVA-TA (PT) adhesive allows materials-independent bonding by hydrogel network entanglement in a few minutes mediated by sequential swelling and heat treatment at 130°C using a hair iron. For example, the interfacial toughness of two glued stainless steel and two glued polyimide sheets by PT adhesive was 3.6±0.8 MPa and 0.62±0.09 MPa, respectively. Utilizing hydrogels as a soft electrode materials, the heat treatment process for the integration should be avoided to prevent the deformation and degradation of the hydrogel. The developed PT adhesive allows hydrogels to be bonded without further heat treatments via polymer chain diffusion and entanglement, which occurs when the dried PT glue chain absorbs interfacial water of the adherend hydrogel. We demonstrated applications of PT adhesive for soft electronics through a flexible ionic hydrogel touch panel and a hydrogel strain sensor. A poly(acryl amide) (PAAm)-based ion gel was connected to the controller board with PT adhesive-coated FFC cables to fabricate a flexible touch panel. The connection point between the ion gel and the FFC cable maintained a stable attachment in the vigorous stretching test. The ring-shaped strain sensor is fabricated with poly(acrylic acid) (PAA)-based conductive gel attached to an eco-flex ring by PT adhesive to detect the bending motion of a finger. The conformally contacted strain sensor successfully detects finger-bending motion with 26.1% sensitivity.

5:00 PM EL18.13.16
Strategy to Implement PEDOT:PSS Spin-Coating on the Oxide-Metal-Oxide Electrode for Ink-Jet and Stretchable OLEDs Donghyun Kim, Changmin Lee, Geonwoo Jeong, Dong Hyun Choi, Tae Wook Kim, Sye Hamad Ullah Shah, Hyun Woo Jo, Yeong Beom Kim, Amjad Islam, Keum-Jin Ko and Seung Yoon Ryu; Korea University, Korea (the Republic of)

Organic light-emitting diodes (OLEDs) has emerged as the next-generation display technology due to its many interesting traits, such as high brightness, low power consumption and excellent mechanical flexibility. Although indium tin oxide (ITO) is the most commonly used materials for transparent conducting electrode (TCE) of OLEDs. However, the brittle nature of ITO electrodes and their poor tolerance to external mechanical stress have substantially limited their application in flexible OLEDs. To address this issue, we developed a mechanically robust oxide/metal/oxide (OMO) structured TCE for high performance OLEDs.
In OMO structure, Molybdenum trioxide (MoO_3) with MoO_3/Au/MoO_3(MAM) electrode has proven very useful for this structure. In addition, the solution process of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) can achieve solution process, easily tunable of structure and electrical properties. However, owing to its susceptible nature to water, MoO_3 can damage the entire structure of the MAM electrode. Even though MoO_3/PEDOT:PSS layer could act as hole injection layer, the surface of film could be rough, which results in the instability of OLEDs. Herein, we investigated to maintain the surface morphology of upper MoO_3 electrode for developing the core technology of soluble OLEDs with PEDOT:PSS coated on MAM electrode after UV/ozone(UVO) treatment. Mo receives energy and oxidizes to Mo^{+5} and Mo^{+6}. Through the UVO treatment, the concentration of Mo^{+5}, which acts as an reactor with PEDOT:PSS, decreases and the reaction of MoO_3 with PEDOT:PSS is weakened. Thus, the stable surface morphology could be achieved without affecting the electric and optical properties. The champion OLED device with UVO treatment MAM/PEDOT:PSS TCE achieved the turn-on voltage of 2.66 V and a maximum current efficiency of 105 cd A^{-1} by decreasing energy gap between MoO_3 and TAPC for smooth current injection. This findings shows that OLEDs based on MAM/PEDOT:PSS TCE has the great potential for future display and lighting applications, as well as novel application in soft mechanical electronics.

5:00 PM EL18.13.17
Exploring Reduced Thickness of Au in Oxide-Metal-Oxide (OMO) Electrode for Stretchable Organic Light-emitting Didoes Yeong Beom Kim, Seung Yoon Ryu, Keum-Jin Ko, Amjad Islam, Donghyun Kim, Changmin Lee, Geonwoo Jeong, Dong Hyun Choi, Tae Wook Kim, Hyun Woo Jo and Sye Hamad Ullah Shah; Korea University, Korea (the Republic of)

The challenges for organic light-emitting diodes (OLEDs) with a perfect form factor have led to research into advanced manufacturing processes. Incorporation of OLEDs into wearable, epidermal, and stretchable electronics, with color stability, and high brightness under intensely strained bending/stretching has been of major interest. This interest has led to various studies on electrodes as a replacement of indium tin oxide (ITO). Transparent electrode based on an oxide-metal-oxide (OMO), where a thin metal layer is sandwiched between two dielectric or oxide layers, is similarly a promising candidate. In terms of flexibility and stretchability, a thin and ductile metal layer has the role of resisting fracture since it acts as the crack stopper or retardation on an elastomeric substrate. Therefore, a thin OMO electrode could be proposed for stretchable electronics because of its better hole injection and optical transmittance. However, since the Au electrode greatly affects the transmittance of the device, the thickness should be sufficiently considered. In many studies, it has been reported that noble metals form drivable films from 5 nm or more. When Au or Ag is deposited with a thin thickness (1 ~ 5 nm), island growth occurs and it is difficult to play a role as an electrode. Herein, we demonstrate that the OLEDs can be driven sufficiently even with a 3 nm electrode and can achieve electrode characteristics for flexibility and stetchability. Without lower oxide layer, noble metals grow as islands, however, with oxide buffer layer, grain growth is suppressed with increased surface energy. The ultra-thin Au based tri-layer electrode showed properties that could replace ITO and was helpful for out-coupling of OLEDs. Additionally, we confirmed ultra-thin Au is efficiently worked at various oxide layers (MoO_3, WO_3 and V_2O_5).

5:00 PM EL18.13.18
Scalable and Multifunctional Sensors by Inkjet Printed Graphene Network Feiran Wang, Nathan Cottam, Jonathan S. Austin, Jisun Im, Jonathan H. Gosling, Mark Fromhold, Richard Hague, Christopher Tuck, Oleg Makarovsky and Lyudmila Turyanska; University of Nottingham, United Kingdom

As a novel layered 2D material, graphene has induced a boom in the field of sensor research around the world due to its advantages in mechanical, thermal, and electrical properties.[1] However, the need for high quality mass production, large area fabrication and the homogeneous deposition on various substrates poses a great challenge. We employ inkjet printing as an advanced and convenient fabrication method for achieving comparative effectiveness and multimaterial vertical stacking.[2] A scalable fully inkjet printed graphene multifunctional sensor matrix which integrated humidity, thermal, and pressure sensors was fabricated using two layers of graphene arrays separated by a dielectric layer. The integration of all three sensors into a matrix required that each sensor provide output responses to a specific stimulus without being interfered by other stimuli. The bottom graphene layer can sense the temperature change and the top graphene layer were as the humidity sensing arrays. The dielectric layer sandwiched between two graphene arrays acted as an active layer for the capacitive pressure sensors. The responses have been modelled by inter flake tunnelling of the printed graphene network.[3] Further functionality can be integrated by bringing in additional layers, such as detecting hazardous chemicals and gases. [4] Such multifunctional sensors can be fabricated on flexible substrates such as fabrics and have wide applications in environment monitoring and healthcare devices.

5:00 PM EL18.13.20
Integration of Electric Circuits into Microprinted Cell Culture Scaffolds for Three-Dimensional Microelectrode Arrays Malte Siegmund[1], Jann Harberts[1], Robert Zierold[1] and Robert H. Blick[1,2]; [1]Universität Hamburg, Germany; [2]University of Wisconsin-Madison, United States Minor Outlying Islands

Microelectrode arrays (MEAs) for non-invasive electrical readout of neurons are a valuable tool for long-term studies of neuronal network signaling on a single-cell level. However, conventional MEAs are traditionally built only in 2D and thus do not represent the three-dimensional network topology of the human brain. Here, we present an approach to equip planar MEAs with 3D microscaffolds featuring circuitry for enabling three-dimensional brain-on-a-chip (BoC) devices with electrical readout on a cellular level. Recently, we presented such microscaffolds prepared by direct laser writing (DLW) for enabling human induced pluripotent stem cell (hiPSC)-derived guided neuronal networks in 3D. Tower-like structures with cavities on the top determined specific locations for neuron settling while interconnecting tunnels confined axonal outgrowth for neuronal network formation. Therefore, changes in the arrangement would reflect onto the formation of the respective networks. However, the electrophysiological readout was limited to individual—and invasive—patch clamp measurements on selected cells from the network.[1],[2] For collective and non-invasive long-term experiments, i.e., *in situ* studying during the cell culture period, this approach for its part needed an addressable extracellular electrical readout system to be implemented into the tailor-made scaffold structure. Herein, we utilized electrodeposition (ED) of gold to form integrated electrodes inside the in this case hollow towers.

Specifically, by printing directly onto electrodes of tailor-made or commercially available MEAs, each tower was individually addressed for ED, and gold was deposited until the vertically growing electrodes filled the entire tower and the gold reached the scaffold cavities. Note, the porosity of the gold can be tuned by changing the deposition rate which allows for optimizing the surface topography to enhance cell coupling to the electrode.[3] The versatile nature of the MEA production as well as the DWL and the ED enables the production of addressable electrodes within the third dimension of almost any shape. Thus, these results take a significant step toward application in analyzing the information transmission within neuronal networks and understanding of underlaying mechanism orchestrating information procession in 3D.[4]

Wide Range Pressure Detection Using Highly Sensitive, Flexible Organic Thin-Film Transistor Sensors Dong Hyun Park, Su Jung Kim and Keun Hyung Lee; Inha university, Korea (the Republic of)

Solidified ionic liquid known as ion gels have been investigated in various applications because of their exceptional material characteristics such as high specific capacitance, outstanding chemical, thermal, and electrochemical stability, non-flammability, negligible vapor pressure, and rubber-like mechanical robustness. Flexible pressure sensors that convert various external mechanical signals can be employed in a wide range of applications including human health monitoring, soft robotics, and artificial intelligence. A variety of sensing mechanisms including piezoelectric, capacitive, and piezoresistive can be used in flexible pressure sensors. Flexible sensors require high sensitivity, a wide sensing range, and a short response time. Capacitive sensors based on ion gels have advantages for being used as flexible pressure sensors because of their stability, fast response, and simple device architectures. However, low sensitivity of the pressure sensors often limits their applicability and practicality. To overcome this issue, we employed organic thin-film transistors and high capacitance ion gels for highly sensitive flexible pressure sensors. By utilizing organic thin-film transistors, weak mechanical stimuli can be amplified into large electrical signals, leading to very high sensitivity. Furthermore, the resulting transistor sensors operated at low voltages below few volts owing to the high capacitance of the ion gel gate dielectrics. In addition, performance of the transistor sensors was enhanced by optimizing the morphology and composition of active layers. As a result, transistor-based pressure sensors can reliably and sensitively convert external mechanical stimuli to electrical signals.

5:00 PM EL18.13.26
Flexible Microfluidic Platform for Heavy Ion Detection Stavros Chatzandroulis[1], Myrto-Kyriaki Filippidou[1], Aris Kanaris[1], Sotiris Ntouskas[1], Evangelos Aslanidis[2], Angeliki Tserepi[1], Georgios Tsekenis[3] and Dimitrios Tsoukalas[2]; [1]NCSR, Greece; [2]National Technical University of Athens, Greece; [3]Biomedical Research Foundation of the Academy of Athens, Greece

Heavy metal ions, such as lead (Pb), cadmium (Cd) and mercury (Hg), are important global environmental threats as they accumulate throughout the food chain causing chronic diseases. We can find them in soil, air or water. Conventional detection methods (i.e. high performance liquid chromatography, HPLC) consist of bulky and expensive equipment, while the required sample handling processes are usually time consuming, limiting their use to specially designed laboratories. Thus, there is an urgent need for the development of portable devices for heavy ion detection in order to replace or complement the conventional detection methods. The solution can be provided by developing new detection systems based on the combination of microfluidic technolog and electrochemical sensing, such systems are lightweight, compact and portable, low cost and can be used in both laboratory and on-site measurements. To date, efforts towards this direction have been proposed, yet there is still room for new approaches which can facilitate the uptake of these novel approaches.
In this work, we propose a fast and easy way to implement a microfluidic device made of a mixing unit and detection unit incorporating an array of six Pt nanoparticle (PtNP) heavy metal ion sensors, on a low-cost polyimide (Kapton) flexible substrate using standard lithographic techniques. The mixing unit is necessary for the passive mixing of the sample (i.e. water) with a buffer solution prior to the detection of the heavy metal ions. The mixing unit takes the form of a square wave channel with two inputs: one for the sample and the second for the buffer solution. The design of the mixing unit accommodates an effective mixing index over a wide range of flow rates on a small footprint, while the detection unit encompassing six interdigitated electrode pairs (IDEs) is placed after the mixing unit. The device fabrication process consists of the following steps: First an array of six IDEs is deposited on a kapton substrate, consisting of an adhesive 10 nm thick Ti layer and 40 nm thick Au layer. The IDEs are patterned using photolithography having inter-finger spacing of 10μm. Then, a layer of a dry resist film is deposited on the kapton substrate using a laminator, followed by a lithography step to pattern the microchannels on the dry resist and unveil the IDE array. Afterwards, platinum nanoparticles (PtNPs), having a mean diameter of 4 nm, are deposited between the IDEs using a modified DC magnetron sputtering system that allows the control of the surface density covered by the PtNPs. The surface coverage of the PtNPs is close to 49%, which results in an interparticle distance of few nm. The resistance of the devices is of order the of a few hundreds of kOhms. To functionalize the sensors, the device is first treated in oxygen plasma to activate the channel followed by immersion in APTES solution. Applying this chemical functionalization procedure DNAzymes may be immobilized in between the PtNPs. The presence then of metal ions over the sensor area leads to the cleavage of the double-stranded DNAzymes which is then registered as a resistance increase enabling the detection of heavy metal ions. The device is finally ready to be used after sealing with a polyolefin film coated on one side with a silicone adhesive.
For the evaluation of the mixing channel a syringe pump was used, while the device was placed inside a pmma chip holder which enables the solutions to flow in and out of the flexible chip using silicone tubes. Yellow and blue food coloring solutions were used as starting solutions. These two solutions were inserted from the two inputs and were mixed before reaching the detection unit. The final solution at the channel output was green verifying the successful mixing of the two solutions. The same chip holder was then used to test the PtNPs sensors. As a proof of concept, the detection of 20 μM of Pb^{2+} ions using the prototype microfluidic device was achieved.

Highly Integrated Stretchable Electronics by Photo-patternable Elastic Polymer Electrolyte Jiyeon Ha[1], Wanho Cho[2], Hyukmin Kweon[1], Ukjin Jeong[1], Seokran Choi[1], Borina Ha[1], BongSoo Kim[2] and Do Hwan Kim[1]; [1]Hanyang university, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Recently, interest in ion-based materials has emerged, leading to the development of stretchable electronics such as healthcare monitoring, soft robotics, biosensors, wearable devices, and skin-like electronics. Stretchable polymer electrolyte is the best applied to organic electrochemical transistors (OECTs) for flexible neuromorphic circuits and various skin electronics due to ion-driven signal processing with low power consumption and its biocompatibility. To outstanding electronic devices functionality, the OECTs are required to have high integration capabilities through high-resolution patterning.

Nevertheless, this is challenging because of their intrinsic rubbery nature of the elastic polymer electrolyte, which is not accomplished simultaneously by microfabrication techniques.
In this work, we demonstrate an unprecedented photo-patternable elastic polymer network electrolyte (elastic-PNE), which thermoplastic polyurethane with ionic liquids (i-TPU) and azide ($-N_3$) photo-crosslinker with ethylene oxide (EO) could form the network structure by crosslinking through direct UV(254nm) exposure. The azide moieties in the crosslinker can be activated by UV exposure, which react with the alkyl chain of TPU to occur the C-H insertion reaction. With the increase of EO chains, the elastic-PNE retains their electrochemical properties even after the rinsing process as well as mechanical characteristics. These result from the EO structure of the crosslinker, which can supply superior ionic interaction and flexible chain segmental motion to electrochemical and mechanical properties. In addition, the elastic-PNE can achieve a high-resolution photo pattern with microscales size ($<$ 10µm) by direct microlithography process. Consequently, we believe that our approach will present new guidance for next-generation neuromorphic and skin electronics.

5:00 PM EL18.13.28
3D Printing of Conversion Cathodes for Enhanced Custom-Form Lithium Batteries Jorge A. Cardenas, John P. Bullivant, Bryan Wygant, Igor Kolesnichenko, Aliya Lapp, Devin J. Roach, Timothy Lambert, Eric Allcorn, A. A. Talin, Adam Cook and Katharine Harrison; Sandia National Laboratories, United States

Additive manufacturing techniques can enable the fabrication of batteries in nonconventional form factors, enabling higher practical energy densities due to improved power source packing efficiency. Furthermore, energy density can be improved by transitioning from conventional Li-ion materials to lithium metal anodes and conversion cathodes. Iron disulfide (FeS_2) and iron trifluoride (FeF_3) are two promising conversion cathodes of commercial and academic interest, but the 3D direct-ink-write (DIW) printing of inks made from these materials for custom-form battery applications has yet to be demonstrated. In this work, the deposition of FeS_2 and FeF_3 inks are investigated and optimized using DIW 3D printing to produce custom-form batteries. Two distinct custom form-factors, one on wave-shaped current collectors and the other on cylindrical current collectors, are demonstrated and shown to exhibit performance similar to coin cells when conventional Celgard separators are used. Additionally, FeF_3 cells are integrated with a DIW printed separator consisting of an electrolyte exchanged PVDF-HFP based ionogel [1], which resulted in 5-7 stable charge/discharge cycles before degradation occurred. Meanwhile, in FeS_2 inks, it was found that cathodes with a ridged surface, produced from the filamentary extrusion of highly concentrated inks (60-70% solids w/w%) exhibited optimal power, uniformity, and stability when cycled at higher rates (in excess of C/10) [2]. Overall, DIW printing of conversion cathodes is demonstrated to be a viable path toward the making of custom-form conversion lithium batteries. More broadly, surface ridging is found to optimize rate capability, a finding that may have broad impact beyond FeS_2, FeF_3 and DIW extrusion.

5:00 PM EL18.13.29
Hybrid Elastomers with Variable Electromechanical Properties Guolin Yun[1], Tim Cole[2], Yuxin Zhang[2], Jiahao Zheng[2], Shuaishuai Sun[3], Yiming Ou-yang[3], Jian Shu[3], Hongda Lu[4], Qingtian Zhang[4], Yongjing Wang[2], Duc Truong Pham[2], Tawfique Hasan[1], Weihua Li[4], Shiwu Zhang[3] and Shi-Yang Tang[2]; [1]University of Cambridge, United Kingdom; [2]University of Birmingham, United Kingdom; [3]University of Science and Technology of China, China; [4]University of Wollongong, Australia

As two fundamental properties of any material system, mechanical stiffness and electrical conductivity typically remain unchanged. However, an increasing number of emerging applications in structural engineering, robotics, and intelligent electronics demand materials with programmable conductivity and stiffness. Such materials that can respond to environmental changes have attracted widespread attention. However, previous attempts show significant limitations as they usually require external control systems to change the electromechanical properties of materials. In addition, these materials fail to harness variable electrical and mechanical properties synergistically to achieve independence from external control. To address this drawback, we present an electro-mechano-responsive hybrid elastomer comprising hybrid fillers of Field's metal and spiked nickel microparticles. As a low melting point alloy, Field's metal can adjust the resistance and stiffness of the elastomer through phase transitions. The spiked nickel particles as secondary fillers further endow the composite with unconventional negative piezoresistivity and high strain sensitivity. Combining the elastomer's high strain sensitivity and variable resistance/stiffness, we demonstrate a self-triggered multi-axis compliant compensator for robotic manipulators. Our system can adjust its stiffness under deformation without external control, offering an order of magnitude better performance than the best commercial products. We also show a highly compact self-recovering resettable current-limiting fuse with a ten times faster response than the state-of-the-art. With such an extraordinary tunable electromechanical property, our new material is expected to revolutionize resilient robotic systems and intelligent electronics.

5:00 PM EL18.13.30
Conductive Electrospun PCL Fibers for use in Electrospun Photovoltaics Luke J. Suttey[1,1], Dennis J. Moritz[2], Ellie L. Ostermiller[1,1], John J. Borkowski[2], Jessica M. Andriolo[1,1] and Jack L. Skinner[1,1,1]; [1]Montana Technological University, United States; [2]Montana Statue University, United States

In recent years an interest in conductive electrospun (ES) microfibers has gained traction in the world of flexible electronics and hybrid perovskite photovoltaic applications. ES fibers are attractive for their large surface area to volume ratio and relative strength. Traditionally, conductivity in ES nanofibers has been accomplished using conductive or semiconducting polymers. Alternatively, conductivity in polymer thin films can be accomplished through addition of carbon nanotubes (CNTs) or graphene.

Previously, we have successfully formed hybrid perovskite crystals encased in ES fibers in situ, showing improved crystal stability. In other work, we demonstrated conductivity in melt ES graphene doped polymers. In current work, we will utilize the previously established method of multiwalled CNT (MWCNT) dispersion by combined use of a hydroxy-functionalized and unfunctionalized MWCNT blend in polycaprolactone (PCL) in preparation for electrospinning of a multi-layer solar cell structure.

Triaxial ES will be used to form the multi-layer solar cell structure described. In the design, a conductive PCL core will be coated with the previously established perovskite-polymer composite. Most exterior to the ES device will be a polymeric electron transport layer (ETL). Each layer of the device will be characterized. Here, conductivity of a PCL thin film doped with a mixture of functionalized and unfunctionalized MWCNTs will be characterized via a non-destructive four-point probe method. Conductivity characterization will be used to determine the percolation threshold and preferable ratios for the MWCNT-doped PCL composite used as the core of the functional fibers proposed. MWCNT dispersion in the composite as a function of sonication time will be characterized through crystallinity analysis via Raman spectroscopy and electron microscopy.

Presented work will include fabrication methods of a four-layer thin film system consisting of the conductive MWCNT-PCL composite, a polymer encapsulated hybrid perovskite layer, a polymeric ETL, and a transparent conductor. This work will provide the foundational preliminary data for future fabrication of an ES perovskite solar cell. The design will not include a hole transport layer as it has been previously established as non-consequential to perovskite solar cell performance. After proof of concept has been established the conductive ES nanofibers will be used as a central electrode in a triaxially ES photovoltaic cell. Fibers created during the final triaxial ES process will have a three-layer structure (from core to outer shell) consisting of: (1) a conductive PCL composite, (2) a hybrid perovskite active layer, and (3) a polymeric ETL.

5:00 PM EL18.13.31
Enhanced Dielectric Properties of Bio-materials Derived from Renewable Resources for Electrostatic Chuck (ESD) Baekjin Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

Dielectric materials are being applied in a variety of industries and used as electrical insulators in capacitors such as semiconductor devices and electrostatic chuck (ESD). Flexible materials for electric capacitors are getting more attention due to their superior processability, flexibility, and chemical resistance compared to inorganic materials. In our study, biomass based derived monomers and flexible oligomer were used to synthesize urethane materials with high dielectric constant. Especially we have adapted step by step method which synthesized well defined molecules in the desired position to confirm the effect of the two materials used on the dielectric constant. Sequentially synthesized UV curable urethane were qualitatively analyzed step by step through FT-IR and quantitatively analyzed through ^{1}H-NMR. In order to synthesize photo curable materials, acrylate were terminated at the both end of urethane oligomer chains and printed out disc type output (OD: 30mm) using Digital Light Process (DLP) 3D printer. Dielectric constants were observed $\varepsilon>5$ for printed out disc type urethane materials. In addition, we investigated that curing kinetics, film properties and mechanical properties of UV curable urethane materials.

5:00 PM EL18.13.32
External Electric Field Treatment to Printed N-Type Conjugated Polymer Films Applied for the Active Layer of Organic Field-Effect Transistors and Organic Photovoltaics Yina Moon, Nara Han, Dongseong Yang and Dong-Yu Kim; Gwangju Institute of Science and Technology, Korea (the Republic of)

External electric field (EEF) treatment could be a promising simple non-contact method for controlling the morphology of conjugated polymers during organic electronics printing process. Because EEF treatment uses an electric field to induce dipole alignment in molecules and expansion and alignment of molecular crystals, it is possible to control the morphology in the desired direction by freely controlling the direction of the electric field according to the channel direction of the electrical device. So, with EEF treatment, the aligned polymer and the enlarged crystal of the polymer can show improvement in the charge carrier transport. In this study, an n-type conjugated polymer, P(NDI2OD-T2), which has high electron mobility, improved the electrical performance as the active material of organic field-effect transistors (OFETs) and organic photovoltaics (OPVs) by EEF treatment with the printing process.
First, in this study, it was confirmed that improved electron mobility of OFETs by applying an EEF treatment during solidifying of the P(NDI2OD-T2) film right after blade coating, so, the average electron mobility improvement was improved from 1.22 cm^2/Vs to 1.98 cm^2/Vs. This achievement can be caused by aligning the dipole, enhancing the planarity of this polymer backbone, and enlarging polymer crystal by EEF treatment right after printing process. Furthermore, organic solar cells were fabricated using P(NDI2OD-T2) as an acceptor with PTB7-Th as a donor in the active material, and the power conversion efficiency was increased by EEF treatment with adding a polar solvent. Because a polar solvent was introduced as a solvent additive to improve the contribution of EEF effect to thick bulk-hetero junction film. As a result, by contrast to without solvent additive, 42% of enhancement of PCE from printed solar cells was achieved from EEF treatment compared with polar solvent additive approach only. The correlation between EEF treatment and morphology of conjugated polymer was analyzed by using UV-vis absorption, AFM, 2D-GIWAXS measurements and electrical performance of OFETs and OPVs. Consequentially, the improvement of electron mobility and PCE of this study suggests an effective way to advance the electrical characteristics of the device by applying the external electric field treatment.

5:00 PM EL18.13.34
Thick Lattice Electrodes with Core-Sheath Structure for Supercapacitors Manufactured by Material Extrusion 3D Printing Yuqi Gao and Junjun Ding; New York State College of Ceramics at Alfred University, United States

Manufacturing thick electrodes is a promising strategy to enhance energy storage per unit area. However, the electrochemical performance is still limited by the low electrical conductivity due to either the properties of materials or geometrical thickness. Material extrusion 3D printing has received enormous attention to potentially overcome the limits by tailoring and designing thick electrodes.

In this work, we prepared a thick reduced graphene oxide:carbon nanotube-reduced graphene oxide:manganese oxide/carbon nanotubes: carbon nanotubes (rGC-rGMC) electrode with controlled lattice architectures, core-sheath structure, and hierarchical porosity by material extrusion 3D printing, freeze-drying, and thermal treatment. The volume ratios of core to sheath, including 100%-0%, 0%-100%, 20%-80%, 30%-70%, 40%-60%, 50%-50%, and 30%+70%, were designed to investigate the influences of core-sheath structure on thick electrodes. Specifically, 100%-0% electrode, only including rGO and CNT, had an excellent rate capability and low capacitance (80.8 mF cm^{-2} at 1 mV s^{-1}) contributed by double-layer electrical capacitance. While 0%-100% electrode (rGMC only) showed a high area specific capacitance (356.0 mF cm^{-2} at 1 mV s^{-1}) due to introducing MnO$_2$/CNT composites, but a significant capacitance decay from 1 mV s^{-1} to 100 mV s^{-1} was observed. Either the rGC or rGMC was not desirable for the practical applications of thick electrodes. The thick electrode with core-sheath structures improved electron transportation by the conductive rGC core, and the fast ion diffusions via the thinner rGMC sheath layer. As a result of the competition between material compositions and structures, 20%-80%, 30%-70%, 40%-60%, and 50%-50% electrodes exhibited the area specific capacitance of 310.3 mF cm^{-2}, 528.9 mF cm^{-2}, 410.0 mF cm^{-2}, and 390.2 mF cm^{-2} at the scan rate of 1 mV s^{-1}, respectively. All capacitance decays from these core-sheath electrodes were smaller than rGMC (0%-100%) electrodes, indicating the improved rate capability from the core-sheath structure. rGC core was found to be effective as a conductive channel, and thus the rGMC concentrated in the sheath region could be more efficiently utilized. Electrodes with a core-sheath volume ratio of 30%-70% were compared with electrodes made of homogenous 30% rGC and 70% rGMC mixture to show the influence of the core-sheath structure on the electrochemical performance. Lower capacitance (400.1 mF cm^{-2}at 1 mV s^{-1}) of 30%+70% mixture electrode without core-sheath structure suggested less efficiency to harvest electrons from the redox reactions. Electrochemical impedance spectroscopy (EIS) data further supported and explained the resistances of thick electrodes with different volume ratios.

5:00 PM EL18.13.35
Fully-printed Micro-OECT Patch for Real-time Sweat Multi-analytes Detection Mohammad Shafiqul Islam, Brince Kunnel, Md Farhad Hassan, Angsagan Abdigazy and Yasser Khan; University of Southern California, United States

Wearable devices have gathered substantial consideration in recent years owing to their great potential in personalized health care and fitness analysis.

Amongst these, advances in wearable technology have empowered the fabrication of sweat monitoring devices for in situ real-time and continuous analysis of proteins, ions, and metabolites. However, these sensing platforms should be disposable and scalable. In this regard, printing technologies show promise as a quick, high-throughput, and inexpensive alternative to the more time-consuming multi-step photolithography techniques. In this work, we present an epidermal wearable chemical sensing patch for sweat ions analysis fabricated using inkjet printing and direct 3D writing, which fully unleashes the advantages of using the OECT in wearable applications. Compared to conventional potentiometric sensors, OECTs offer signal amplification, improved miniaturization, and circumvent reference electrode requirements. We demonstrate for the first-time fabrication of the short channel micro-OECTs (~100 µm) by printing techniques for the detection of lithium (Li+) and sodium (Na+) ions from sweat. The concentration of Li+ in biological fluid plays an essential role in assessing bipolar disorders, while Na+ facilitates tracking the dehydration status of individuals. We hope this work will inspire further development of printed OECT-based biochemical sensors

5:00 PM EL18.13.37
A Novel Screen-Printed Platform for *In Situ* Soil pH Sensing Catherine Crichton, Elliot Strand, John-Baptist Kauzya, Anupam Gopalakrishnan, Madhur Atreya, Eloise Bihar and Gregory L. Whiting; University of Colorado Boulder, United States

Soil pH significantly affects agriculture by regulating available nutrients and water-soluble chemicals available to plants, thus driving the need for low-cost, durable soil pH sensors. A few potential solutions include expensive commercial pH sensors and printed sensors that only work in liquid media. Each of these solutions poses its own set of unique challenges perpetuating the affordable soil pH sensing dilemma. Here, we present a novel pH sensor platform based on an array of low-cost, durable, screen-printed electronics for in situ soil sensing. We show the stabilization of the pH-sensitive dye, alizarin, in the printed pH devices allowing for extended sensing periods in soil. We compare different alizarin dye immobilization techniques and have evaluated the effects of soil pH on sensor durability. This new affordable, stable printed pH system pioneers the development of printed electronics for new alternatives to assess soil pH.

5:00 PM EL18.13.38
Printed Potentiometric Sensors for Soil Nitrogen Monitoring Carol Baumbauer, Lucas Lahann, Payton Goodrich, Carolyn Schwendeman and Ana Arias; University of California, Berkeley, United States

Managing nitrogen is a central concern for precision agriculture and environmental science in order to maximize fertilizer use efficiency and minimize nitrate leaching and greenhouse gas emissions. However, measurement methods for in-soil nitrogen are limited. State-of-the-art soil nitrogen analysis requires taking soil or liquid samples to laboratories for chemical or spectrographic analysis. These methods are accurate, but costly, labor intensive, and cover limited geographic scope. Printed potentiometric nitrate and ammonium sensors are a promising alternative method for nitrogen monitoring because they are small, low power, involve no moving parts, and are mass-producible. Printing techniques are scalable and compatible with unconventional materials used for environmentally-benign sensors.

Potentiometric sensors are composed of two electrodes: an ion-selective electrode (ISE) and a reference electrode (RE). The signal output is the potential difference between the two electrodes at zero-current conditions. Potentiometric ion sensors have been widely studied for health monitoring applications, however, several unique challenges arise when developing potentiometric sensors for environmental applications. Sensors used for soil monitoring must 1) exhibit very low drift to enable functional lifetimes of several months, 2) be insensitive to other chemicals at concentrations commonly found in soils 3) be paired with stable printed references, and 4) be robust to biofouling and damage from microbial activity in soil.

Here we present work towards achieving these aims. Materials for the sensing electrode, ion-to-electron transducer layer, and ion selective membrane are compared and chosen for sensitivity, selectivity, and stability. The reference electrode transducer and membrane layers are likewise optimized for stability minimal drift. Encapsulation techniques are explored for robust production of sensitive electronics, enabling long lifetimes.

5:00 PM EL18.13.39
Enhancing Hydrophilicity of the Skin-interfaced Microfluidic Systems for Sweat Monitoring Fina Lu, Ji Hyun Yang and Ahyeon Koh; Binghamton University, United States

Sweat sensors are an emerging technology for real-time, non-invasive health monitoring and analysis at the skin-interface. This skin-interfaced wearable system allows for a detailed analysis of sweat, a biofluid that contains a wide range of essential biomarkers that possess a powerful potential in clinical diagnostics and commercialization. Polydimethylsiloxane (PDMS) is the most commonly used material in microfluidics due to its characteristics such as biocompatibility, low elastic modulus, and moldable structure at high resolutions. The most notable drawback is the intrinsic hydrophobicity of PDMS, inhibiting non-specific protein adsorption and wettability issues that affect how sweat is driven up the microfluidic device. Previous studies focused on the blending of PDMS and copolymer polyethylene glycol (PEG) to improve hydrophilicity. They have reported on the biofouling of these block copolymers, affecting the structure of the material. However, the distribution and behavior of these compounds in the PDMS still need to be fully understood.

In this study, we aim to improve the hydrophilicity of the PDMS and reduce the threshold pressure for sweat collection at the skin-interface. We explored engineering strategies to exploit the material's chemical and physical properties. The PEG block-co-polymer was used as an additive and contact angles were tested for the PDMS/PEG as a function of wt% PEG block-co-polymer. To test this, we conducted a set of experiments on four different surfaces over time. PDMS thin films were prepared using soft lithography by mixing a PDMS solution comprising of a PDMS base and a crosslinking agent in a ratio of 10:1. PDMS was set as the control for each experiment, coupled with PDMS/PEG wt% of 0.5 wt%, 1.0 wt%, and 3.0 wt%. Each experiment consisted of these four samples cured on four surfaces of polystyrene (PS), polyamide (PI), polycarbonate (PC), and polyethylene terephthalate (PET) films. The PDMS/PEG thin film specimens were approximately 1000 µm thick using a thin film applicator. All samples were cured for 24 hours at 60 °C, and contact angle measurements were carried out at 0 hours, 24 hours, 1 week, 2 weeks, 3 weeks, and 1-month marks. We observed the difference in the water contact angle for the PDMS/PEG interface and air and how it differs across different types of surfaces over time. The results from the initial contact angle measurements showed a difference between the air and polystyrene (PS) interface, for PDMS (air-102.9°, PS surface-99.2°) and 3.0 wt% PDMS/PEG (air-51.0°, PS surface-8.6°). The water contact angle is minuscule between the air and surface for 0 wt%, while 3.0 wt% shows a significant difference.

The initial material surface hydrophilicity is lower on every surface except for PDMS control, for PI (3.0 wt%, air-51.6°, PI surface-13.6°) and PC (3.0 wt%, air-29.3 °, PC surface-11.2°), meaning the type of surface does affect the contact angle and hydrophilicity of the PDMS material. Polycarbonate (PC) shows the least difference in contact angles between the air and interface. The percent recovery of the polystyrene surface at 1 month for PDMS (air-99.2°, 3.6% recovery; PS surface-93.6°, 5.6% recovery) and 3% PDMS/PEG (air-41.7°, 19.5% recovery; PS surface-32.5°, 26.5% recovery). The slow recovery of PDMS hydrophobicity is promising for commercialization. Continuous contact angle measurements are to be made in the subsequent months. Mechanical testing included bending, peeling, and shear stress using a Mark-10 tensiometer. The microfluidic flow threshold pressure will be quantified using Fluigent Flow EZ equipment for each material.

The polystyrene (PS) surface shows the most promising results for fabricating sweat sensors. Our research shows insight into the PDMS/PEG block copolymer system and offers engineering strategies to improve PDMS/PEG hydrophilicity for use in skin-interfaced microfluidic devices.

5:00 PM EL18.13.41

Stretchable and Conductive Polydimethylsiloxane/Liquid Metal Composites by Material Extrusion 3D Printing Chao Liu and Junjun Ding; New York State College of Ceramics at Alfred University, United States

Gallium-based liquid metal (LM) alloy is a promising material in applications such as flexible electronics and thermal management due to its outstanding electrical conductivity, thermal conductivity, and reconfigurable under harsh stretching conditions. Polymeric elastomers are extensively used as matrix materials to embed LM reinforcement to form composites for better electromechanical performance. Polydimethylsiloxane (PDMS) is a widely used elastomer due to its stretchability, biocompatibility, and moldability. Research has shown that PDMS/LM composites demonstrate excellent electrical conductivity and robust elasticity as flexible conductors and strain sensors. LM particles are homogeneously dispersed in the PDMS matrix, which demonstrates an isotropic performance of electrical conductivity. However, these composites usually require mechanical activation process to create electrically conductive channels in the composites. In addition, little research has focused on forming non-uniform structure for an anisotropic electrical property which is required in many electrical devices.

In this work, we fabricate an inhomogeneous PDMS/LM composite by material extrusion 3D printing method. LM particles sink down and deposit on the bottom of the composite due to a larger density compared to PDMS. A higher viscosity PDMS (SE 1700) and a lower viscosity PDMS (Sylgard 184) are used to study the influence of matrix viscosity on the sinking down process. The experimental results are compared to the simulation results for the understanding of the self-assembly process. The deposited LM layers demonstrate a larger local density of electrical pathways compared to structure with homogeneous dispersion. Therefore, the hierarchical PDMS/LM composite demonstrate a better electrical conductivity on the bottom surface, but nonconductivity between top and bottom surface. The material extrusion 3D printing method is used to fabricate the composites due to its advantages of building complex structures in line-by-line and layer-by-layer mechanisms. Rheological analysis, such as viscosity and storage/loss modulus, is studied before 3D printing process for a printable ink. Prepared ink is transferred into a syringe and extruded from the nozzle by a stepper motor. The influence of printing parameters, such as nozzle size, line width, and printing speed, on the conductivity of the composites will be further investigated.

5:00 PM EL18.13.42

Reliable Fabrication of Freely Scalable and Designable Porous-type Tactile Sensor Using Micro-Patterned Water-Soluble Sacrificial Layer Bon-Jae Koo and Min Ho Seo; Pusan National University, Korea (the Republic of)

Recently, polymer-based micro/nano-porous structured pressure sensor has gained significant interest in tactile sensor applications because of their high sensitivity and fast response & recovery time. Conventionally, the porous structured pressure sensors have been produced utilizing a solvent-soluble bulky porous template, such as a sugar cube. However, the bulky template makes the sensor inevitably voluminous, obstructing miniaturization essential for recent robotics, virtual reality (VR), augmented reality (AR), and biomedical Engineering. Moreover, the conventional methods unavoidably form randomly located porous structures, which constrains the reproducibility and reliability of the tactile sensor required for industrialization. Therefore, a reliable manufacturing method for high-performance miniaturized porous pressure sensors with high reproducibility and scalability is required.

Here, we report a simple and reliable method to fabricate a freely designable and scalable micro-porous type pressure sensor. The proposed fabrication method exploits a micro-machined and ultra-thin water-soluble sacrificial layer (Polyvinyl Alcohol, PVA) instead of the bulky template. By conventional screen-printing, a thin tri-layer of a conductive polymer-micro machined sacrificial layer-conductive polymer can be produced. Then, by removing the sacrificial layer, the designable porous structure inside the pressure sensor formed. Importantly, the shape, location, and dimension of the porous structure inside the pressure sensor are freely designable since the sacrificial layer is manufactured by UV-Laser machining. In addition, the thickness of the polymer also can be freely adjustable by controlling a stencil mask during the screen-printing method. Thus, the micro-porous inside the conductive layer can be easily scalable and designable, finally providing reproducibility at the sensor device level. To practically prove the proposed concept, we first screen-printed a 100 µm-thick conductive polymer, C-PDMS (Carbon Black-polydimethylsiloxane), layer on the electrode-formed substrate. Then, the pre-porous layer was formed by an 80 µm-thick micro-machined PVA, and 200 µm-thick C-PDMS for the upper layer was fabricated by screen-printing. Finally, after the PVA layer etching process in the water, we demonstrated the designed micro-porous embedded ultra-thin (380 µm) piezoresistive pressure sensor. The fabricated sensors showed a sensitivity of 0.08176 ($R \times kPa^{-1}$) which is 200 % higher than that of a non-porous sensor ($R \times kPa^{-1}=0.03725$), in the pressure range of 25 kPa to 100 kPa. More importantly, we practically confirmed the highly reproducible base resistance and sensitivity ($219.8612 \pm 8.3028\ \Omega$ and $0.1163 \pm 0.0048\ R \times kPa^{-1}$ in 0.5 kPa to 100 kPa, respectively) of the fabricated sensors (n=8) that were achieved by the designed porous structure. Based on the proposed concept, we further fabricated a tactile sensor array composed of 3x3 miniaturized micro-porous sensors. The fabricated sensor array not only successfully recognized the magnitude and location of the static pressure of various weights but also detected the dynamic pressure of tapping the finger in real time.

Self-Cooling Transformative Electronics with a Radiative Cooler for Reliable Stiffness Tuning in Outdoor Use JooHo Yun[1], Sang-Hyuk Byun[2], Seyeon Heo[1], Gil Ju Lee[3], Jae-Woong Jeong[2] and Young Min Song[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Pusan National University, Korea (the Republic of)

Traditionally, electronics are designed to have invariant mechanical properties to serve specific purposes. For example, rigid electronics provide convenient and robust handling, optimized for handheld or tabletop setup, and soft electronics are capable of deforming their shapes and geometries dynamically, enabling comfortable wearing on the body. Unfortunately, however, current electronics cannot provide advantageous features of both rigid and soft electronics due to inherent limitations in their form factors. To leverage key features of both rigid and soft electronics, we have developed a transformative electronics system (TES), which can change their shape and stiffness to realize both rigid handheld and soft wearable configurations as needed [1]. The TES integrates flexible, stretchable electronics onto a thermally responsive transformative platform which is composed of gallium (T_{melt} = 29.76 °C, where T_{melt} represents a melting point of gallium) to implement stiffness tuning by changing its phase between solid and liquid. However, the TES have difficulties converting into a rigid form outdoors because excessive heat is accumulated from themselves or the environments such as the sun. Integrating a flexible thermoelectric device with TES [2] can address this issue, but it requires a huge amount of power to maintain rigid operation mode outdoors.

Here, we present a design of transformative electronics with the integration of a radiative cooler (TER-RC), enabling reliable bidirectional stiffness tuning in both indoor and outdoor environments. Specifically, rigid-mode outdoor operation under the sunlight has been substantially improved by a radiative cooler. We fabricated a flexible and stretchable radiative cooler (FSRC) that achieves ~97% of reflectivity in the solar spectrum and ~90% of emissivity in an atmospheric window so that it can effectively block solar energy and radiate internal thermal energy [3]. The radiative cooler can maintain its temperature 3.9 °C below the melting temperature of gallium under 1000 W/m^2 of direct sunlight and an additional 4469 mW/m^2 of external heat input. Based on this, we have demonstrated a transformative optoelectronic device that can convert between rigid handheld and stretchable wearable forms. The integrated radiative cooler successfully reduces the temperature of electronics and enables stable rigid mode operation even in the hot outdoor environment, thus making transformative electronics highly reliable both in rigid handheld setup and soft wearable form.

In conclusion, the transformative electronics with radiative cooler (TER-RC) enables desired stiffness tuning between rigid and soft modes without dependence on ambient temperatures and environments. The integrated FSRC can effectively reflect solar energy and radiate thermal energy so that it cools down the TES to allow rigid mode under sunlight. Finally, we verified the design concept through the demonstration of an optoelectronic device that can convert between rigid handheld and stretchable wearable forms to overcome the limited applications of the existing TES.

Optical Physically Unclonable Functions Device Using Random Fibrous Media Fabricated by Electrospinning MinSeok Kim, JooHo Yun, Dong Hyun Seo and Young Min Song; Gwangju Institute of Science Technology, Korea (the Republic of)

Recently, the demand for encryption to verify user identity and authenticated products for protection against counterfeit products and privacy/confidential information is increasing in daily life. The physically unclonable functions (PUFs), which is a non-algorithmic one-way functions composed of stochastic random factors, have been mentioned as new cryptographic physical devices. Because PUFs are generated in a random or probabilistic process, each manufactured PUFs devices exhibit unique characteristics. Since the initial introduction of the PUF concept, various types of PUFs using optical, magnetic, and electronic have been reported. Compared with other PUFs, the optical-based PUF has the advantages of high entropy, high output complexity, and high security against modeling and replication attacks.
Optical-based PUFs using a random laser is an attractive researched field, unlike conventional lasers. Random laser has no optical resonator and uses a feedback loop of scattering particles in a random material to randomly emit light. Random lasers are generated through a phenomenon of Anderson light localization generated in a random region when light is strongly scattered through a random medium. However, manufacturing large-area random media that causes random lasing at low cost remains a challenge. In this paper, we propose a method of extracting bits by fabricating an optical PUFs device with random lasing characteristics using electrospinning, which can implement a random structure in a large-area process, and apply it to security devices.
To implement optical PUF, a method of fabricating nano/microfibers using electrospinning is used. 2 g of polymethyl methacrylic acid (PMMA) was dissolved in 9 g of dimethylformamide (DMF) and acetone, respectively, to prepare a solution usable for electrospinning. To sufficiently dissolve the PMMA in the solvent, a heat stirrer was used at 60 °C for 8 hours. To have emission characteristics ranging from 560 nm to 640 nm, 4-(dicyanomethylene)-2-methyl-6-(4-dmethylaminostryl)-4H-pyran (DCM) was dissolved in 2 mM at a temperature of 60°C for 2 hours. The prepared solution was subjected to an electrospinning process through a high voltage of 14 kV at an extraction rate of 1 mL/hr using a 23 gauge nozzle. The micro random fibers produced by the electrospinning method have a similar diameter distribution and thickness. The fabricated samples have similar fiber diameters across the entire area, but have different random laser properties due to different fiber structures at different locations in the sample. To confirm the random lasing phenomenon, an optical pumping method was used to obtain random peaks representing random lasing. For optical pumping, a 3rd Harmonic ND:YAG laser with a wavelength of 355 nm was used at a repetition rate of 10 Hz. The 355 nm laser was focused on the fabricated sample with a plano-convex lens with a focal length of 50 mm. A 60x objective lens and a UV-visible spectrometer were used to acquire the generated wavelength data of a random laser. The wavelength data measured at four different points within the same sample shows a random peak from 580 nm to 620 nm at each location. In order to use the peak obtained with optical PUFs devices, the baseline of the spectrum was decomposed to remove the spontaneous emission component. The positions of the obtained peaks were digitized through binning. In order to improve the uniformity of the digitized data and final bit was extracted using the Von Neumann De-biasing method to improve the uniformity of the digitized data.

Statistical Analysis of Printed Graphene Coating using Optical Imaging Kh M Asif Raihan[1], Bepeh Amama[2] and Suprem R. Das[1]; [1]Kansas State University, United States; [2]Manhattan High School, United States

Materials for functional coating have significant technological implications in modern society starting from building smart building to aerospace applications. However, a single material is difficult to achieve to fulfil many of the requirements for a wide variety of applications. Despite challenges to address in a case-by-case basis, with the advent of nanomaterials and nanotechnology, multifunctional coating has emerged as a practical avenue often developed from laboratory benchtop experiments to emerging industries. Graphene, a material discovered in 2004, is presently representing a leading material to address many applications in the form of functional coating. However, the quality of coating is the first step to understand in order to further apply it in real applications. In our laboratory, we print graphene on flexible substrates with the intention to use in various flexible electronics. In this poster presentation, we study the quality of coated graphene, fabricated by printing and by capturing hundreds of optical images and subsequently performing its statistical data analysis. The analysis not only predicts the coating uniformity but high-resolution imaging guides further the need of future printing technology to further push the resolution of such coating technology.

5:00 PM EL18.13.46
Metallic Micro-Pattern Embedded Stretchable Conductive Dry Electrode for Long-term Reliable and Wearable ECG Monitoring Onyu An, Sang-Min Kim and Min Ho Seo; Pusan National University, Korea (the Republic of)

An active electrocardiogram (ECG) can record a continuous heartbeat and is therefore utilized to accurately monitor the presence of arrhythmias. Conventional biopotential electrodes for the ECG measurement in clinical-level are based on wet Ag/AgCl (conductive gel) electrodes, reducing skin-electrode contact impedance. However, as the conductive gel dries over time, there is a problem in that the contact resistance increases and signal degradation occurs, finally limiting the long-term reliable ECG measurement. To address the long-term reliability issue, a dry electrode, generally based on conductive-polydimethylsiloxane (C-PDMS), has been developed. The dry electrode is not only flexible, also stable without physical and chemical degradation, thus, it has shown the long-term reliable and continuous ECG measurement with wearable configuration. Nevertheless, interconnection of the polymer electrode with conventional instrumental systems still remains a challenge for the development of the polymer-based dry electrode to industrial grade and for the practical usage in widen applications.
Here, we introduce a novel design of dry C-PDMS electrode that includes an optimized micro-scale copper (Cu) pattern inside. The developed dry electrode exhibits electromechanically stable interconnection with commercial instrumentation systems because it includes the Cu micro-pattern compatible with conventional interconnection methods, such as soldering and mechanical connector. Importantly, since dimension of the Cu pattern is theoretically optimized, using finite element method (FEM), the developed dry electrode maintains its high flexibility and stretchability; quantitatively, we confirmed the effective stiffness of electrodes can be reduced and become similar to the stiffness without the Cu pattern when area of Cu pattern is 20% of the radius of the C-PDMS layer. To demonstrate the designed electrode, a simple microfabrication process using laser ablation and screen printing was developed. The fabricated dry electrode does not only show stable impedance characteristics (4kohms @1kHz) with high reproducibility (36.1 of resistance variance, n=95), but also show stable adhesion to human skin even with various movements. More importantly, the fabricated electrode shows successful electrical interconnection with a commercial wire through the conventional soldering and conductive magnet. We also tested the long-term reliability of the electrode. After exposing the fabricated dry electrode to a 40°C oven for 12, 24, and 36 hours, the developed dry electrode stably maintains its electrical properties (1.74 % resistance change), while the wet electrode showed crucial performance degradation (-67.5 % resistance change). Finally, we further

developed a wearable ECG hardware that can be connected to the developed electrode through the conventional soldering. Then, in the continuous ECG measurement for 24 hours, the developed dry electrode-based ECG module successfully measured a clear PQRST peak without significant signal degradation. More importantly, the developed sensor reliably detects ECG signals even while a person is walking.

5:00 PM EL18.13.48
Tailoring the Internal Structure of Porous Copper Film via Size-Controlled Copper Nanosheets for Electromagnetic Interference Shielding Ho Kwang Choi, Seungyeon Kim, Young-Seok Song and Tae-Wook Kim; Jeonbuk National University, Korea (the Republic of)

The advances of technologies, such as latest telecommunications, electric vehicle and electronic device has prompted demand for ultra-high performance and cost-effective shielding materials to protect against the potentially harmful effects of electromagnetic interference (EMI) on human health and electronic devices. Materials commonly used as shielding for EMI are metal-based thin films, foils, and meshes. Currently, several types of conductive filler materials, two-dimensional (2D) materials and polymer composite materials are being studied as core materials for EMI shielding because of their cost, performance, and weight. Among them, large-area 2D metal nanosheet enables more efficient film formation on a substrate compare to other conductive fillers such as nanoparticles or nanowires. The existing strategy for preventing EMI is to block electromagnetic waves using mechanisms such as reflection or absorption, which depend on impedance differences and skin depth. The multiple reflections caused by scattering inside the shield are considered to be a third shielding mechanism. Multiple reflections can be caused by various porous structures formed inside the shielding material. Therefore, 2D copper nanosheets (Cu NSs) have been introduced to enhance EMI shielding effectiveness (SE) by forming an internal layer by- layer stacked structure inside the films. In the case of 2D nanomaterials such as graphene, transition metal dichalcogenides, and MXene, it is difficult to control the spacing between each atomically thin layer when forming a thin film due to the strong van der Waals force. On the other hand, Cu NSs enable the formation of an internal porous structure in films with submicron or micron scaling gaps between the layers of stacked Cu NSs, and the size-controlled Cu NSs can realize various internal structures. In that context, it is important strategy to control the internal structures of such porous films for EMI shielding applications and the requires size-controlled Cu NSs. Metals have highly symmetrical lattices and their 2D morphology for a metallic crystal is not thermodynamically favored during bottom-up growth or synthesis. For this reason, the control of crystal growth is achieved by controlling the total free energy of the metal nanostructure and the rate at which metal ions are reduced to metal clusters. Because the surface energy could dominate in the total free energy of 2D nanostructures with a high surface-to volume ratio, this strategy often involves reducing the surface energy of 2D metals with capping agents. Here, we observed the use in EMI shielding of hierarchical porous Cu foils with various internal structure according to assembly of single-crystalline, nanometer-thick range, and micrometer-length range size-controlled copper nanosheets and characteristic changes according to various state of hierarchical porous Cu foils. Cu NSs were size controlled by adjusting the concentrations of the shape modifying agent (iodine), the stabilizer(hexadecylamine) and the reductant (glucose). Size-controlled Cu NSs were synthesized in various sizes from 3 to 30 μm. The layer-by-layer assembly of the synthesized Cu NSs enabled formation of a hierarchically-structured porous Cu NSs film with features such as multi-layer stacking. The hierarchical porous Cu foil exhibited superior EMI shielding performance compared to the same thickness of dense copper and other materials, resulting in EMI SE values of up to 100 dB depending on the thickness. In addition, the EMI SE of the hierarchical porous Cu NSs film exhibited various EMI SE values according to changes in the internal structure, and showed various characteristics according to oxidation through high-temperature heat treatment. These findings suggest that Cu NSs and their layer-by-layer assemblies are one of the promising EMI shielding technologies applicable to a variety of practical electronic applications.

Understanding the Effects of Polar and Non-Polar Surfactants on the Oxidation Performance of Copper Nanoparticles LaRico J. Treadwell; Sandia National Laboratory, United States

Copper nanoparticles (Cu-NPs) have garnered attention due to their high electrical and thermal conductivity, high melting point, and relatively low cost compared to other metals (i.e., gold and silver). The wide spread usage of Cu-NPs is hindered due to their susceptibility to oxidize and corrode, as well as the difficulty to achieve an synthetic route that easily scalable with controlled morphology and does not encompasses parasitic conditions (i.e., harsh reactants, high temperature). Many of the published routes involve harmful/toxic compounds and reducing agents, as well as very high temperatures/long reaction times, and despite the harsh synthetic conditions the nanoparticles are extremely susceptible to oxidation. Therefore, developing a cost effective and green synthesis that can produce Cu-NPs that is resilient/controllable to oxidation and corrosion environments is critical for Cu-NPs to be usable in industrial and commercial usage. In this work, a novel microwave-assisted synthetic route is demonstrated using an organometallic precursor (Copper (I)-Mesityl) and a variety of green solvents (glycols) and surfactants (hexadecylamine [HDA]). Numerous synthetic parameters (i.e., solvent/surfactant combinations) were systematically investigated to evaluate their effect on the particle size and morphology as well as how the solvent/surfactant prevent oxidation/corrosion in atmospheric corrosion environments. The various surfactant/solvent coated nanoparticles were subjected to a variety of environments such as 100% relative humidity (RH) and 10 ppm H_2S/50% RH. The nanoparticles were characterized pre- and post-exposure to understand the role of the solvent and surfactant species effect on hindering oxidation. Particles were characterized via powder X-ray diffraction (PXRD), thermogravimetric analysis (TGA), transmission electron microscopy (TEM), and Fourier transform-infrared (FT-IR) spectroscopy. Results show the combination of glycols/HDA yielded a synergistic effect that lead to a reduction in the oxidation kinetics upon exposure to atmospheric corrosive environments, yielding oxidative resistant nanoparticle (> 14 days).
Details on the synthesis route, characterization, and oxidation stability are presented.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Functional Paper for Magnetically Controlled Soft Actuators and Deformable Sensors Jeong Woo Chae[1], Gooyoon Chung[2], Wooseok Kim[1], Yoonseok Park[2] and Sang Min Won[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of)

Since its invention from more than 2200 years ago, paper has been indispensable in many parts of our everyday life such as writing, printing, cleaning, and packaging. In recent years, growing interest in the creation of functionalized paper has expanded the application scope of paper for batteries, energy harvesters, actuators, sensors, conductors, semiconductors, and biomedical uses, which exploit the inherent characteristics of paper, namely flexibility, foldability, bendability, recyclability, and lightness in weight. In this study, reprogrammable, magnetically controlled actuators, and highly deformable electrodes and sensors are fabricated by a simple and low-cost process. For the fabrication, commercially available water-soluble cellulose paper, consisting of wooden pulp and sodium carboxymethyl cellulose (Na-CMC) is used, and either Neodymium-Ferro-Boron (NdFeB) microparticles or ethanol-treated carbon black (CB) nanoparticles are uniformly dispersed in an aqueous solution of cellulose paper by sonication. The compound is heated for solvent evaporation where the coating of wooden pulp by CMC and filler particles composite takes place. The CMC-containing paper allows the final product to be glued together or recycled in the easiest way that needs no shredding or chemicals owing to its water-solubility at any temperature. Therefore, conductive paper strips can be joined to form an extended wiring, and recycling can be achieved by dissolving the paper in water and drying the solution to produce a new sheet of paper.

Magnetic cellulose paper for shape-morphing soft actuators is designed to perform dynamic locomotion such as crawling, rolling, sliding, and folding in magnetic fields. To form magnetization profiles on the paper that initially has random domain orientation, magnetic torque is applied to the paper under a programming magnetic field and reorient the NdFeB particles to align the local magnetization, either in-plane or out-of-plane, which determines the locomotion mode. The paper is then folded in origami or selectively integrated onto pristine paper for desired actuation that is driven by an electromagnet with 2-axis Helmholtz coils at a very low magnetic field down to 0.3 mT. Increasing the magnetic field to 2 mT leads to a large-degree deformations up to ±90°. The magnetization profile can be reprogrammed by repeating the same procedure above, but with different alignment under a programming magnetic field. In such manner, the initially torque-driven magnetization changes its orientation and thus the modes of locomotion straightforwardly.
Electrically favorable properties and durability of conductive cellulose paper are illustrated through mechanical deformation tests and sensor demonstrations. The electrical conductivity of the paper is saturated to 118 S/m when the mass ratio of CB to pristine cellulose paper is over 0.4 as the binding sites for CMC/CB in wooden pulp are restricted in amount. Bending up to a bending radius of 60 µm or repeated 180° folding cause no mechanical or electrical damage to the paper-based electrodes (resistance change below 0.1 % and 0.3 %, respectively). While the electrode dissolves completely in DI water, its partial dissolution can be recovered merely by drying the dissolved area without damaging the electrical characteristics. A paper-based parallel plate capacitor manifested negligible difference between the experimental and modeling data, and a capacitive touch sensor with paper electrodes evinces stable capacitance values during repetitive touching. The results unlock the implementation limit of the conductive paper for a variety of conditions that require bending, folding, instant dissolution, recovery after dissolution, lightweight capacitor, etc. Furthermore, the combination of the two types of functional paper provides magnetically controllable electric circuits whose wire connection can be steered and recuperated by maneuverable locomotion under magnetic fields.

5:00 PM EL18.13.52
Laser-Induced Graphene-Based Structures Derived from Cellulosic Materials for Flexible and Green Electronics Applications Sara Silvestre, Tomás Pinheiro, Ana Carolina Marques, Rodrigo Martins, Luís Pereira and Joao Coelho; CENIMAT|i3N - NOVA School of Science and Technology, Portugal

In recent years, with the evolution of modern societies, new and emerging technologies, such as flexible and wearable electronics, have improved overall well-being and human quality of life. Toward what can be introduced in the future, from the evolution of current technology to the development of new smart devices, researchers around the world are pushing technology barriers further, exploiting the full potential of such systems. In this context, flexible electronics have been increasingly growing, integrating sensors, capacitors, antennas, and so on, offering a novel range of applications, such as biological and environmental monitoring, energy harvesting and storage, intelligent robotics, smart clothing, flexible displays, healthcare sensors, and much more. These technological trends also require exploring novel materials, being carbon substrates some of the most promising options over the past decade. For instance, graphene presents amazing properties, such as remarkable conductivity, flexibility, high strength, and thermal and chemical stability. Although graphene-based materials stand out for their great features, the conventional fabrication processes are complex, expensive, and not industrially scalable, highlighting the need to find sustainable alternatives. Therefore, exploring renewable materials and environmentally friendly methodologies is necessary to develop high-efficiency, lightweight, flexible, durable, and low-power consumption devices[1–4].
This work reports an eco-friendly approach for the production of green, flexible, and discrete structures based on a single-step direct laser writing (DLW) approach. Using this process, it is possible to convert cellulosic derivatives, such as agglomerated cork and paper substrates, into three-dimensional porous laser-induced graphene (LIG). By using different wavelength lasers (CO_2 and fiber), applying different substrate pre-treatments, varying the laser parameters, and studying the interaction mechanism of the laser and materials, LIG structure properties were easily tuned. The obtained "Green LIG" exhibits the typical Raman spectra along with high electrical conductivity, presenting exceptionally low sheet resistance between 5-10 ohm sq^{-1}. The friendliness of the used production method makes it an interesting tool for future technological applications. To show its applicability, the production of sensitive pressure resistive sensors and micro-supercapacitors was demonstrated, which paves the way for its integration into self-sustaining technological platforms and smart wearable systems.

Photosynaptic Transistor Memories Based on Solution-Processing Semiconductors and Donor-Acceptor Electret Polymer Dots Waner He and Tsuyoshi Michinobu; Department of Materials Science and Engineering, Tokyo Institute of Technology, Japan

Organic field-effect transistor (OFET) memories have attracted considerable attention due to their variety of applications in organic electronics. In contrast to conventional electrical memories, OFET memories have the advantages of structural flexibility, low-cost fabrication, and integration with CMOS technology. Recently, a light energy source was employed to erase recorded memory information. This data deletion/recovery process is considered as a green technology because light replaces electrical stress. Therefore, using an electronic device with the photo communication capability must become the mainstream technology in the future. To enhance the photo-responsive OFET memory characteristics, further improvement of polymer electrets is required. It was expected that polymer electrets with nonplanar conjugated structures show efficient photoelectric and charge-trapping properties. In this work, nonplanar donor-acceptor units were introduced, which can be readily constructed in quantitative yields by [2+2] cycloaddition-retroelectrocyclization (CA-RE) of electron-rich alkynes and electron-deficient olefins under mild conditions. The charge-trapping polymer electret dots of the OFET memory architecture was thus fabricated by the [2+2] CA−RE reaction between the dialkylaniline-substituted alkyne polymer P1 and 7,7,8,8-tetracyanoquinodimethane (TCNQ) polyester P2. Due to the crosslinked polymer electret, semiconducting layers (PBTTT-C14 and N2200) could be fabricated by wet process. Finally, OFET memory characteristics were systematically investigated in both electrical and optical operation modes. In addition, phototransistors are also applicable in the artificial synapse to fulfill short/long-term memory or plasticity and multilevel information recording.

5:00 PM EL18.13.55
Comparing Electronic Properties of Spin-Cast and Inkjet-Printed Indium Oxide Thin Films Andrew K. Lambert[1], Jacob Manzi[1], Harish Subbaraman[1], Tom Weller[1] and John Labram[2]; [1]Oregon State University, United States; [2]University College London, United Kingdom

Additive manufacturing is an emerging technology which enables relatively low-cost, high-volume device fabrication, with modest capital equipment requirements. Printable electronics refers to devices fabricated using different additive manufacturing processes such as inkjet printing, dispensing, and aerosol printing. The more traditional deposition techniques such as solution processing, vacuum deposition, sputtering, and evaporation currently offer higher quality, but at a higher cost due to material use and infrastructure investment. One of the challenges that printable electronics face is device quality optimization. While recent advances in solution-processed metal oxide thin film transistors (TFTs) have been impressive, most high-performance devices have been reported using spin-coating rather than additive manufacturing. Spin-coating is a useful technique for laboratory testing but is not industrially scalable. Ultimately, comparable performance needs to be achieved using techniques such as additive manufacturing for solution processed metal oxides to be commercially viable.

In this study, we compare device performance between inkjet printed and spin-coated metal oxide TFTs. The device under consideration is the indium oxide TFT, a material known to exhibit a high electron mobility in spin-cast TFTs. We study how conversion temperature, a critical parameter for compatibility with mechanically flexible substrates, affects performance in both sets of devices. We observe non-negligible differences in mobility and threshold voltage between the two deposition methods. For spin-coated devices, the mobility ranged from 5 cm^2/Vs to 9 cm^2/Vs going from thinner to thicker indium oxide layers. The thinner devices were more subject to defects which increased resistance against the carriers. The threshold voltage for solution processing ranged from -75 V to 10 V where the thickest layers have the lower voltages. This is likely due to trap states. This information will be critical for future efforts to optimize additive manufacturing processes for mechanically flexible electronics.

5:00 PM EL18.13.56
Facile Method for Crystallinity and Alignment Tuned Organic Semiconductor Layer through Solution Shearing Process Kibeom Nam, Dong Yun Lee and Kwang Woo Jeon; Kyungpook National University, Korea (the Republic of)

In this study, we introduce the patterning method for the thin film transistor with organic conducting materials. We exploited the flow coating method to control the physical and electronic properties of the conducting layer. Here, we demonstrate a high-performance Poly(3-hexylthiophene-2,5-diyl) regioregular (p3ht), and 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-PEN) as conducting film. It is because that both materials have a fine holes transfer property that it becomes a common material for various application such as organic field-effect transistors (OFETs) or organic photovoltaics (OPV). However, it is difficult to make them into a superb positive charge transfer layer. Because or that they need to form aromatic π- π stacking structures which allow holes hop to the adjacent polymer. To solve such problems, the flow coating system was adopted as a patterning method. The flow coating system is the solution shearing method that gives mechanical shear to solutions on a substrate. As solutions evaporat, the solutes moved toward the contact line to replenish the evaporated solvent and maintain the contact line due to the pinning force of the liquid on the substrate. With the movement of the blade, the solution also moved along the direction of the blade, leaving behind a tail of the meniscus. Such a process could control the stick-slip motion and the deposition volume of the solute. Therefore, various width of organic conducting patterns were fabricated within a minute. Furthermore, flow coating gave shear stress on the solution into a certain direction and it induced alignments of linear polymer chains. The aligned such as p3th showed an excellent electric property and its structures were measured x-ray diffraction. Clear (100) and (001) peaks mean regularly stacked parallel p3ht layers. To develop high-efficiency, cost-effective electronic devices, the technology that can print each element of the functional materials of the device without lithography is required. The solution shearing coating could be a powerful method to control the crystallinity of the organic semiconductor material and to improve the pattern and device efficiency below micrometer. The identification of the crystallization mechanism of organic materials that depends on the correlation between the coating speed, concentration, and gap size would be a core technology for next-generation organic semiconductors.

Targeted Nanomaterial Delivery via Self-Limiting Electrospray Deposition for Device Fabrication Michael Grzenda[1], Kelly Hughes[1], Maria Atzampou[1], Rachel Vladimirsky[1], Christopher E. Shuck[2], Yury Gogotsi[2], Jeffrey Zahn[1] and Jonathan P. Singer[1]; [1]Rutgers, the State University of New Jersey, United States; [2]Drexel University, United States

Electrospray deposition (ESD) uses strong electric fields to produce generations of monodisperse droplets from solutions/dispersions that are driven towards grounded targets. Self-limiting electrospray deposition (SLED) is a phenomenon recently discovered by our group in which targeted, 3D coatings can be achieved by spraying insulating polymers below their glass transition temperatures, which trap charge and repel incoming spray droplets. However, when conductive particles are added to SLED sprays to add functionalization, the buildup of charge required to repel incoming material becomes disrupted as particle loading increases. On the other hand, recent work from our group has shown that methylcellulose (MC) exhibits self-limiting behavior when sprayed from water/ethanol solutions and is capable of forming nanowire morphologies due to its fibril gelling behavior. By employing this unique material as a composite binder, we are able to separate conductive particles and prevent percolation with relatively low binder concentrations. We are also able to show that the morphology of these composites depends on the particle shape, size, and concentration, creating a high level of control over our deposited films. After spray, the MC can be removed which collapses the particles slightly into a connected network. Through this highly controlled spray regime, we are able to selectively target conductive and charge mobile substrates including metals and laser induced graphene, as well as nylon, high-humidity glass, and even plant material. Tested deposition materials include 2D MXene ($Ti_2C_3T_X$), ITO, and silver nanoparticles. All told, we demonstrate a novel and unique platform for upgrading flexible patterned substrates with high efficiency and low cost. As one example, we show that we can easily upgrade interdigitated electrodes patterned on flexible polyimide backings with MXene particles to vastly improve capacitance.

5:00 PM EL18.13.59
Aerosol Jet Printing of 3D Pillar Arrays from Photopolymer Ink Vitor Vlnieska[1], Evgeniia Gilshtein[1], Danays Kunka[2], Jakob Heier[1] and Yaroslav Romanyuk[1]; [1]EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]Karlsruhe Institute of Technology (KIT), Germany

An aerosol jet printing (AJP) printing head built on top of precise motion systems can provide positioning deviation down to 3 µm, printing volume as large as 20 cm x 20 cm x 30 cm, and five-axis freedom of movement. Typical uses of AJP are 2D printing on complex or flexible substrates, primarily for applications in printed electronics. Nearly all commercially available AJP inks for 2D printing are designed and optimized to reach desired electronic properties. In this work, we explore AJP for the 3D printing of free standing pillar arrays. We utilize aryl epoxy photopolymer as ink coupled with a cross-linking 'on the fly' technique. Pillar structures of 550 µm in height and with a diameter of 50 µm were printed. Pillar structures were characterized via scanning electron microscopy, where the morphology, number of printed layers and side effects of the AJP technique were investigated. Satellite droplets and over-spray seem to be unavoidable for structures smaller than 70 µm diameter. Nevertheless, reactive ion etching (RIE) was investigated as a post-processing step, and it can mitigate AJP side effects. AJP-RIE together with photopolymer-based ink can be promising for microstructure 3D printing, offering fast and maskless manufacturing process without wet chemistry development and heat treatment post-processing steps.

5:00 PM EL18.13.60
Higher Molecular Weight Polymer Yields Higher Performing Organic Electrochemical Transistors Lucas Flagg[1], Jonathan W. Onorato[2], Christine Luscombe[3,2] and Lee Richter[1]; [1]NIST, United States; [2]University of Washington, United States; [3]Okinawa Institute of Science and Technology, Japan

Organic Electrochemical Transistors (OECTs) are an important platform for benchmarking emerging applications in polymeric mixed ionic/electronic conductors. In such applications, the polymer semiconductor is swollen by the electrolyte, which leads to drastic changes in design rules compared to the more well understood alkyl-side chain polymers that have been studied for flexible electronic applications for the past few decades. Here we study the model mixed conductor poly(3-(methoxyethoxyethoxymethyl)thiophene) (P3MEEMT) as a function of molecular weight, thermal annealing, and regioregularity. We first show that OECT performance increases with increasing molecular weight. We next show that low molecular weights are unable to withstand even moderate thermal treatments. We hypothesize this is due to less inter-crystal connections in the lower Mn polymers and that this detrimental effect is enhanced in OECTs, compared to conventional Organic Field Effect Transistors (OTFTs), due swelling. Finally, we investigate the role of regioregularity on the OECT performance. Surprisingly, we find reduced regioregularity increases the volumetric capacitance of these films at the expense of carrier mobility. However, these competing effects tend to offset resulting in device performance that is largely independent of regioregularity. These findings will help establish design rules for novel polymeric mixed conductors going forward.

SESSION EL18.14: Flexible, Stretchable and Printed Energy Devices

Process Development of Flexible Thermoelectric Modules Based on Printing and Sintering Technology Lu-Cheng Hou, Shih-Yao Chien and Chien-Neng Liao; National Tsing Hua University | Taiwan (ROC), Taiwan

Thermoelectric generators (TEGs) that can convert environmental thermal energy into electricity are regarded as a potential solution to support the intermittent energy consumption of wearable devices and remote wireless sensors. Flexible TEGs (*f*-TEGs) based on printing technology have gained growing interests due to their design flexibility, ease of fabrication, and low cost. In this report, we have demonstrated a planar *f*-TEG with 8 pairs of Bi-Te based thermoelements prepared by dispenser printing and pressured sintering processes. The *f*-TEG can deliver a power of 68 μW under a temperature difference of 33 K. A modular assembly of 7 planar *f*-TEGs is sufficient to power a light-emitting diode and charge a 1.2 V NiMH battery. In addition to planar TEG configuration, a *f*-TEG with vertical thermoelement arrangement is also under development. The major issue associated with the vertical TEG fabrication is the poor electrical and mechanical contacts between Cu electrodes and thermoelements caused by gross interfacial reaction during the pressured sintering process. We have introduced a Pd/Ni composite barrier metallization in between the Cu electrode and the printed thermoelements by a selective chemical deposition method to resolve the contact issue. The influence of pressured sintering conditions on the microstructure and contact property of the Cu/thermoelements is investigated.

Thermocleavable Sidechains Prevent Phase Separation of Polymer Photovoltaic Blends in Extreme Desert Temperatures Nathaniel L. Prine[1], Haoyu Zhao[1], Andrew Bates[1], Guorong Ma[1], Stephanie Samson[2], Jordan Shanahan[2], Wei You[2] and Xiaodan Gu[1]; [1]The University of Southern Mississippi, United States; [2]University of North Carolina at Chapel Hill, United States

The morphology of organic photovoltaic (OPV) polymer blends remains unstable if exposed to temperatures above the combined glass transition temperature (T_g) of the OPV blend. Incorporating thermocleavable sidechains onto the backbone of polymer donors enables the solution processability of the blend while reserving the option to cleave those sidechains from the backbone thermally. Cleaving the sidechains drastically slows chain dynamics by raising the polymer backbone's Tg and preventing the morphology from shifting toward equilibrium. In this work, a polythiophene polymer donor featuring cleavable sidechains (P3ET) is blended with a PCBM small molecule acceptor and examined to determine the effect of cleavage on morphology. The blend is examined pre- and post-cleavage using atomic force microscopy paired with infrared spectroscopy (AFM-IR) to determine the nanoscale composition of the topography. First, we studied the effect of cleavage temperature on BHJ morphology. We observed that thermal cleavage at 140 ^{0}C, near the donor's crystallization temperature, induces undesired crystallization of the donor and drives large phase separation. In contrast, the blend annealed at 200 ^{0}C allowed efficient cleavage and exhibited similar morphology to the as-cast film, albeit some dewetting occurs. For long-term stability measurements, the sidechains were cleaved entirely from the backbone by heating the blend at 200 ^{o}C for two hours. We demonstrated that after cleavage, the sample was stable over a long period of thermal stress (e.g. 100 ^{o}C over multiple days) without significant changes in morphology. Overall, incorporating thermally-cleavable sidechains onto a polymer electron donor is a suitable strategy for preventing significant morphology shifts in OPV blends exposed to temperatures up to 100 ^{o}C.

8:30 AM EL18.14.03
High-Performance, Stretchable Thermoelectric Generators with Reduced Internal Resistance for Fully Untethered Wearables Dongju Jang[1], Hyeon Cho[1], Jinsu Yoon[1], Byeongmoon Lee[2], Seungjun Chung[2] and Yongtaek Hong[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Emerging sustainable energy sources are keys to realizing the concept of Internet of Things (IoT), precluding the necessity of human interference and extending the potential of electronics towards self-powered and fully-automated systems. Among various candidates, thermoelectric energy generators (TEGs) represent a promising technology for implementing such systems due to their ability to convert waste heat into electricity.

Stretchable TEGs have recently been developed for efficient energy harvesting from shape-changing, arbitrary-shaped heat sources such as the human body. Moreover, integrated platforms with high-performance conventional thermoelectric (TE) materials and soft electrodes have been widely explored with the rising demand for high-performance soft and stretchable TEGs for practical applications. However, previously reported TEGs of such forms have displayed low power generation capacity due to poor interfacial properties between rigid-soft materials and unsatisfactory electrical and thermal performance of soft components.

In this presentation, we will report facile and effective strategies to improve the TE performance of stretchable TEGs for low power, wireless and wearable applications. First, functional interlayers that bridge discrete electromechanical properties at the rigid-soft interface are introduced into the platform using a scalable approach. Second, a solution-based welding method [1] is applied to generate a highly conductive stretchable electrode based on a volumetrically connected network of one-dimensional metal nanowires. Third, intrinsically soft thermal conductors are incorporated into the soft substrate to match the thermal impedance between the TEG and heat source [2]. Such techniques effectively resolve the issues in previously reported high-performance stretchable TEGs and enhance the power generation capacity by 540 % of the original value of a reference TEG. This corresponds to the highest normalized power density of ~1.48 μW cm^{-2} K^{-2} when excluding the applied temperature and device dimensions for accurate comparison. These results highlight the viability of our strategies to realize high-performance stretchable TEGs for self-powered wearable applications. The detailed methods and results will be discussed at the conference.

Tunable Thermoelectric Performance of Thin-Film Multilayered PEDOT:PSS for Flexible Devices Tzu-Yi T. Yu, Bokai Zhang, Hasan Emre Baysal and Francisco Molina-Lopez; KU Leuven, Belgium

Power supply is a main challenge for wearable electronics and thermoelectric generators (TEGs), which directly convert a temperature difference into electrical power, are a promising solution. Owing to their great mechanical flexibility, material abundance, printability, and low toxicity, TEGs based on organic materials (OTE) show greater potential than their inorganic counterpart to power wearable devices. Among the OTE materials, PEDOT:PSS exhibits one of the best thermoelectric performance. The performance of thermoelectric materials/devices is usually evaluated by the power factor, which is the product of electrical conductivity to the square of the Seebeck coefficient. Many strategies – such as using secondary dopants, post-treatments, and morphological alignment – have been reported to boost the power factor of PEDOT:PSS via increasing the electrical conductivity. However, thus far, the only method to increase the Seebeck coefficient of PEDOT:PSS is de-doping it by the addition of reductive agents. However, de-doping strongly harms the electrical conductivity, which limits the strategies for TEGs design. Herein, we demonstrate a new structure-based approach to improve the Seebeck coefficient of PEDOT:PSS without strongly degrading its electrical conductivity. Inspired by the energy filtering effect used in inorganic TEs, our approach consists of the fabrication of a thin-film multilayer stack that promotes the interfacial scattering of the low-energy carriers detrimental to the Seebeck effect. Optical spectroscopy and X-ray scattering techniques will be used to study the oxidation level and morphology of the produced stack, shedding light on the structure-performance relationship in the material and paving the way to the optimization of the thermoelectric performance. To demonstrate the suitability of our approach for wearable devices, a flexible version of the multilayered material will be produced.

9:00 AM *EL18.14.05
A soft future - From Electronic Skins and Triboelectric Nanogenerators to Autonomous Wearables and Soft Robots Ying-Chih Lai; National Chung Hsing University, Taiwan

Deformable and wearable soft devices (including sensors, electronics, and machines) have attracted huge interest because they cannot only extend the scope of smart systems but also provide compliant and safer user experience. Operating those devices inevitably need power sources. However, traditional batteries suffer from heavy weight, bulky volume, and limited capacity and lifetime, hindering the practical uses of those emerging devices. Toward the soft future, it is necessary to explore new energy and electronics technology. In this talk, deformable and mechanically-durable energy-harvesting nanogenerators will be demonstrated for not only serving as new energy providers but also self-powered e-skin uses. First, super-stretchable triboelectric nanogenerators will be presented for generating electricity by contacting with other materials regardless of various extreme deformation required from uses, such as extreme stretching, multiple twists and folds. Surprising, even experiencing severe tearing damages, the device can retain its functionality. Such technology can be introduced into fabrics for wearable energy and sensing uses. Then, we will discuss the use in self-powered and deformable electronic skins that can actively sense proximity, contact, and pressure to external stimuli via self-generating electricity. The perfect integration of the tribo-skins and soft actuators enables soft robots to perform various actively sensing and interactive tasks including actively perceiving their muscle motions and working states, checking baby diaper conditions, and even detecting subtle human physiological signals. The self-generating signals enable visual communication and can be processed for diverse sophisticated uses. Then, let’s imagine a self-healing robotics in science fiction turning into reality. We will show you a self-healing, highly-transparent, and super-stretchable device with energy-extracting and activity-sensing abilities. Finally, a new energy harvesting technology that can convert ambient electromagnetic energy into available electricity for soft devices will be presented. These works will inspire you lots of great ideas and show tremendous potentials of wearable/stretchable/deformable electronics, artificial e-skins, smart interfaces, and soft robots.

9:30 AM EL18.14.07
All-Solid-State Printed Graphene Aerosol Gel - Polymer Energy Storage Devices for Flexible and Twistable Electronics Suprem R. Das, Kh M Asif Raihan and Surjit Sahoo; Kansas State University, United States

The continual evolution and rapid implementation of smart electronic appliances and many microelectromechanical systems have led to growing interest in developing micro or nanoscale power sources [1]. With exceptional electrochemical performances such as rapid charge-discharge rate, prolonged cycle life, and ultrahigh power density, supercapacitors (SCs) possess substantial potential as an effective energy storage device, as an alternate storage framework, besides batteries. However, conventional SCs are too bulky to combine with micro-scale electronic devices. Therefore, the design and manufacture of high-end micro-scale SCs, known as micro-supercapacitors (MSCs), with desired device dimensions (of the order of few centimeters/millimeters) and high-performance metrics are needed [2]. During last few years, considerable efforts have been dedicated to fabricating 2D planar interdigitated configuration patterns for MSCs using inkjet printing techniques due to their geometric flexibility and wearable applications [3]. Herein we designed the inkjet-printed graphene aerosol interdigitated electrodes based on flexible all-solid-state MSCs with highly stable and reliable energy storage performance. The fabricated graphene aerosol-based solid-state MSC obtained a high volumetric specific capacitance of 376.63 mF cm^{-3} (areal specific capacitance of 76.23 μF cm^{-2}) at the applied current of 0.25 μA with excellent cyclic stability (~99 % of capacitance retention over 10000 cycles). Further, MSCs with modular connections in series and parallel were made to achieve tunable operating voltage and capacitance output. To elucidate the mechanical flexibility of the as-fabricated MSC, the electrochemical performances of the graphene aerosol-based solid-state MSC under different bending and twisting states and results in outstanding mechanical flexibility. The electrochemical performance of as-fabricated graphene aerosol-based all-solid-state MSC creates a promising way to develop highly scalable and reliable future miniaturized energy storage devices for integrated wearable electronics.

A Smart Wound Dressing with Self-Powered Electrical Stimulation and Monitoring Capabilities Zong-Hong Lin[1,2]; [1]National Taiwan University, Taiwan; [2]National Tsing Hua University, Taiwan

Electrical stimulation based therapy are known to accelerate the healing of the chronic wounds. However, its usage is limited by requirement bulky power-consuming sources that definitely requires patient hospitalization. To resolve these constraints, we have developed a self-powered multi-functional wound dressing which can be activated by both triboelectric and thermoelectric effect. The integrated electrodes are connected to wearable nanogenerators to provide electrical stimulation for accelerated wound closure. The dressing is coated with thermocatalysts to kill the bacteria in the wound owing to the formation of reactive oxygen species. In addition, a wireless measurement module was incorporated into the system to realize remote wireless monitoring of wound recovery in a non-invasive way. The reported self-powered dressing holds great potential in facilitating personalized and user-friendly wound care with significantly improved healing and monitoring outcomes.

Autonomous Self-Healing Strategy for Deformable Electronics Based on Ionic Copolymer-Mediated Ion Clusters Yong Min Kim and Hong Chul Moon; University of Seoul, Korea (the Republic of)

Implementing self-healing capability on a deformable platform is one of the critical challenges for achieving future wearable electronics with high durability and reliability. Moreover, self-healing materials are expected to maximize the utility of electronic equipment in extreme conditions not easily accessible to humans, such as the space and deep-sea. Nonetheless, most systems required external energy (e.g., heat or UV) to promote polymeric chain mobility and to be quickly and completely healed, irrespective of the utilization of covalent and non-covalent bonds. In this work, we propose an innovative self-healing process driven by the rapid dynamic formation/dissociation of ion clusters (ICs). The novel aspect of this work lies in (1) achieving record-high self-healing performance (efficiency > 90% even in 1 min at 25 °C), with no energy injection, (2) overcoming the conventional trade-off between mechanical robustness and healing performance present in previously reported systems, (3) unveiling underlying fundamental science related to IC-driven mechanism that does not require significant movement of polymeric chains for self-healing, and (4) successful demonstration of a new future electronics platform, “reconfigurable electronics”, which can change shape according to the users’ demands through a cutting/healing protocol. Overall, the present results highlight the high potential impact of self-healable ionoconductor and provide insights into future electronics platforms.

Tailoring Auxetic Mechanical Metamaterials of Strain-Engineered Transparent Elastomeric Substrates for Distortion-Free Stretchable Display Jun-Chan Choi[1], Jae-Hong Sun[1], Seunghyun Lee[2] and Seungjun Chung[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University of Science and Technology, Korea (the Republic of)

Form factor innovation is essential for the future of display technology. Representatively, flexible, foldable, and rollable displays shed light on various electronic devices such as monitors, smartphones, and smartwatches by allowing a high degree of design freedom. Recently, stretchable displays, evaluated as the end point of shape-deformable display technology, are attracting attention as the next-generation display technology. Due to their free-form deformability, stretchable displays can be combined with various future electronic applications such as wearable electronics, biosensors, and robots to expand the application fields of display technology. From an actual application perspective, it is desirable to exhibit a stable tensile/recovery deformation in the range of about 30% and use transparent elastomeric polymers having a relatively low Young's modulus as substrate materials. However, elastomeric materials inherently have a Poisson's ratio of ~0.5, which is defined as the ratio of transverse strain to longitudinal strain resulting in compressive strain in the direction perpendicular to the tensile direction. When the substrate deformation by the Poisson’s effect occurs in stretchable displays, undesirable image distortion, so it has to be addressed to provide accurate information. Here, we propose a strain-engineered transparent elastomer composite as a substrate of stretchable displays. To control the Poisson's ratio of the stretchable substrate, a relatively rigid mechanical metamaterial frame was embedded into the elastomeric matrix material. Among various mechanical metamaterial structures, a ribbon-shaped auxetic structure was employed with the consideration of both display pixel movement and bidirectional independent deformation control under stretching conditions. According to the tensile direction of the stretchable substrate, both intrinsic tensile deformation of the elastomer and the structure-dependent deformation occurred simultaneously in a complex manner, and it was possible to realize the biaxially zero Poisson's ratio by overcoming the deformation limit of the existing mechanical metamaterial. As a result of quantitatively evaluating the tensile axis-dependent Poisson's ratio according to the Young's modulus ratio of the frame and the matrix materials, when Young's modulus deviation was about 20 times, the Poisson's ratio (< 0.1 irrespective of the tensile axis) was significantly reduced compared to that of the pristine elastomer substrates. In addition, by matching the refractive indices between the heterogeneous elastomer materials used for the frame and the matrix, the scattering effect caused by the refraction of the light incident on the substrate was suppressed, thereby showing excellent light transmittance (~87% in the visible range) and visibility. Our work will provide a key pathway to demonstrate the programmable deformation of stretchable platforms overcoming the Poisson’s effects of conventional elastomeric substrates, which is necessary to realize further reliable stretchable display applications.

SESSION EL18.16: Flexible and Stretchable Devices III

1:30 PM *EL18.16.01
A Processable, High-Performance Dielectric Elastomer and Multilayering Process Erin Askounis[1], Ye Shi[1], Roshan Plamthottam[1], Tom Libby[2], Zihang Peng[1], Kareem Youssef[1], Junhong Pu[1], Ron Pelrine[2] and Qibing Pei[1]; [1]University of California, Los Angeles, United States; [2]SRI International,

United States

Dielectric elastomers (DEs) can act as deformable capacitors that generate mechanical work in response to an electric field. DEs are often based on commercial acrylic and silicone elastomers. Acrylics require prestretching to achieve high actuation strains and lack processing flexibility. Silicones allow for processability and rapid response but produce much lower strains. In this work, a processable, high-performance dielectric elastomer (PHDE) with a bimodal network structure is synthesized, and its electromechanical properties are tailored by adjusting cross-linkers and hydrogen bonding within the elastomer network. The PHDE exhibits a maximum areal strain of 190% and maintains strains higher than 110% at 2 hertz without prestretching. A dry stacking process with high efficiency, scalability, and yield enables multilayer actuators that maintain the high actuation performance of single-layer films.

2:00 PM EL18.16.02
A Nanomesh Skin-Sensor that Rapidly Learns Hand-Based Tasks with Limited Trials Kyun Kyu Kim and Zhenan Bao; Stanford University, United States

With the help of machine learning, electronic devices — including gloves and electronic skins — can track the movement of human hands and perform tasks such as object and gesture recognition. However, such devices can be bulky and lack an ability to adapt to the curvature of the body. Furthermore, the existing models for signal processing require massive amounts of labelled data for individual tasks and users.
Here, we report a nanomesh receptor that is integrated with an unsupervised meta-learning scheme and can be used for data-efficient user-independent recognition of different hand tasks. The nanomesh is based on biocompatible materials and can be directly printed onto the skin without the need for an external substrate, which improves user-comfort and avoids potential substrate mechanical constraints. The system can translate skin stretches into proprioception information, analogous to the way cutaneous receptors provide feedback for hand. With the approach, complex proprioceptive signals can be decoded using a single sensor along the index finger, without the need for a multi-sensing array. Highly informative multi-joint proprioceptive information can thus be produced in low-dimensional data, reducing computational processing time of our learning network. Our learning framework does not require large amounts of data to be collected for each individual user. We develop a time-dependent contrastive learning algorithm to provide an awareness of temporal continuity and to generate a motion feature space. Our system pretrains unlabelled signals collected from three different users to distinguish user independent, task specific sensor signal patterns from random hand motion. We show that the pretrained model can quickly adapt to different daily tasks —motion command, keypad typing, two-handed keyboard typing, and object recognition — using only a few personal hand signals. Towards More Sustainable Organic Electronics Julianna Panidi, Martina Rimmele, Nicola Gasparini and Martin Heeney; Imperial College London, United Kingdom

Organic semiconductors are an emerging class of materials with various optoelectronic applications. The high commercialization potential of this technology is evidence by few companies that have already launched their products into the market or working towards this goal. More specific, organic solar cells have recently attracted immense attention due to the development of a new family of semiconductors which allows highly efficient light harvesting in both indoor and outdoor conditions. In addition, solution processed organic photovoltaics in conformable substrates have been recently demonstrated, which broadens the applications range. Solar cells can now be part of the Internet of Things ecosystem by light harvesting and delivering enough output power to drive microelectronics. One currently limitation, though, is the use of not eco-friendly solvents and materials during the device development stages. Most of the organic electronic devices require halogenated and non-halogenated aromatic solvents during their fabrication. For large scale production and further commercialisation, this is a key limitation. This arise from the fact that organic semiconductors are highly soluble in this category of solvents, which are often carcinogenic or toxic to the human reproductive systems, as well as inducing negative impact on the environment.

Here we will show high performing organic solar cells developed from novel more sustainable organic semiconductors (in terms of less waste during synthesis and less energy consumption) as well as eco-friendly solvents. In particular, solvents derived from biomass have been explored for their application in delivering high performing organic photovoltaics. Eco-friendly flexible organic solar cells have also been developed on natural transparent materials. Electrical device characterisation and morphological studies were conducted in order to evaluate their performance. Overall, this work highlights the importance of replacing harmful chemicals and materials in the organic electronics fabrication stages, which it will result in faster and wider commercialisation and create new market opportunities.

2:30 PM EL18.16.04
Stretchable Light-Emitting Electrochemical Cell Fabricated by Spray Coating Sandra Gellner[1,2], Etienne Auroux[2], Ekaterina Nannen[1] and Ludvig Edman[2]; [1]University of Applied Sciences Niederrhein, Germany; [2]Umeå University, Sweden

The prospect of a stretchable light-emitting device is attractive since it enables a wide variety of applications that require adaptability to a dynamic environment. The light-emitting electrochemical cell (LEC) is a promising technology in this regard, due to its simple three-layer device architecture and its inherent tolerance to local active-material thickness variations. The latter advantages also render the LEC suitable for a scalable and low-cost solution-based fabrication. A number of reports on stretchable LECs have been reported,[1–3] but they either employ a poorly scalable spin-coating fabrication of the active material or a lamination of the top electrode on top of the active material. This renders the fabrication wasteful with materials and expensive and results in a poor long-term stability because of delamination issues. Here, we report on a material-efficient and lamination-free fabrication of the entire stretchable LEC structure, including both electrodes, using scalable spray coating under ambient air.

The global market for printed, flexible and organic electronics is dominated by the display industry. Innovation is needed to increase screen resolution and displayable colour space in solution-processed displays. This requires the development of new printing methods and light-emitting material systems. The compatibility of solution-based materials with such scalable fabrication techniques has driven research towards new devices within the field of organic and hybrid optoelectronics.

The European Union's Horizon 2020 funded project *Hi-Accuracy* aims at developing high-resolution printing technologies to target a fully printed electroluminescent display incorporating quantum dots (QDs) as the light-emissive material [1]. This includes both the so-called front plane, which incorporates the luminescent components, as well as the so-called back plane, which incorporates the tiny electrical logic elements under each pixel.

QDs have found increasing use in display applications because of their high colour purity and fluorescence quantum yield, enabling devices with higher brightness and efficiency. But in order to access large-area printing and coating methods in ambient conditions, it is necessary to, firstly, move away from toxic cadmium [2], and secondly, to target materials that are air-stable. We have synthesised a new zinc selenide-based blue QD material which can be used in fully air-processed light-emitting diodes (LEDs) [3].

Multi-shell-structured ZnSeTe/ZnSe/ZnS (core-shell-shell) QDs show pure deep blue / purple fluorescence emission with a high photoluminescence quantum yield of 98%. Using these materials, LED devices are fabricated in ambient air conditions in a conventional structure with bottom light emission. The analysis of electron-only and hole-only devices using the same materials confirm the underlying transport mechanisms.

The QD-LED devices show maximum luminance of 3000 cd m^{-2} at 7 V with a turn-on voltage of 3 V and current efficacy of 0.6 cd A^{-1}. These results show for the first time air-processed and Cd-free QD-LEDs and pave the way for scaling display applications in order to move towards high-performance electronics [3].

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 862410 (HI-ACCURACY).

Omni-directional Deformable Shear Sensor with Shear-Pressure Decoupling by Analyzing Frequency-Dependent Ion Dynamics Wonjeong Suh, Jaehyun Kim, Yebin Park, Dongbeom Kim and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

Artificial tactile sensor realizes touch by mimicking human skin and receptors. They have been used for healthcare monitoring devices, human-machine interfaces, and artificial skin for robots. Especially, this sensor is attached to the robot's skin and recognizes the stimuli, as if it was felt by a human. When human grabs an object, they feel applied normal and shear force and control the pressure to prevent the object from breaking or falling. To realize this delicate grasping motion in the robot, a shear force sensor is essential. However, the shear force sensor is structurally complicated because the electrode must be configured in a three-dimensional structure to recognize the force applied horizontally. Moreover, during the grasping motion, also minimal pressure is applied so that both pressure and shear force need to be recognized.

Herein, we fabricated an ionic conductor-based soft sensor that can detect pressure and shear force separately. In an ionic conductor, various information can be obtained because the behavior of ions varies depending on the frequency. To use these advantages, the ion gel is placed between a hemispherical upper electrode and a flat lower electrode. The pressure is measured in low frequency to detect the electrical double layer(EDL) capacitance between the ion gel and the dome-shaped upper electrode, and the shear force is perceived in high frequency to detect bulk resistance of the ion gel. Therefore, with only ion gel, the sensor can perceive and differentiate pressure and shear force in different frequencies. Furthermore, the sensor can recognize shear force in any direction with 1 x 4 electrodes. Finally, the sensor can perceive various grasping in any direction and even delicate gestures such as opening a bottle cap.

Two-Dimensional Graphene and MXene Electrodes for Flexible and Stretchable Optoelectronics Huanyu Zhou[1], Shin Jung Han[1], Yury Gogotsi[2] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Drexel University, United States

Two-dimensional (2D) materials such as graphene and MXenes have great potential applications in a variety of flexible and wearable optoelectronic devices as a replacement for conventional brittle indium tin oxide electrodes. However, the practical applications of such materials have been limited due to the high charge injection barrier at the electrode and organic interfaces. Here an environmentally stable MXene conductive electrode with high conductivity and work function (*WF*) = 5.84 eV was demonstrated; this provides the solution to the poor environmental stability of MXene thin films without sacrificing electrical properties. Besides, to tackle the charge injection problem occurred at the one-dimensional metallic nanowire/organic interfaces, a graphene layer was introduced on top of silver nanowire percolation networks to form a complete two-dimensional contact stretchable electrode (TCSE). The graphene layer significantly modifies the work function, promotes charge spreading, and impedes the inward diffusion of oxygen and moisture. Unprecedently, the low *WF* of 3.57 eV is achieved by forming a strong interfacial dipole after deposition of a newly-designed conjugated polyelectrolyte on the TCSE, which significantly facilitate the electron injection property. We have demonstrated intrinsically stretchable organic light-emitting diodes (ISOLEDs) with a record efficiency of 20.3 cd/A. These works lay a solid platform and provide a general guideline for designing highly-efficient flexible and stretchable optoelectronic devices.

Fermi-Level Pinning in Organic Thin-Film Transistors Tobias Wollandt, Kathrin Küster, Sabrina Steffens and Hagen Klauk; Max Planck Institute for Solid State Research, Germany

Organic thin-film transistors (TFTs) are of interest for flexible electronics applications, such as flat-panel displays and sensors. An important performance parameter is the transit frequency, which is the highest frequency at which the TFTs are able to amplify electrical signals. The transit frequency is determined by several parameters, including the intrinsic channel mobility, the channel length, the gate-to-contact overlaps, and the contact resistance. It can be shown that in organic TFTs that have an intrinsic channel mobility of at least 5 cm^2/Vs and critical dimensions of a few microns, the transit frequency is limited almost entirely by the contact resistance. This implies a significant incentive for reducing the contact resistance to improve the dynamic TFT performance.

The contact resistance is determined mainly by the energy-level alignment at the interface between the semiconductor and the source/drain contacts, and (in the case of TFTs fabricated in the inverted coplanar device architecture) by the thin-film morphology of the semiconductor on the contact surfaces [Adv. Mater. **32**, 2104075, 2022]. Functionalizing the contact surfaces with a chemisorbed monolayer (e.g., a thiol) prior to the organic-semiconductor deposition can be helpful in improving the semiconductor morphology and in adjusting the Fermi level of the contacts by introducing an interface dipole. In principle, this dipole lowers the Schottky barrier between the Fermi level of the contact and the transport level of the semiconductor, thereby reducing the contact resistance. For TFTs fabricated on flexible polyethylene naphthalate (PEN) substrates using the small-molecule semiconductor diphenyl-dinaphthothienothiophene (DPh-DNTT) and gold source/drain contacts functionalized with a monolayer of pentafluorobenzenethiol (PFBT), we have measured an average contact resistance of less than 100 Ωcm (and an intrinsic channel mobility of 9 cm^2/Vs, a subthreshold swing of 65 mV/dec, a threshold voltage of -1 V, and an on-off current ratio above 10^8).

Perfect energy alignment at the interface between metal contacts and an organic semiconductor is, however, often prevented by a pinning of the Fermi level to the energy of localized electronic states in the semiconductor. Measurements have shown that any work-function changes induced by functionalizing the contacts with a thiol are eliminated once the organic semiconductor is deposited. Further significant reductions of the contact resistance will thus require that the Fermi level is depinned to allow energy-level alignment.
A promising approach to depinning the Fermi level is to introduce an interlayer between the metal and the semiconductor in order to decouple the metal from the localized states in the semiconductor. To investigate the effectiveness of this approach in organic TFTs, we fabricated DPh-DNTT TFTs using a wide range of interlayer materials. The interlayers and the organic semiconductor were deposited by thermal sublimation in vacuum. The interlayer thickness was limited to a few nanometers to balance the beneficial effect of charge decoupling and the detrimental effect of the tunneling barrier.

In the literature, it has been suggested that in the case of p-channel TFTs, the interlayer needs to have a large ionization energy [Adv. Electron. Mater. **6**, 1901352, 2020]. However, we have found that a high ionization energy alone is insufficient and that other factors, including the semiconductor morphology, the interlayer thickness and possibly electronic interactions such as doping must be considered. For some interlayer materials, we have observed a substantial reduction in contact resistance compared to TFTs without any interlayer (contact resistance as small as 15 Ωcm in TFTs fabricated using a 2-nm-thick tetratetracontane interlayer), but a clear correlation to the ionization energy of the interlayer remains elusive.

4:15 PM EL18.16.09
UV-light Monitor Based on Poly (vinyl alcohol)/Titanium Oxide Hybrids Abdulaziz Aldubayan and Natalie Stingelin; Georgia Institute of Technology, United States

Exposure to ultraviolet (UV) radiation can have a profound impact on human health, as about 90 precent of nonmelanoma skin cancers are associated with exposure to UV radiation, and more than 9,500 people are diagnosed with skin cancer every day in the United States. The excessive UV rays damage DNA in skin cells, and produce genetic mutations that subsequently lead to skin cancer and premature ageing. Yet, controlled quantities of UV rays offer several benefits, such as the production of vitamin D and treatment of various inflammatory skin diseases including eczema, psoriasis, and atopic dermatitis. We present, here, a highly versatile, eco-friendly and mechanically flexible UV sensor able to detect and measure harmful UVB rays. The sensor utilizes the dielectric constant change due to the formation of Ti^{+3} (from Ti^{+4} to Ti^{+3}) in poly (vinyl alcohol)/titanium oxide hydrates organic:inorganic hybrid materials upon irradiation, to provide instantaneous and cumulative analysis of property change upon UV light exposure. Thus, our work not only demonstrates a sustainable system to UV detection but also opens a new versatile and mechanically robust materials class towards an inexpensive reusable wearable device to help monitor personal recommended UV doses.

4:30 PM EL18.16.10
2D/3D Printed Metal Oxide Transistors Gabriel Cadilha Marques, Pooja Arya, Ben Breitung, Jasmin Aghassi-Hagmann and Hongrong Hu; Karlsruhe Institute of Technology, Germany

Metal oxide based nanoparticle inks allow to print electronic devices such as thin film transistors processed at low temperatures (around 100 °C). In addition, 3D printed assist structures can help to define key dimensions such as the width of inkjet printed transistors. The combination of 2d inkjet printing and laser printing of 3D structures based on two photon polymerization can yield novel device architectures that allow to reduce the variability in particular of important parameters such as the threshold voltage and enable small channel length smaller than 10 um. In addition to novel device architectures p-type oxides are explored with a matching performance to their n-type counterparts. This would improve the performance and power efficiency of CMOS type oxide circuits.
Along these lines transistors with In_2O_3-semiconducting nanoparticles printed into a 3D laser written polymer reservoir with 10 um height are presented. Electrical characteristics are discussed including transfer and output curves as well as FIB cuts and cross-sectional SEM images. Our devices show high Ion currents in the range of several hundreds of µA for typical widths of few hundreds of micrometers.
Furthermore, the performance of p-type based oxide semiconductors is improved by element doping. Thereby, copper oxide is doped with magnesium to improve the electronic band structure of pristine copper oxide. The magnesium improves the bonding between anions in the conduction band maximum, lowering the effective mass of holes and hence increasing the mobility of p-type oxide materials. The doped copper oxide compounds are based on nanopowders that are formulated into nanoparticle inks. This will enable to print high performance p-type oxide semiconductors at low temperatures.
In summary, the presented work will pave the way for high performance printed oxide based transistors with stable threshold voltages that can be used for reliable complementary circuits in printed electronics.

Efficient and Stable Organic Solar Cells with PM6:Y6-Based Photoactive Layer Enabled by p-Type Doping Nara Han, Yina Moon, Dongseong Yang and Dong-Yu Kim; Gwangju Institute of Science and Technology, Korea (the Republic of)

The introduction of molecular doping process is necessary to enhance the optic and electronic properties of organic semiconductors for facilitating charge transport. In particular, since the doping process has a positive influence on the charge transfer interaction between the host semiconductor and dopant, improved mobility has been efficiently achieved via these doping methods using p- or n-type dopants. Despite its advantages, doping technologies in organic solar cells (OSCs), which are generally known to have better hole mobility, are restricted to the development of n-type dopants used for balancing the electron and hole as increasing the electron mobility. In addition, since the bulk-heterojunction (BHJ) microstructure in OSCs has randomly blended phases of the donor and acceptor, it is important to optimize charge extraction without loss by controlling the morphology. In this study, we report OSCs by p-type doping with formic acid into a BHJ photoactive layer comprised of PM6 and Y6. The resulting champion device yields a significantly improved power conversion efficiency from 14.3% to 15.3% with a high fill factor of 71.7%. It is found that the p-doped photoactive layer exhibits enhanced conductivity, carrier mobilities, and suppressed charge recombination. The p-type dopant, formic acid, also acts as a film morphology modifier of the photoactive layer with enhanced phase separation to transport the charge efficiently. This work demonstrates that controlling the charge transport via introducing a small amount of dopant into the devices with not-only small-area but also printed large-area photoactive layers is a promising strategy for further improvement of device efficiency and stability in OSCs.

8:15 AM EL18.17.02
Flexible Capacitive Pressure Sensor based on Dielectric Nanocomposite of Porous Polydimethylsiloxane and Zinc Oxide Nanowire Liang-Cheng Shih, Chih-Chun Hsiao and Gen-Wen Hsieh; National Yang Ming Chiao Tung University, Taiwan

Elastomeric polymer films, owing to their flexibility, chemical resistance, biocompatibility and low cost with ease of fabrication, have became a popular choice of stress-sensitive dielectric layers for flexible and wearable pressure sensors. However, the pressure response of these flat polymer films is rather poor to tiny pressure change, and also insensitive to large applied pressure. Finding a flexible dielectric film that can be operated in a wider pressure range (e.g., from a few Pa to tens or hundreds KPa) remains a crucial challenge.

Toward this task, we propose the polymer-based dielectric nanocomposite based in porous polydimethylsiloxane and zinc oxide nanowire for capacitive pressure sensing. We anticipate that the porous matrix can improve the compressibility of the nano composite film, meanwhile, the incorporated nanowire can increase the dielectric permittivity. Primary results shows that the zinc oxide nanowire-porous polydimethylsiloxane capacitive pressure sensor exhibits an enhanced sensitivity of 21-100 times (in different pressure range) compared with that of flat, pristine polydimethylsiloxane device. Moreover, an ultra-low detection limit of 1 Pa, and remarkable pressure response behavior during 4000 pressing cycles can be archived. To sum up, this proposed strategy may provide broad application prospects in wearable electronics, health monitoring, and intelligent artificial robots/prosthetics.

8:30 AM EL18.17.03
Effects of Substituted Alkyl-Chain Length and Substitution Position in High Performance Organic Semiconductors—Case of *mono*-Alkylated-BTNTs. Satoru Inoue[1], Toshiki Higashino[2], Mutsuo Tanaka[3], Ryo Miyata[1], Shunto Arai[1], Hiroyuki Matsui[4], Sachio Horiuchi[2], Reiji Kumai[5], Seiji Tsuzuki[1] and Tatsuo Hasegawa[1]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]Saitama Institute of Technology, Japan; [4]Yamagata University, Japan; [5]Institute of Materials Structure Science, High Energy Accelerator Research Organization (KEK), Japan

Solution-processable organic semiconductors (OSCs) are mostly composed of π-electron cores bonded with functional substituents. It was recently shown that normal alkyl-chain substitutions of rod-like π-cores are useful for obtaining high-performance OSCs as used in printed organic thin-film transistors (TFTs). It was demonstrated that self-organized alkyl-chain layers play essential roles in enhancing the layered crystallinity, which contributes to the formation of perfectly aligned semiconductor-insulator interfaces in the TFT device structure. In particular, one-sided unsymmetric substitution of semiconductive π-core, such as benzothieno[3,2-*b*][1]benzothiophene (BTBT), with an alkyl chain allows the formation of a *bilayer-type* layered herringbone packing (*b*-LHB), eventually enhancing the layered crystallinity. We suggest that such alkyl-chain substitutions should be effective for many other extended π-cores, though the application of this strategy has been limited so far.
In this study, we investigated the effect of substituted alkyl chain length and substituting positions on the structure-property relationships of high-performance and solution-processable OSCs of *mono*-alkylated-benzothieno[3,2-*b*]naphtho[2,3-*b*]thiophene (*mono*-C$_n$-BTNT). As the extended π-electron core of BTNT does not have inversion and mirror symmetry, we could select four unique (or independent) substituting positions at the peripheral positions of the rod-like π-core for the alkyl-chain substitutions, with roughly keeping the rod-like molecular shape over the whole molecule.
As a result, we found that the four kinds of regioisomers of *mono*-C$_n$-BTNT afford isomorphous *b*-LHB-type crystal packings. The intralayer herringbone arrangement of the BTNT cores are almost the same for all the regioisomers, while the all-trans chain planes of the substituent form two kinds of interchain ordering. Such difference affects the crystal stability correlated with the solubility, thermal property, and TFT device performance. Among them, the *mono*-C$_n$-BTNT substituted at the most peripheral position form the most stable crystal packing, and the stability is more enhanced with increasing the alkyl chain lengths. In particular, we found that a TFT device based on the *mono*-C$_n$-BTNT shows much higher intrinsic field-effect mobility that reaches as high as 14 cm^2/Vs. We will discuss the structure-property relationship in various *mono*-C$_n$-BTNTs based on the variation of crystal packings as revealed by full crystal structure analyses of all the compounds.

A Neuron-readable Artificial Photoreceptor Composed of Photodeformable Liquid Crystal Polymers and Piezoelectric Materials Yanlei Yu, Bo Peng, Jia Wei, Guodong Zhu and Lang Qin; Fudan University, China

Artificial photoreceptors have been extensively developed to help the patients with serious eye diseases by conversion from light into electric signals. The researchers focus on the development of intelligent materials and novel mechanism in the new-generation photoreceptors to simplify the camera visual systems like Argus II. Photovoltaic materials such as cadmium sulfide nanorods, single-crystalline silicon photodiodes output photoelectric signals by the generation and migration of the photocarrier, but the reactive oxygen generated in photoelectrical conversion process is concerned in cytotoxicity and limits the organism application. Pyroelectric materials such as ZnO, poly(vinylidene fluoride-co-hexafluropropylene) are used for electric power output under NIR by the spontaneous polarization change with temperature; however, the photothermal effect of NIR limits the miniaturization of devices.
The conversion of light-stress-electric signals can be realized by the combination of photodeformable materials and piezoelectric materials, which provides an opportunity for the construction of novel artificial photoreceptors without above-mentioned disadvantages. Azobenzene moieties are usually used as a trigger to generate photo-induced stress in the polymers by trans-cis isomerization upon exposure to light irradiation. Combined with azobenzene polymers, the piezoelectric polymers convert the stress into electric signals due to the density change of dipoles. However, the existing systems still suffer from poor output signals, restricting signal transduction to cells.

Azobenzene-containing liquid crystal polymers (LCPs) provide a feasible solution to improve the photo-induced stress and output large electric signals, because the microscopic geometry variation of azobenzene moieties can be amplified into a macroscopic large deformation of the entire LCP materials owing to the alignment change of LC mesogens. Much effort has been made to develop photoresponsive soft actuators with the azobenzene-containing LCPs by ultilizing their quick and various deformation, including contraction/expansion, bending, twisting, oscillating, etc. Due to the cooperative effect of the LC mesogens, as long as 1 mol% of azobenzene moieties reach the photostationary state upon illumination, the generated alignment change can lead to the deformation of the whole LCP systems; therefore, photodeformable LCPs are an excellent candidate for the construction of the photoreceptor featuring a large photo-induced stress.
Here, a neuron-readable artificial photoreceptor with significant voltage output is constructed by using LCPs and polyvinylidene fluoride trifluoroethylene (P(VDF-TrFE)). The significant voltage output originates from light-stress-electricity conversion, where the photo-induced stress is attributed to the change of mesogens alignment in the photodeformable LCPs and subsequently converted into strong electric signals by the P(VDF-TrFE) layer. The photo-induced open-circuit voltage reaches up 0.79 ± 0.02 V, which is, to our knowledge, 19 times higher than the maximum voltage (0.04 V) that has been reported to date. Hence, such artificial photoreceptor successfully transduces photo-induced electric signals to cells and tissues, communicates with the neurons and triggers spiking activities in blind retinas. Besides, visual image recognition is demonstrated in a pixelated matrix by analyzing electric signals of each unit. This artificial photoreceptor opens new opportunities for the combination of the photodeformability and piezoelectricity, providing an avenue to develop neuron-readable artificial retinas and implantable sensors.

9:05 AM EL18.17.05
Self-Healable Printed Magnetic Field Sensors Using Alternating Magnetic Fields Rui Xu[1], Gilbert Santiago Cañón Bermúdez[1], Oleksandr V. Pylypovskyi[1], Oleksii M. Volkov[1], Eduardo Sergio Oliveros Mata[1], Yevhen Zabila[1], Rico Illing[1], Pavel Milkin[2], Leonid Ionov[2], Jürgen Fassbender[1] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf (HZ, Germany; [2]University of Bayreuth, Germany

Percolation network of fillers plays a critical role in rendering printable electronics functionality and durability. We employ alternating magnetic fields (AMF) to drive magnetic fillers actively and guide the formation and self-healing of percolation networks.[1] Relying on AMF, we fabricate printable magnetoresistive sensors revealing an enhancement in sensitivity and figure of merit of more than one and two orders of magnitude relative to previous reports. These sensors display low noise, high resolution, and are readily processable using various printing techniques that can be applied to different substrates. The AMF-mediated self-healing has six characteristics: 100% performance recovery; repeatable healing over multiple cycles; room-temperature operation; healing in seconds; no need for manual reassembly; humidity insensitivity. It is found that the above advantages arise from the AMF-induced attraction of magnetic microparticles and the determinative oscillation that work synergistically to improve the quantity and quality of filler contacts. By virtue of these advantages, the AMF-mediated sensors are used in safety application, medical therapy, and human-machine interfaces for augmented reality.

Additive Manufacturing of IoT Housings with Integrated Electronics Thomas Schmiedinger, Markus Ehrlenbach, Martin Schafferer, Michael Petke, Bernhard Rittenschober and Christian Schmid; University of Applied Sciences Kufstein Tirol, Austria

Additive manufacturing (AM) is an established fabrication method for diverse applications. Due to the versatile manufacturing possibilities, AM provides totally new approaches in designing objects. An emphasis in the field of research was set to the development of unique materials for AM. Among them, conductive filaments were examined for applications in printed electronics. The combination of new materials and the innovative design approach offered by AM generates a comprehensive field of applications. Promising applications can be found on the “Internet of Things (IoT)” sector. The development of connected products includes physical and electronic components. Traditionally, the fabrication process of these products is linear, thus, the design and the fabrication of the physical components is separated from the electronic part. To overcome this separation, an AM approach can be applied in the fabrication of IoT devices. This hybrid fabrication approach enables the fabrication of mechanical and electric components in one fabrication process.
To prove this hybrid fabrication approach, we designed housings of IoT devices with integrated electronics such as an antenna for signal transmission. The housings were fabricated by material extrusion combining non-conductive and conductive filaments. Different antennas were designs focusing on two specific frequencies ranges: 2.4 GHz (Wi-Fi, Bluetooth), and 868 MHz (LoRa). To compare the AM antenna, reference antennas have been fabricated by milling and 2D-printing. Antenna behaviors were characterized by assessing quality parameters by a vector network analyzer. The hybrid IoT housings were tested in a real-world scenario for sensing temperature and humidity remotely.
Integrated fabrication of electronics by material extrusion is a feasible approach for IoT housings. The characteristics of AM based antennas in comparison to milled patch antennas are limited which is attributed to the lower conductivity of the applied filaments. Nevertheless, the hybrid fabrication process enables an integrated production approach which led to functional devices. In this sense, electronics and physical components are merged into a truly smart product.
Based on the findings, further applications of the hybrid approach will be investigated e.g., signal traces, passive electrical components to further strengthen the extensive application possibilities of additive manufacturing.

9:35 AM EL18.17.07
Effect of Sintering Atmosphere for the Fabrication and Characterization of Flexible RFID Antenna Tags Using Printed Copper Nanoparticulate Patterns Rajib Chowdhury[1], Karl Young[1], August Gallo[1], Rafael Cueto[2] and Seonhee Jang[1]; [1]University of Louisiana at Lafayette, United States; [2]Louisiana State University, United States

RFID is playing an essential role in the Internet of Things (IoT) technology by enabling contactless communication and information transfer between digital and physical entities. Different research procedures are being developed aiming for the highly precise pattern for metal conductivity, low electrical resistivity, low cost of material, and flexibility of the substrate. Among the electronics materials, copper (Cu) nanoparticle (NP) inks can be the main material for flexible printed electronics because it possesses high electrical conductivity, stability, and low price in addition to anti-ionic migration capability.

Cu NP ink (CP-008, NovaCentrix) was selected for printing and characterizing the conductive patterns. The ink had the following compositional properties: solids content of 88 wt%, a viscosity of 20-40 Pa.S at 50 s^{-1}, and a density of 3.9 g/ml. Kapton polyimide (PI) sheets with a thickness of 0.102 mm were used as the flexible substrate. Metallic ink comprises metal NPs, capping molecules, additive organic materials, and solvents. Terpineol was included as a solvent in ink, according to the ink specification, but the rest of the composition in ink was not revealed. Removal of organic substances is required to have electrical conductance along with the diffusion of particles resulting in neck growth and grain boundary to obtain electric conductance of the Cu NP patterns. Air, N_2, and five different carboxylic acid vapor groups were used as sintering atmospheres. The sintering temperature varied from 140 to 260 °C, and sintering times varied from 15 to 60 mins. Sintering temperatures were maintained below 260 °C to avoid any deformation and degradation of the substrate, considering the glass transition temperatures of the PI substrates.

Scanning electron microscopy (SEM) was used to analyze the shape and size of the Cu NPs, microstructure, and thickness using cross-section imaging. Then Avizo software was utilized to determine the size distribution and average particle size of the Cu NPs from the SEM images. Using a thermogravimetric analysis (TGA) with an N_2 gas flow rate of 100 ml/min and a temperature ramp of 10 °C/min to achieve 600 °C, the decomposition temperatures and metal weight contents of Cu NP ink were evaluated. The surface roughness of the sintered Cu NP pattern was measured with an atomic force microscope (AFM). Crystallinity and grain sizes of sintered Cu NP patterns were observed using X-ray diffractometry (XRD) with Cu Kα (1.5406A) radiation. Electrical characteristics were evaluated using a four-point probe. The hardness of the sintered Cu NP patterns was measured using micro indentation. An adhesion test was conducted following ASTM-D3359-09 standard cross-cut tape test. Folding tests evaluated the flexing or bending capabilities of the conductive lines. The electrical characteristics of the RFID antenna were evaluated in a 13.56 MHz band using a network analyzer.

The electrical performance of the Cu NP patterns was evaluated using RFID antenna fabrication. The antennas were printed and sintered using optimized sintering conditions of Cu NP ink. Three spiral and three-square patterns were designed with different dimensions, such as the number of turns, line width and spacing, inner/outer radii for spiral patterns, and inner/outer diameters for square patterns. Their resonance frequency, return loss (S_{11}), and quality factor (Q-factor) for each antenna were measured using a network analyzer. The Q-factor characterized the capability of the antenna to communicate with an RFID reader and an RFID antenna. 13.56 MHz RFID system was followed due to its excellent performance. Too low or too high a Q factor might result in not being able to read the frequency or narrow peak, along with interference between the RFID reader and RFID antenna. The Q-factors in the range of 5-20 are preferred for RFID antenna tags fabricated in the 13.56 MHz band.

9:50 AM EL18.17.08
Interfacial Events in Graphene-Based Technologies for Neural Interfaces Marta Delgà, Jose Antonio Garrido and Elena del Corro; ICN2, Spain

Active implantable neural interfaces have experienced great advances in the last years, partially thanks to the use of novel materials. Graphene is one of these new materials contributing to the recent progress thanks to its outstanding mechanical, electrical and electrochemical properties. Neural interfaces based on graphene have the potential to make these implants softer and more conformable, adapting better to the tissue morphology; furthermore, it is possible to prepare smaller devices while maintaining high performance, which can lead to improved spatial selectivity and specificity. Yet, this flourishing technology presents important challenges related to two-dimensional nature of graphene, in particular the impact of interfacial phenomena on its properties. Among the existing interfacial phenomena impacting on the graphene properties, and thus on the device performance and stability, in this work we explore two main phenomena: electrolyte intercalation between graphene and the substrate and residue deposition over graphene during fabrication.
To address water intercalation, we combine electrical and morphological (KPFM and Raman) characterization. We study the influence of different factors on the amount of water under graphene, including device size and aspect ratio, the passivation layer design or the cleanness of graphene surface. Furthermore, we will present a novel methodology to investigate the amount of residual charge on graphene; this approach is based on the response of graphene electronic properties to the electrolyte pH and ionic strength, which is monitored by immersion Raman spectroscopy.
Our results reveal the existence of trapped water between graphene and the substrate and of non-controlled residual charges on graphene after fabricated. Finally, graphene protection strategies are presented revealing promising improved capabilities of graphene-based device performance.

Puncture-Resistant and Self-healing Multifunctional Electronic Skin Cheng-Hui Li; Nanjing Univ, China

Flexible electronic skins play a very important role in the development of human-machine interaction and wearable devices. To fully mimic the functions of human skin, electronic skins should better be able to perceive multiple external stimuli (such as temperature, touch and friction) and resistant to injury. However, both objectives are highly challenging. The fabrication of multifunctional electronic skins is difficult because of the complex lamination scheme and the integration of different sensors. The design of skin-like materials is hindered by the trade-off problem between flexibility, toughness and self-healing ability. In the past a few years, we designed and synthesized a series of polymer which have modulus similar to that of skins, and shows good flexibility, puncture-resistance, notch-insensitivity, and fast self-healing ability. Upon incorporating conductive filliers or liquid metals, the as compared conductive composites can convert changes in temperature and strain into electrical signal changes, thus leading to multifunctional sensing performance. Based on these superior properties, we have prepared a series of flexible electronic skin sensor, demonstrating its great potential in the wearable field and physiological signal detection.

11:00 AM EL18.18.02
Etching of Scandium-Doped Aluminum Nitride using Inductively Coupled Plasma Dry Etch and Tetramethyl Ammonium Hydroxide Zadid Shifat[1,2], Isaac Stricklin[1,2], Ravi Kiran Chityala[1,2], Arjun Aryal[1,2], Giovanni Esteves[3], Aleem Siddiqui[3] and Tito Busani[1,1,2]; [1]The University of New Mexico, United States; [2]UNM Center for High Technology Materials, United States; [3]Sandia National Laboratories, United States

Properties such as wide bandgap, higher electromechanical coupling, and low dielectric permittivity have made Scandium-Doped Aluminum Nitride ($Sc_xAl_{1-x}N$) a promising material for optoelectronics and RF applications. devices are challenging to fabricate because $Sc_xAl_{1-x}N$ films are complex to etch, especially with greater scandium concentrations. Our group has developed a process to etch of $Sc_xAl_{1-x}N$ (x=0.125, 0.20, 0.40) thin films (~ 730 nm thick), which results in vertical sidewalls that approach 90° (±0.2°) and reduces the degree of undercut. As part of this process, etching homogeneity among different Sc compositions is maintained by high-temperature annealing in nitrogen atmosphere, followed by a wet etching in a tetramethyl ammonium hydroxide (TMAH) bath. The wet etch step used a 25% concentrated TMAH (TMAH: Water in 1: 3 ratio) solution at 78°C~82°C to etch the films. The etching rate of $Sc_{0.125}Al_{0.875}N$, $Sc_{0.20}Al_{0.80}N$, and $Sc_{0.40}Al_{0.60}N$ was found to be 365 nm/min, 243 nm/min, and 81 nm/min, respectively. An identical etching profile can be obtained by TMAH vapor as well.

$Sc_xAl_{1-x}N$ etching was found to be independent of the SiO_2 hard mask thickness andwe have analyzed the prospective reasons behind the factors that affect verticality during etching. We also demonstrated how the annealing process significantly repairs the surface damage introduced into the $Sc_xAl_{1-x}N$ by the ion-bombardment effect caused during the SiO_2 hard mask dry etch step, thereby ultimately prevents lateral etching. We can also reduce sidewall roughness of a post etched $Sc_xAl_{1-x}N$ film with the combination of inductively coupled plasma (ICP) etch and annealing without affecting the sidewall verticality in all Sc compositions. Preliminary results of ongoing device fabrication that use this developed etch approach will also be presented.

11:15 AM EL18.18.03
P(VDF-TrFE)/ZnO Composite Film as a Wearable Piezoelectric Energy Harvester Sepide Taleb, Wiebren M. van Lingen and Mónica Acuautla; University of Groningen, Netherlands

This research reports a novel flexible wearable piezoelectric energy harvester made on copper textile. For fabrication of the piezoelectric energy harvester, the optimal concentration of ZnO nanoparticles in P(VDF-TrFE) is initially obtained by the fabrication of piezoelectric films with casting method. Afterwards, Ultrasonic Spray coating technique has been used for the first time to produce composite piezoelectric sensors. Such sensors are produced on conductive copper textile as substrate, to be worn comfortably, and easily on clothes for producing energy from daily activities. The experiments performed under simple movements on the elbow shows a peak-to-peak voltage of around 500 mV. This device can not only provide the electrical power for microelectronic devices or health monitoring systems, but it can also be used as a tactile sensor due to its high sensitivity and biocompatibility.
Several piezoelectric wearable energy harvesters and sensors have already been reported with high output voltage, most of them based on well-known lead-rigid PZT ceramics [1]. However, flexibility and biocompatibility of polymer piezoelectric materials, like P(VDF-TrFE), have motivated many researchers to apply these materials in wearable devices to bring more comfort for the users. Adding various fillers into P(VDF-TrFE) is one of the methods to enhance the piezoelectric coefficient of piezopolymers. One of the promising fillers used in this regard is ZnO nanoparticle, which is a piezoelectric material with wurtzite crystal structure. P(VDF-TrFE)/ZnO composite films have been already fabricated with different methods, like spin coating [2] and electrospinning [3]. To the authors knowledge, fabrication of P(VDF-TrFE)/fillers by ultrasonic spray coating system has not been reported. Though, this method can be advantageous for producing large-scale, high quality piezoelectric films with good reproducibility and control of the fabrication parameters [4].
In this research, initially the optimal concentration of ZnO nanoparticles in P(VDF-TrFE) for piezoelectric properties was obtained using a simple casting method. To do so, piezoelectric films from different concentrations of ZnO (0, 10, 20, and 30 wt%) in 5 wt% P(VDF-TrFE) solution were casted, and their crystallinity, morphology, ferroelectric, and piezoelectric properties were studied.
Higher Piezoelectric coefficient (d_{33}) and lower dielectric constant result in higher mechanical to electrical energy conversion, and therefore higher output voltage of the energy harvester. The 20 wt% ZnO in P(VDF-TrFE) provided the highest piezoelectric coefficient and peak-to-peak output voltage when a force of 100 N was applied by a mechanical testing system. Therefore, such concentration was used to make the ultimate energy harvester by ultrasonic spray coating method.
To improve comfort and compatibility with normal clothing, a conductive copper textile was used as a substrate, thus the energy harvester does not need to be firmly attached to the skin. The optimal solution has been sprayed on top of the copper textile, and annealed at 100 °C to obtain a 19-µm-thick piezoelectric layer. Then, a 15-nm gold layer was sputtered as top electrode and the energy harvester with copper wires were encapsulated in PDMS to protect the system. The wearable energy harvester produces the peak-to-peak output voltage of 250 and 500 mV, by bending the elbow with a small (~30°) and large angle (~90°), respectively.

Preparation and Characterization of Epoxy-Siloxane-Silica Hybrid Hard Coating for Foldable Display Galbadrakh Altantsetseg, SeungCheol Yang, Yeon-Gil Jung, Huynhee Choi and Hye-Yeong Park; Changwon National University, Korea (the Republic of)

Surface protective coatings have been widely used in various applications, such as medical and surgical instruments, electronic displays, optics, antifouling, antifogging, energy storage devices, and automotive and aerospace coatings. The purpose of this study is to produce a protective hard hybrid coating material with high transparency and high scratch resistance for flexible display. For this work, a novel protective hybrid coating was fabricated by photo cationic polymerization of dispersion solution prepared with epoxy oligosiloxane resin and silica sol. The dispersion solution was prepared by simple mixing including ultrasonication. The property change of the epoxy-siloxane-silica composites were studied depending on their composition variation. The mixed solution showed good dispersion stability without precipitant after storage of the solution for 7 days. The 10µm thick transparent hybrid coating formed on PET film with 50 µm thickness had pencil hardness of 3H. The morphology and properties of the coating were characterized by SEM, FTIR, and UV-vis.

An Effective and Rapid Soldering of Electrical Components on Flexible Printed Circuits via NIR-Assisted Heating Venkat Kasi, Amin Zareei, Sarath Gopalakrishnan and Rahim Rahimi; Purdue University, United States

Achieving effective and rapid integration of electrical components onto digitally printed conductive traces on flexible substrates, without compromising the electrical and mechanical properties of temperature-sensitive components, has been one of the main challenges in the field of flexible hybrid electronics (FHEs). While convection oven-reflow soldering is the most widely applied method for connecting electrical components onto the traditional rigid printed circuit boards, this high-temperature method is not suitable for flexible substrates and digitally printed components. To address this challenge, we introduced a novel technology, near infrared (NIR) radiation-based technology, as an effective tool for rapid and effective soldering of a lead-free Sn-Bi-Ag solder paste for connecting electrical components onto conductive traces printed on flexible substrates. In this approach, the NIR technology utilizes the highest energy densities to heat certain materials, such as metal particles, via a selective thermal process, while keeping other materials such as polymers at relatively low temperature. Since many polymer substrates including PET have low or negligible absorbance in the near-infrared range, the NIR radiation specifically heats alloy particles in the solder paste and enables them to reach their melting temperature. The conditions such as NIR power and the time of exposure were optimized to obtain improved spreading and adhesion of solder on conductive traces and the substrate. The formation of interfacial region, which represents the degree of soldering process, was investigated using cross-sectional SEM and EDX analysis. As a proof-of-concept, we demonstrated the use of this technology in the fabrication of wearable FHE device that allows the remote assessment of the exudate absorption in wound dressings and indicates the appropriate time for dress change to prevent from any potential infection at the wound site.

Sustainable Processes to Produce and Scale-Up Metal Oxide Devices Emanuel A. Carlos, Rita Branquinho, Pedro Moreira, Asal Kiazadeh, Jonas Deuermeier, Alexandra Gonçalves, Ana Carolina Marques, Maria Morais, Joana Figueira, Joana Pinto, Elvira Fortunato and Rodrigo Martins; CENIMAT|i3N, Department of Materials Science, School of Science and Technology, NOVA University Lisbon and CEMOP/UNINOVA, Portugal

Nowadays, the number of electronic devices that each person has is quite impressive and it tends to increase exponentially in the next 30 years. This will lead to a high quantity of electronic waste accumulation that will not be recycled and will most likely end up in landfills in developing countries. To overcome this serious societal problem, it is necessary to rethink the production process of some electronic devices and to reconsider their life cycle assessment, more specifically their environmental footprint.

Coating and printing electronics can be a solution and its market is expected to have a compound annual growth rate of 18.3% from $9.9 billion in 2021 to $23 billion by 2026. By adopting more sustainable materials and processes electronics waste is reduced, leading to the reduction of the carbon footprint, and paving the way for green electronics.

In this presentation, we report suitable processes (blade and spray coating; inkjet, screen, and flexographic printing) and solution-based materials (In_2O_3, IGZO, ZTO, NiO and Al_2O_3) are developed to assure the scale-up of metal oxide-based devices, such as thin film transistors, diodes, memristors, thermochromics and transparent heaters to low-cost industry levels.[1-5] These devices will lead to great societal impact since they can power up the speed and efficiency of lighter and thinner wearables, as well as smart windows and packaging applications highly needed for the emergent IoT. To reach a real product soon these metal oxide devices should be combined with silicon integrated circuits, also called hybrid electronics. This will be crucial to achieve high performance and sustainability standards.

Laser Processed Flexible Electronics Joana Pinto, Maria Morais, Jaissica Vassantrai, Ana Carolina Marques, Joao Coelho, Sara Silvestre, Tomás Pinheiro, Ricardo Correia, Elvira Fortunato and Rodrigo Martins; Department of Materials Science, School of Science and Technology, NOVA University Lisbon and CEMOP/UNINOVA, Portugal

The demand for flexible electronic devices has been increasing, mostly driven by the emerging markets of consumable electronics and the Internet of Things (IoT). Among several processing techniques, Direct Laser Writing (DLW) has been regarded as an alternative to conventional microelectronics manufacturing processes. DLW is a cost-effective, one-step, and mask-less technique enabling the production of flexible electronics for a variety of applications, such as PCB boards and other components.[1–3] Using laser processes, different materials and devices can be directly synthesized through precursors chemical reduction, or even the production of graphene through the conversion of carbon-based substrates, such as paper and cork.[1, 3, 4]

This work presents the capabilities and versatility of DLW writing for electronic components development. By this method were obtained silver, copper, and graphene conductive tracks exhibiting sheet resistances of 0.23 ohm.sq^{-1}, 0.53 ohm.sq$^{-1,}$ and 30 ohm.sq^{-1}, respectively. These conductive layers led to the production of radio-frequency antennas, micro-supercapacitors, and simple circuits on paper and cork, further demonstrating the relevance of this method. This technique is compatible with a set of recyclable and bio-compatible substrates, adding a layer of sustainability to the production method.[1–3, 5] Finally, DLW was also applied to synthesize metal oxide semiconductors (WO_3, ZnO, among others) broadening the prospect of fabricating sensors and other devices through this direct and simple technique.

11:50 AM EL18.18.09
Defect Quantification of MOCVD Deposited Monolayer MoS_2 Using Kelvin Probe Force Microscopy Technique Moha Feroz Hossen[1,2], Olubukola Ayanbajo[1,2], Sachin Shendokar[1,2], Swapnil Nalawade[1,2] and Shyam Aravamudhan[1,2]; [1]Joint School of Nanoscience and Nanoengineering, United States; [2]North Carolina A&T State University, United States

Defects are unavoidable during synthesis of materials due to thermodynamical equilibrium. In the synthesis of two-dimensional transition metal dichalcogenide (2D TMDC), point defects emerge as a dominant defect due to the absence of chalcogen atoms in the lattice structure. Having the few or less than one nanometer level thickness of monolayer film of TMDC materials, the presence of defect states on the film surface changes the carriers concentration. The changing of carrier concentration in monolayer TMDC film shifts the position of fermi level towards either conduction band edge or valence band edge depending on the type of majority carriers. The shifting of fermi level changes the work function of the TMDC monolayer film. The conventional hall measurement is not feasible to measure surface carrier concentration of 2D materials films. Instead, kelvin probe force microscopy (KPFM) is used to measure surface carrier density. The carrier density is calculated by measuring the work function of the monolayer film using KPFM. Each point defect in 2D TMDC materials increases the certain amount of carriers concentration that facilitate the defect quantification. In this work, we tried to quantify point defect in metal-organic chemical vapor deposited (MOCVD) monolayer MoS_2 using kelvin probe force microscopy (KPFM) by measuring the position of the fermi level that is shifted due to the unbounded electrons of MoS_2.

Gigantic Effect Due to Phase Transition on Thermoelectric Properties of Ionic Sol-Gel Materials Jin Liu[1], Xiao-ming Tao[1] and Wei Zeng[2]; [1]Hong Kong Polytechnic University, Hong Kong; [2]Guangdong Academy of Sciences, China

Sol-gel phase transition in ionic thermoelectrical (i-TE) materials can induce large rapid changes in viscosity and ionic transport process. Based on these properties, the phase-transition is expected to give a drastic variation in thermoelectric properties, crucial in low-grade waste heat harvesting for Internet of thing (IoT) and wearable electronic applications. In this work, we prepare and examine four different types of i-TE materials featured with non-phase-transition, thermal sol-to-gel phase transition, thermal gel-to-sol phase-transition and UV-induced sol-to-gel phase transition. For the first time, we observe a significant rise of the thermopower by around 6.5 times during the sol-gel transition of the poloxamer/LiCl system (thermal sol-to-gel phase-transition system). In addition, due to the stable value of electrical conductivity and thermal conductivity during phase transition, an even greater ionic figure of merit by around 23 times is also achieved. These phenomena are found to be universal as the large variation in thermopower is confirmed in the other thermal gel-to-sol transitional and UV-induced transitional materials. We further reveal the mechanism based on the Onsager's relations and propose a model that can deal with the pre-, post- and during phase-transition processes. Finally, we probe six factors that can influence the huge variation of the thermopower during the phase transition and shed light on the possible gigantic changes in thermopower during the phase transition. This work indicates the gigantic effect that phase transition can have on thermoelectric properties in i-TE systems regardless of the type of phase transition and discovers a possible route to design and control the desired TE performances of materials, which can lead to a new sight in tunable i-TE devices for low-heat energy harvesting applications.

Hybrid, Compliant Implantable and Wearable Neural Systems Stephanie P. Lacour; Ecole Polytechnique Federale de Lausanne, Switzerland

The introduction of soft materials and microtechnology provides an opportunity to tailor the design of neural transducers and explore interfaces with increased selectivity and improved biointegration. Soft carrier materials and elasticity engineering support neural devices with mechanical signature closer to that of the neural host tissue and potential for long-term biointegration. Microfabrication allows for customized electrode layouts with micrometric to millimetric electrode diameter, low to high (0.1 to >10 /mm^2) electrode density and small to large (mm^2 to 10s cm^2) surface area. Hybrid integration of conventional, rigid electronic hardware with the compliant neural transducers is explored to enable on-board signal processing, data transfer and powering. The design and processing of multilayered thin-film encapsulation are then required to hermetically package the thin form-factor neural systems.
This talk will review our advances in each of the four components, namely soft transducers, integrated LEDs, hybrid interfacing with customized electronics and telemetry and flexible yet hermetic organic-inorganic multilayers. We will illustrate these concepts with neural systems interfacing the central nervous system.

10:30 AM OPENING REMARKS

10:45 AM *EL19.01.01
Material, Strucures, Devices and Architectures Paolo Gargini; IEEE-IRDS, United States

Electronics powered products have permeated all aspects of society and this trend is still accelerating. All of this has been made possible by the integration of larger and larger number of solid-state transistors that have continued to evolve absorbing new materials, morphing into new structures, and adapting to newer and evolving circuit architectures.
The first patents about forming a solid-state device by means of creating two separately spaced electron rich regions to be connected on demand by applying a voltage on an electrically isolated gate straddling between and above them were published between 1925 and 1935; however, actual demonstration of the transistor effect did not occur until 1947-48. It took however, another 20 years before the first silicon-gate planar process produced functional and reliable Metal Oxide Semiconductor (MOS) transistors and for the first time an economically viable Integrated Circuit industry took off. Between 1969 and 1971 multiple types on memories and logic products became a reality. Through the 70s, 80s and 90s integrated circuits were produced with transistors of smaller features that yielded better performance and lower costs from one generation to the next one. During this period, several new materials were introduced to further increase performance and reliability. By the beginning of this century, it became clear that the fundamental materials constituting the MOS transistor were reaching fundamental limits and a complete overall was necessary. Between 2003 and 2011 new dielectric and metal materials were introduced into the manufacturing process and for the first time the planar transistor evolved in an upright structure name FinFET since the new structure resembled a fin. The next structural transition is anticipated to occur around the year 2025 when individual layers transistors will be stacked on top of each other in what is called Nanosheet architecture. This however is not the end! Integration of new resistive materials and new magnetic materials is jut beginning to enter the manufacturing process. Many more exciting device transformations are also reaching the feasibility stage and so the combination of materials, structures, devices, and architectures will continue to produce and widely proliferate products that will make our lives better and more exciting than ever before.

11:30 AM EL19.01.03
Low-Resistivity Molybdenum Nitride Thin Films Deposited by Atomic Layer Deposition for Cu Diffusion Barrier Min-Ji Ha, Jeong-Hun Choi, Na-Gyeong Kang and Ji-Hoon Ahn; Hanyang University, Korea (the Republic of)

As memory devices become ultra-miniaturized, the increase in the resistance of the metal line due to the decrease in the line width has become a very critical issue. Mo-based materials have been studied as candidates for next-generation metal line materials because of their low resistivity at low thickness and excellent oxidation resistance. However, the development of precursors suitable for vapor deposition methods (such as atomic layer deposition) is immature. In this study, we propose a low resistivity MoN_x thin film using a halogen-free liquid precursor as a new metal line and diffusion barrier candidate. Controlling the percentage of H_2 (0-10%) contained in N_2, MoN_x thin films were successfully deposited by PEALD. It was confirmed that the MoN_x thin films (H_2 0-10%) were uniformly and continuously grown on the SiO_2 substrate without an incubation period. Among the deposited MoN_x thin films (0-10%), MoN_x thin films using H_2 10% showed the lowest resistivity of 30-50 μΩcm and maintained the low resistivity even at the thinnest thickness of 4.15 nm. In addition, the diffusion barrier (~7nm) stability tests for Cu metallization were performed up to 600 °C because the thermal budget in the BEOL process was limited to 550 °C. The MoN_x thin films deposited using lower H_2% improved diffusion barrier ability because they form amorphous phase. The MoN_x thin films proposed in this study has the potential to be applied to various applications as a next-generation metal line materials in the semiconductor industry.

11:45 AM EL19.01.04
Poly(lactic) Acid and Highly Conductive Porous Copper Co-Printing via Fused Filament Deposition and Laser Sintering Hybridization Remi Rafael and Paddy K. L. Chan; Hong Kong University, Hong Kong

Additive manufacturing of electronic devices and 3D printed circuit boards (3D PCB) is a complex and challenging endeavor. The major reason is due to the high processing temperature of metals and the incompatibility with the classic polymer-based dielectric or printed materials. Although low temperature processes have been developed to print conductive materials like conductive thermoplastic composites and metal nanoparticle inks, these conductive composites are restricted by low conductivities, and direct ink writing or inkjet printing are often associated with high cost, complex chemical or thermal sintering steps and low throughput. A lot of time they are more suitable for the thin film printing rather than 3D printing. As a result, there is currently no additive manufacturing technology available on the market, capable of printing centimeter scale 3D PCB with embedded 3D vias.
In this work, we present a 3D printing method capable to print together dielectric poly(lactic) acid and a highly conductive porous copper material to produce 3D PCBs. We developed a copper/copper oxide/PLA thermoplastic composite filament which can be utilized for conductive printing in a fused filament deposition (FDM) and laser sintering hybridized setup. The composite, originally dielectric, is first printed using the classic FDM process, before being locally sintered by a laser diode. The sintering process degrades the PLA into volatile compounds and causes the reduction of the copper oxide into its native conductive state. The resulting material is a porous copper network of interconnected copper particles with low resistivity ($< 4 \times 10{-}4$ Ω cm) and high maximum current density (6 A/mm^2) without degradation. Using a custom-made hybrid 3D printer with two FDM extrusion heads and a laser head, those two processes (printing and sintering) are repeated until a complete 3D PCB is formed. To demonstrate the capability of this method, we will present a simple LED blinking circuit, integrating conventional electronic components by soldering, and a centimeter scale solid printed object with embedded 3D vias. The detailed electrical characterization of the printed porous copper will be presented.

ARES™ Autonomous Research Systems Control of Carbon Nanotube Yield and Structure Benji Maruyama; AFRL/RXA, United States

The current materials research process is slow and expensive; taking decades from invention to commercialization. The Air Force Research Laboratory pioneered ARES™, the first autonomous research system for materials development. A rapidly growing number of researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of doing iterative experimentation orders of magnitude faster than today. We will discuss concepts and advances in autonomous experimentation in general, and associated hardware, software and autonomous methods.

For Carbon Nanotubes (CNTs), we show progress in autonomous and data science methods to understand and control the fundamental mechanisms that drive CNT synthesis via CVD. We will explore the importance of the oxidizing or reducing nature of the CVD environment on nucleation and growth.

In the future, we expect autonomous research to revolutionize the research process, and propose a "Moore's Law for the Speed of Research," where the rate of advancement increases exponentially, and the cost of research drops exponentially. We also consider a renaissance in "Citizen Science" where access to online research robots makes science widely available.

2:00 PM EL19.02.02

Enabling Nanoscale Tomographic Materials Analysis with Multi-Probes Scalpel SPM Deepanjan Sharma[1], Matthew Tedaldi[1], A.D.L. Humphris[1], J.P. Hole[1] and Umberto Celano[2,3]; [1]Infinitesima Ltd., United Kingdom; [2]Arizona State University, United States; [3]imec, Belgium

The continuous advances of nanoelectronics device technology are creating an ever-increasing demand for customized chips. The rapid development of three-dimensional architectures such as FinFET, gate-all-around (GAA), and nanosheets requires the use of new approaches for their physical analysis that go beyond state-of-the-art metrology. A promising solution is offered by Scalpel SPM, a concept based on the contact-mode atomic force microscopy (AFM) where tip-induced material removal by abrasive wear has been re-imagined as a valid option to achieve tomographic sensing. Scalpel SPM uses a single asperity nanocontact capable of sub-nanometer material removal, thus enabling a three-dimensional segmentation by alternating sensing and removal scans. Here, we report on the development of a dedicated system – the Rapid Probe Microscope (RPM3D) – for the implementation of Scalpel SPM that leverages the use of three independent probes, alternating their operation on the same area of the sample surface. Thus, separating the scalpel and sensing responsibilities into multiple tips holds benefits both for further studies on the fundamental physics of nanomachining as well as the realization of a tomographic tool. First, we discuss the interlaced high data acquisition rate and an interferometric detection system providing sub nanometer spatial accuracy and automated probe switching and multi-probe sensing. Namely (1) the development of a synchronized multi-probe sensing method, and (2), the creation of an automated data acquisition scheme in which the rate of nanomachining is extracted during tomographic data collection. Second, we show a pathway for automatic extraction of the tip-induced material removal rate (RR) to be combined with automated multi-probe sensing. This is reported with multiple electrical contact-mode techniques including conducting atomic force microscopy (C-AFM) and scanning spreading resistance microscopy (SSRM) as a multiscale 3D analysis platform that does not compromise high-resolution imaging, we propose a specific design that can accomplish both accurate tip re-positioning and a simple technique for switching and using multiple probes.

2:15 PM EL19.02.03

Ge-rich Ge-Sb-Te Phase-Change Thin Films Under the Light of Synchrotron Radiation— Crystallization and Thermomechanical Behavior Philipp Hans[1,2], Cristian Mocuta[3], Yann Le-Friec[4], Philippe Boivin[4], Roberto Simola[4] and Olivier Thomas[1,2]; [1]Aix Marseille Universite, France; [2]CNRS IM2NP, France; [3]Synchrotron SOLEIL, France; [4]STMicroelectronics, France

Phase Change Memory is a very promising non-volatile memory that is being considered by several companies for a wide range of applications (storage-class memory, in-memory computing, neuromorphic computing, eNVM for microcontrollers …). At STMicroelectronics a new Ge-rich Ge-Sb-Te alloy (GGST) has been developed with a crystallization temperature above 350°C [1] for addressing the specific needs of the automotive market where high operating temperatures are needed. To investigate the crystallization and mechanical behavior of these GGST alloys we use X-ray diffraction as a function of temperature during annealing. Capped thin films are heated *in situ* under nitrogen atmosphere on the DiffAbs beamline of SOLEIL synchrotron facility. The incident beam is monochromatic (18 keV) and the incidence is fixed. A bidimensional detector collects the diffraction pattern and is corrected and integrated [2] to yield a 1D diffraction pattern. The diffraction peaks are then fitted with a Voigt function [3] that allows extracting the integrated intensity, integral breadth and position of the Bragg peaks. These parameters allow following the crystallization kinetics and the thermomechanical behavior [4] of thin films as a function of various parameters: doping, film thickness (5 nm – 50 nm), nature of surrounding layers … In addition, we will show that thanks to the high flux and penetrating power of synchrotron X-rays patterned and metallized structures close to real products can be investigated. The results obtained from such in situ investigations bear important consequences for the understanding of the crystallization process in memory cells.

Acknowledgments:
The authors gratefully acknowledge the SOLEIL Synchrotron for allocating beam time. P. Joly, is acknowledged for excellent technical support during the experimental campaign at SOLEIL Synchrotron on DiffAbs beamline. This research was supported by IPCEI/Nano 2022 program.

Scale-Dependent Mechanical Properties of Advanced Materials for Nanopatterned On-Chip Interconnect Structures Ehrenfried Zschech and Kristina Kutukova; deepXscan GmbH, Germany

The mechanical robustness of microelectronic products is an increasing challenge, particularly for microchips and chipsets operated in harsh environments, for use cases that require lifetimes much longer than in the past and for safety-critical applications [1,2]. Microcracks in nanopatterned on-chip interconnect stacks, e.g. introduced during dicing of the wafer, are a serious reliability concern since these they can grow and eventually cause catastrophic failure of the microchip. This reliability-limiting degradation process is pronounced by geometrical shrinking of metal interconnects, novel manufacturing technologies and integration schemes as well as new materials used for interconnect stacks of future electronics. In addition, advanced packaging technologies (e.g. hybrid bonding) can cause local thermomechanical stress on wafer or chip level. The risk of fracture is increased for BEoL stacks of microchips if metal interconnects are insulated with so-called low-k materials. These dense or porous CVD-deposited and UV cured organosilicate glass materials are characterized not only by a low dielectric permittivity but also low Young's modulus and cohesive strength, and consequently low fracture toughness [3]. The understanding of the kinetics of crack propagation provides valuable information for the evaluation of the risk of mechanical failure, however, a quantitative determination of the critical energy release rate for crack propagation is needed for the design of optimized, mechanically robust BEoL structures.

In this talk, the determination of the critical energy release rate in patterned interconnect structures of advanced microchips is described. The implementation of a micro-double cantilever beam (micro-DCB) test in an X-ray microscope allows a 3D imaging of the pathways of microcracks in fully integrated multilevel on-chip interconnect structures with a spatial resolution of about 100 nm [4]. Based on the measured geometric shape of the crack and cantilever bending lines at several loading steps during the micro-DCB test as input data and a data analysis based on the Euler-Bernoulli beam model, the determination of the critical energy release rate G_c for crack propagation was determined in different patterned regions of a wafer manufactured in 14 nm CMOS technology node with a Cu/low-k interconnect stack. The critical energy release rate G_c for crack propagation of a so-called guard ring structure, designed to stop the crack growth, is significantly larger than the respective values in patterned surrounding regions, and about one order of magnitude higher than the G_c values of the respective unpatterned dielectric thin films. These results show that, in addition to the materials properties of the dielectric materials, the geometry of the metal structures is playing an essential role for the fracture behavior of Cu/low-k interconnect stacks [2].

With the methodology described in this talk, conclusions for the robustness of on-chip interconnect stacks can be drawn and input for the design of guard ring structures can be provided. This new approach has important implications for on-chip interconnect technology development and for risk mitigation strategies in semiconductor industry.

The combination of micromechanics and nondestructive high-resolution 3D imaging of opaque materials opens a way for the fundamental study of the structure behavior of nanoscale structures and materials. One century after Griffith's fracture theory, it will cause a new era of fracture mechanics, namely fracture mechanics in small dimensions.

Precursor Development for Direct-Writing of Inorganic Nanostructures Sven Barth, Felix Jungwirth, Fabrizio Porrati and Michael Huth; Goethe University Frankfurt, Germany

Focused electron/ion beam deposition (FEBID, FIBID) allow the spatially controlled formation of nanoparticles, thin film patches, nanowires and free-standing complex nanoarchitectures on a wide range of substrate materials. Moreover, the method enables a growth on structured surfaces and the formation of predefined arrays by this maskless direct-write approach. However, the purity of the as-grown material is typically limited. Therefore, the method requires precursor development to provide chemical impetus driving the methods applicability. This contribution will highlight the precursor development for this nanoprinting approach.[1] Specific examples of precursors will be discussed that enable for the direct deposition of binary deposits. The knowledge gained is applied to the synthesis procedures for metal silicide and alloy formation as well as functional metal carbides.[2,3]

Site- and Shape-Selective Synthesis of Heterostructures by Nano-Micro-CVD Fabrizio Porrati, Sven Barth and Michael Huth; Goethe University Frankfurt, Germany

Recent advancements in additive manufacturing enable the fabrication of free-shaped 3D objects with high accuracy using focused electron beam-and focused ion beam-induced deposition (FEBID and FIBID).[1] We demonstrate the formation of 3D core-shell heterostructures by combination of direct-write 3D FEBID scaffolds and the successive site-selective chemical vapor deposition (CVD). In particular, conductive 3D nanobridges are printed by FEBID and used as resistors allowing deposition induced by Joule heating. The successful combination of both approaches is demonstrated using two material systems of specific physical properties.[2] The fabrication of complex 3D core-shell heterostructures promises to add new functionalities by combining free-shaped 3D surfaces to layers of materials with different properties. Specifically, shape dependent physical properties can be investigated by this highly adaptable approach.

Optical Micro-Patterning of Electronic Polymers for Device Applications Meghna Jha, Joaquin Mogollon Santiana, Tucker L. Murrey, Harishankar J. Manikantan and Adam J. Moule; University of California, Davis, United States

The largest need in organic electronic devices is a universal method to produce micro- to nano-scale features for devices from semiconducting polymers cheaply, and at scale. We recently developed a solution method to optically pattern conjugated polymers with sub-micrometer resolution. We examine the relationship between optical write intensity, write speed, and write wavelength on the resulting pattern fidelity. Finite element modeling reveals that nearly all polymer patterning occurs as a result of dissolution due to local optical heating. The dissolution rate as a function of light wavelength, intensity, and solvent quality can be quantitatively predicted with upper patterning rates of 5 m^2/hr possible. We demonstrate the fabrication of polymer nanowires with cross section of 250x40 nm, which demonstrates the efficacy of this process for device fabrication. We also demonstrate optical patterning of conjugated polymers using a cleanroom photolithography instrument (Alvéole PRIMO). This is significant because it means that every organic electronics group can pattern with similar resolution using their own local commercial equipment. This patterning technology enables a whole new class of patterned conjugated polymer devices.

4:15 PM EL19.03.04
Process Development and Material Characterization for ALD Indium Tin Oxide (ITO) Thin Films Qi Jiang[1], Nathalie Moreno[1], Shuhan Liu[1], Xinyi Wen[1], Kasidit Toprasertpong[2], Vijay Narasimhan[3], Graham J. Ewing[1], Michelle Rincon[4], Angelica Zacatzi[3], Swaroop Kommera[1], Ravi Kanjolia[3] and H.S. Philip Wong[1]; [1]Stanford University, United States; [2]The University of Tokyo, Japan; [3]EMD Electronics, United States; [4]Onsemi, United States

Indium Tin Oxide (ITO) is a conducting material widely used for transparent electrodes in various applications such as batteries, touch screens, and solar cells. When thinned down to sub-10nm, ITO can be used as the channel material for transistors because an applied electric field in the gate can completely deplete the channel and turn off the transistor. The common method to deposit ITO is sputtering; but sputtered ITO tends to be rough, non-uniform, and non-conformal. Besides, the ITO composition is pre-defined by the sputtered target and has little tunability for different needs. Atomic Layer Deposition (ALD) provides films that are generally better than sputtering in terms of roughness, conformality, and uniformity, as well as having better control in thickness and composition.
In this work, we developed the ALD ITO process, compared two different precursors, and studied how the process parameters affects the ITO thin film Characteristics. Tetrakis(dimethylamino)-tin (TDMASn) is used as the Sn precursor. As for the In precursor, both Indium Cyclopentadienyl (InCp) and Trimethylindium (TMI) have been used and compared for the ALD ITO films. Oxygen plasma is used as the source of oxygen. ITO films are deposited onto both SiO2/Si(100) and glass substrates and examined using ellipsometry, contactless sheet resistance mapping, X-ray photoelectron spectroscopy (XPS), etc. We have characterized how the ALD ITO resistivity changes with different In precursors, In: Sn composition ratio, film thickness, deposition temperatures, and annealing conditions, and have studied the underlying physics associated. We will present transistor results comparing the process conditions.

4:30 PM EL19.03.05
Additive Manufacturing of Amorphous Metal Soft Magnetic Composites Luis C. Delfin, Mingqi Shuai, Melody Wang, Kawin Surakitbovorn, Juan Rivas-Davila and Wendy Gu; Stanford University, United States

Soft magnetic composites (SMCs), consisting of metallic regions separated by insulating layers, have gained increased interest for power and electronic applications due to their excellent magnetic properties, low eddy current losses, and low coercivity. SMCs made of amorphous metal soft magnets are of interest for high-frequency applications. However, the brittle nature of amorphous metals limits their geometry to thin ribbons. This work presentsthe synthesis of Fe-based amorphous metal nanoparticles, which are then oxidized to achieve a core-shell structure. The synthesis method is scaled-up to the 100 g scale to be used as feedstock material in additive manufacturing processes such as Laser Powder Bed Fusion (LPBF). The small size of the nanoparticles is predicted to lead to low core losses, as well as improved ductility. Nanoindentation is used to determine hardness and elastic modulus. Through plane resistivity measurements and B-H curves were performed to evaluate their performance as SMCs. Then, single layers are printed to determine power, scanning speed, and hatch spacing for dense structure and optimized microstructure.

SESSION EL19.04: Sensors

9:00 AM EL19.04.01
Colorimetric Multigas Sensor Arrays-Based Artificial Olfaction for Volatile Organic Compounds Healin Im[1,2], Jihho Kim[3], Zakaria Al Balushi[1], Donghyuk Park[3] and Sunkook Kim[2]; [1]University of California, Berkeley, United States; [2]Sungkyunkwan University, Korea (the Republic of); [3]Inha University, Korea (the Republic of)

Artificial olfaction conceives multigas sensor arrays for gas-fingerprint pattern recognition, which is attributed to its specificity for multiple gases. It is a series of interactive sensor arrays compatible with electronic circuits and data analysis software from a sensor architecture perspective. It can sense and transform information on gas mixtures into readable digital outputs and compute their concentration based on statistical models. Herein, we develop colorimetric multigas sensor arrays assembling chemo-reactive fluorescent porous nanofibers and 10 <!--[if gte msEquation 12]><m:oMath><i style='mso-bidi-font-style: normal'><m:r>×</m:r></m:oMath><![endif]--><!--[if gte vml 1]><v:shapetype id="_x0000_t75" coordsize="21600,21600" o:spt="75" o:preferrelative="t" path="m@4@5l@4@11@9@11@9@5xe" filled="f" stroked="f"> <v:stroke joinstyle="miter"/> <v:formulas> <v:f eqn="if lineDrawn pixelLineWidth 0"/> <v:f eqn="sum @0 1 0"/> <v:f eqn="sum 0 0 @1"/> <v:f eqn="prod @2 1 2"/> <v:f eqn="prod @3 21600 pixelWidth"/> <v:f eqn="prod @3 21600 pixelHeight"/> <v:f eqn="sum @0 0 1"/> <v:f eqn="prod @6 1 2"/> <v:f eqn="prod @7 21600 pixelWidth"/> <v:f eqn="sum @8 21600 0"/> <v:f eqn="prod @7 21600 pixelHeight"/> <v:f eqn="sum @10 21600 0"/> </v:formulas> <v:path o:extrusionok="f" gradientshapeok="t" o:connecttype="rect"/> <o:lock v:ext="edit" aspectratio="t"/></v:shapetype><v:shape id="_x0000_i1025" type="#_x0000_t75" style='width:8.4pt; height:28.2pt'> <v:imagedata src="file:///C:/Users/LGE1/AppData/Local/Temp/msohtmlclip1/01/clip_image001.png" o:title="" chromakey="white"/></v:shape><![endif]--> 10 IGZO phototransistor arrays as a next-generation artificial olfactory platform to recognize five different volatile organic compounds (VOCs). Porous nanofibers, coupled with two different organic emitters and emitting fluorescence, rapidly respond to gas-phased VOCs and offer a prominent fluorescent alarm. In addition, the composition between fluorophores and polymers provides a selectivity against VOCs. The VOCs-induced variation in fluorescence of nanofibers is quantified and amplified by IGZO phototransistor arrays, resulting in the gas-fingerprint patterns in terms of electrical signals. Thus, the pattern library associated with VOCs and their concentration enables us to determine each airborne analyte as the artificial olfactory platform. Therefore, this system could achieve rapid, early quantitative recognition of hazardous gases and be applied as a preventative, portable, and wearable multigas identifier in various fields.

9:15 AM EL19.04.02
Low-cost, and Robust Printed Sensors for Monitoring Gaseous Oxygen Flux Through Soil John-Baptist Kauzya, Brenna Schwartz, Eloise Bihar, Catherine Crichton and Gregory L. Whiting; University of Colorado Boulder, United States

Oxygen content in soil has been shown to promote plant growth and crop production, therefore, it is important to monitor oxygen gas flux through the soil. In order to accurately perform such in-situ characterization of gas fluxes through soil, high spatial resolution in the sensing system is imperative. Printed gas sensors for monitoring oxygen content in the air have been designed and documented in the literature. In order to apply these technologies to soil, a harsh environment that experiences fluctuations in properties such as moisture, temperature, and density, we have modified/adapted the current devices' configuration. In this work, we demonstrate the design, construction, and testing of robust devices that utilize printed oxygen sensors to transduce gaseous oxygen flux through soil into a measurable signal, without succumbing to the negative impacts of its transient properties. The accuracy of these devices is explored alongside their sensitivity, stability, and longevity. By building these gas sensing systems for in situ monitoring of oxygen flux in soil, we can provide a better understanding of how farming and agricultural practices affect soil and crop health.

9:30 AM EL19.04.03
Organic Optoelectronic Components in a Smart-Integrated Miniaturized System for Plasmonic-Based Sensing Stefano Toffanin; CNR-ISMN, Italy

The continuous growth of the global population has been remarking the need of early detection systems to prevent the spread of epidemics as well as to improve the standards of living. The emerging demand of sensing technologies has prompted researchers and industrial companies to develop devices able to monitor medical, food, water, and environmental safety/quality indicators in an efficient, simple, and reliable way. While high sensitivity and selectivity must be guaranteed, compactness, user-friendliness and low-cost are key characteristics to enable the use of the sensing technology for point-of-care diagnostics without the need for trained personnel [1].

Among state-of-the-art methodologies for pollutants detection, optical sensing has emerged as one of the most simple, versatile, and powerful approaches for analytical purposes. However, a major obstacle towards the development of a portable system has been the use of bulky optical components (e.g. lasers and optical fibers), which are necessary to ensure a good sensing capability. In particular, huge interest has been attracted by functionalized metallic surfaces based on surface plasmon resonance (SPR), as extremely sensitive, label-free, quantitative systems for real-time detection of single or multiple analytes. However, the need of a fine and precise control of the angle of the incident light ended up in the use of not-portable optical components in the final sensor [2].

In this scenario, organic optoelectronic components might enable the definition of new miniaturized detection schemes to boost the advent of compact optical sensors for on-site analysis, given their inherent capability of smart monolithic integration in nm-thick multi-stack devices on almost any surface. Here, we report an unprecedented ultra-compact system endowed with optical and plasmonic sensing capabilities through the smart integration of (i) organic light-sources such as organic light-emitting diodes (OLEDs) or transistors (OLETs), (ii) an organic light-detector such as organic photodiode (OPD) and (iii) a sensing nanostructured surface such a nanoplasmonic grating (NPG) [3]. The components and the layout of integration were suitably designed to make the elements work cooperatively in a reflection-mode configuration. In particular, the OPD was vertically stacked onto the source electrode of the OLET thus providing electrical switching, light-emission and light-sensing capability in a single organic multilayer architecture. When coupled to the NPG, a multifunctional system with SPR-sensing ability was obtained at a remarkably high level of miniaturization, arising from the direct fabrication of the NPG onto the encapsulating cap of the light-emitting/-sensing platform.

The optimal size and relative positioning of the three elements, as well as the signal variation of the sensor under different conditions, were predicted by means of accurate 3D optical simulation tool. Accordingly, the effectiveness of the final miniaturized integrated system was validated by the dependence of the OPD output signal on the NPG exposure to liquid media with different refractive index, *i.e.* water, ethanol and sucrose solutions at different concentrations [4] by achieving a sensitivity up to 10^{-4} refractive-index units (according to the specific light source used) at a sensor size as low as 0.1 cm^3.

Wearable Neural Sensors Based on Epitaxial Graphene on 3C-SiC on Silicon Shaikh N. Faisal[1], Tasauf Torzo[1], Tien Thong Do Nguyen[2], Daniel Leong[2], Chin-Teng Lin[2] and Francesca Iacopi[1,3]; [1]University of Technology Sydney, Australia; [2]Australian Artificial Intelligence Institute, Australia; [3]ARC Centre of Excellence in Transformative Meta-Optical Systems, Australia

Recent advances in Neuroscience and Artificial Intelligence, particularly in paradigms and related algorithms for evoking and decoding intent from “brain waves”, ie the low-frequency, collective oscillations of millions of brain neurons, have paved the path to the use of electroencephalography (EEG) as a non-invasive platform for brain-computer interface (BCI) [1]. Although the spatial-temporal resolution of EEG is inferior to the use of implanted interfaces, the wearable nature of such BCI is of great importance for most of the large -scale uses that do not involve mitigating severe disabilities. However, one of the main bottlenecks for EEG -based BCIs is now the availability of suitable dry sensors. Dry sensors tend to show a relatively high contact impedance with the skin, which hampers an accurate read-out of the ~μV amplitude biopotential signals to be read at scalp locations, because of their strong capacitive component in the contact [2]. In addition, their contact with the skin needs to be stable during movement and reliable over long-term usage outside lab settings, which is another key challenge due to corrosion, biocompatibility and slipping issues. The use of 2D materials for neural sensors open new promising possibilities in this application area [3].

We have pioneered the use of epitaxial graphene on silicon carbide on silicon as a low- contact impedance EEG sensor which is extremely reliable upon long-term usage [4]. The produced sensors are wafer- thin, biocompatible with the skin, and show a lower contact impedance as compared to bulkier commercial sensors. In particular, we observe that their contact impedance improves once in contact with the skin, thanks to a gradual wetting of the graphene’s surface [4]. In addition, we show that the sensors are remarkably resilient to corrosion as they do not delaminate and show minimal reduction of performance upon storage in a highly saline environment for up to one year. In this contribution, we will share the latest progress in the use of epitaxial graphene sensors mounted on a head helmet for the hands-free control of a remote robotic platform.

10:30 AM EL19.05.01
Stable Resistive Switching of Highly Polycrystalline Two-dimensional Molybdenum Ditelluride based Memristor Array Jihoon Yang[1], Soon-Yong Kwon[1], Zonghoon Lee[1,2], Donghyeok Lim[1], Hongsik Jeong[1], Aram Yoon[1,2], Donghyun Lee[1] and Iljohn Jung[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

Two-dimensional (2D) materials have generated attention for neuromorphic computing applications, and are promising for use in low-power synaptic devices at the atomic scale. However, 2D material-based memristors are disadvantaged by the large stochastic forming process, which results in switching variability. In this study, we present a 2-inch wafer scale memristor array that contains nanometer-sized grains of highly polycrystalline 2H-$MoTe_2$ as an active medium and exhibits reliable resistive switching. The polycrystalline 2H-$MoTe_2$ films were synthesized on a 2-inch SiO_2/Si wafer by tailoring the Te flux through a Te vapor-confined method using a eutectic alloy. The synthesized films contain uniformly sized nanograins (~60 nm) and exhibit ultrahigh-density (1.37×10^{11} cm^{-2}) grain boundaries (GBs). These GBs provide confined defective paths to enable conduction, facilitating reliable resistive switching. Compared to single-crystalline 2H-$MoTe_2$-based memristors, the polycrystalline 2H-$MoTe_2$-based memristor (PMM) arrays show improved resistive switching uniformity and stable multi-level resistance states, along with high device yields (>83.7%), small device-to-device variations (<13.8%), and long retention times (>10^5 s). Finally, this PMM shows linear analog synaptic plasticity under repeated pulses more than 2,500 and exhibits a learning accuracy of 96.05% for MNIST handwritten digit classification. The introduction of nanograins in the PMM represents a novel route to accelerate the use of 2D memristors in practical neuromorphic computing applications.

10:45 AM EL19.05.02
Investigation of Resistive Switching Mechanism in High-Performance High Entropy Oxide-Based RRAM Jing Yuan Tsai[1], Hung-Yang Lo[1], Chun-Wei Huang[2], Jui-Yuan Chen[3] and Wen Wei Wu[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Feng Chia University, Taiwan; [3]National United University, Taiwan

The application of high entropy oxide (HEO) attracts great attention in recent years, due to its unique structural characteristics such as excellent electrochemical properties and long-term cycling stability possibilities that HEO has been used as an anode active material in Lithium-ion batteries. Furthermore, transition metal (TM) oxides have been used as dielectric materials of resistive random access memory (RRAM) owing to the stable structure and variable oxidation state of transition metals. However, the switching mechanism of TM-HEO-based RRAM has not been fully investigated to date.
In this work, We grew the high entropy oxide $(Cr, Mn, Fe, Co, Ni)_3O_4$ on Nb: STO conductive substrate epitaxially, and deposited the Pt metal as the top electrode. The structure of the pristine dielectric layer is spinel. After cycled, we observed that some regions of spinel structure will transform into rock-salt structure by using advanced transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM) characterization, and the result data of X-ray photoelectron spectroscopy (XPS) and Electron Energy Loss Spectroscopy (EELS) support this perspective. Only specific elements will change their valence state, which resulted in excellent resistive-switching properties with a high on/off ratio on the order of 10^4 times, and excellent endurance in the order of 10^3 cycles at room temperature.

11:15 AM EL19.05.04
Regulated Conductive Filament Formation and Evolution for Improved Switching Uniformity in Embedded Metal-oxide Based Memristor - A Phase Field Study Kena Zhang and Ye Cao; The University of Texas at Arlington, United States

The extreme device-to-device variation of switching performance is one of the major obstacles preventing the applications of metal oxide-based resistive random-access memory (RRAM) in large-scale memory storage and resistive neural network. Recent experimental works have reported that embedding highly ordered metal nano-islands (NIs) can effectively improve the uniformity of the RRAM devices, but the underlying role of the ordered metal NI is not fully understood. In this study, to address this specific problem, we develop a physical model to understand the origin of the variability and how embedding metal NIs within the HfO_2 oxide can improve the electroforming and resistive switching performances of RRAMs by reducing this variability. We find that due to dimensional confinement, introducing NIs increases electric fields in their vicinity, leading to high vacancy concentrations even at low forming potentials, and hence a more deterministic formation of the CF from its vicinity, in contrast to the random growth of CFs in the absence of embedded NIs. This deterministic vacancy nucleation in the vicinity of the embedded metal NIs is not only found to reduce the initial electroforming but also the subsequent reset/set voltages, as well as enhance the uniformity of these operation voltages and current ON/OFF ratio. We further demonstrate that modifying the shapes of the metal NIs can modulate the field strengths/distributions around the NIs, and that choosing NI metals that chemically facilitate vacancy formations can further optimize the CF morphology, reduce operation voltages, and improve switching performance. Our work thus provides a fundamental understanding of how embedded metal NIs improve the resistive switching performance in oxide-based RRAMs, and could potentially guide the selection of embedded metal NIs to realize a more uniform RRAM that also operates at higher efficiency than present materials.

Optoelectronic Synaptic Memristors for Bio-Inspired Computing Tseung-Yuen Tseng; National Yang Ming Chiao Tung University, Taiwan

Nowadays, technology is rapidly evolving. Artificial intelligence(AI) is one of the fascinating technologies in the modern world. AI has made significant technological progress in face classification, speech recognition, strategic game, and decision-making [Yao, et al., Nat. Commun., 8, 1, pp. 1-8, 2017;

Jarrahi, Bus. Horiz., 61, 4, pp. 577-586,2018]. The processing of AI computing heavily depends on big data availability and requires a large amount of computation. Bio-inspired neuromorphic computing is expected to develop a more proficient computing architecture that mimics biological neural networks. Neurons and synapses are the two fundamental elements of neuromorphic architecture, where synapse plays an important role in learning and memory(C. Mead, Proc. IEEE, 78(10), 1629–1636, Oct. 1990). Memristors can become a potential candidate to behave as synapse due to their chemical compositions and electrical properties. In the last few years, photonic memristors have attracted increasing attention for AI systems. Such memristive devices have excellent capabilities to reduce the von Neumann bottleneck issue [Indiveri et.al., Proc. IEEE, 103, 8, pp. 1379-1397, 2015]. Additionally, integrated system consists of arrayed optical memristors to accept as building blocks of biospired vision system.

This talk will present that the photonic oxide memristor has high potential for synaptic application. It will report the conduction mechanism of the memristor device and working principle of the synapse. The synaptic features including potentiation/depression, paired-pulse facilitation(PPF) and spike time dependent plasticity(STDP) will be briefly introduced. In our recent work, Zn_2SnO_4(ZTO) based memristor devices are fabricated. The SL device shows over 80% optical transparency for the entire visible region. Significant improvements in bipolar resistive switching properties of the device with low SET voltage and long DC endurance cycles are observed in the 200°C, N_2 annealed device. The linearity of such memristive synapse is improved for 350 training epochs with a total number of 175000 pulses. The STDP learning rule for the annealed device is demonstrated through the electric field. The optical sensing capabilities of this device including photonic potentiation, photonic PPF, learning experience behavior, and multilevel memory feature by the repetition of optical pulse are demonstrated under the blue light illumination. On the other hand, the linearity and on/off ratio of the optoelectronic synapse are further improved by employing ZTO/MgO DL device. Such device has improved reliability with stable endurance and synaptic characteristics. The nonlinearities of potentiation and depression of the device are 1.96 and 0.33, respectively. The device shows 300 training epochs with 300000 pulse numbers. The synaptic features of the ZTO-based memristors make it to be suitable for optoelectronic synaptic application

Electrical Properties Optimization on Resistive Switching Characteristics in Nb_2O_5-based RRAM Devices Chien-Hua Wang and Wen Wei Wu; National Yang Ming Chiao Tung University, Taiwan

In recent years, resistive random access memories (RRAM) has the advantages of simple cell structure, fast switching speed, low cost and the possibility of becoming next-generation non-volatile memories. However, the switching behavior of RRAM device is still not having enough evidence to be confirmed to replace conventional random access memories. In order to improve endurance characteristics and reduce power consumption, we use two distinct transition metal oxides, NiO and Nb_2O_5 for the further study. The dielectric layer NiO served as oxygen reservoir, and the Nb_2O_5 acted as resistance switching layer. In this work, we fabricate two different device structures, the respective structures are single-layer dielectric devices: Pt/Nb_2O_5/Pt, and bilayer dielectric devices: Pt/NiO/Nb_2O_5/Pt. It is found that the single-layer RRAM devices are unipolar operation, and another bilayer RRAM devices are bipolar switching mode. In addition, the bilayer RRAM devices exhibit better on/off ratio and endurance compare to single-layer devices. Besides, both devices also possess long cycling endurance and great ON/OFF ratio ($>10^3$).
To realize the resistive switching mechanism of two different types of devices, the high-resolution transmission electron microscope (TEM) was used to observe the conducting filaments in both dielectric layers. Moreover, the results of energy dispersive spectrometer (EDS) were used to identify the elementary distribution and analyze the filamentary compositions, indicated that the filament type of both devices was composed by a stack of oxygen vacancies. Furthermore, the X-ray photoelectron spectroscopy (XPS) and the electron energy loss spectroscopy (EELS) are used to analyze the oxidation state, bonding condition, and reactive regions in RRAM devices. This study indicated that bilayer RRAM devices enhance the performance of electrical characteristics, and provide insights into the proper structure design to alter the electrical properties of the related RRAM devices.

Deterministic Activation of Resistive switching and Light Emission from TaOx with Nanoscale Resolution Olha Popova[1], Steven J. Randolph[1], Sabine M. Neumayer[1], Benjamin Lawrie[1], Olga Ovchinnikova[1], Liangbo Liang[1], Matthew Marinella[2], Bobby G. Sumpter[1] and Petro Maksymovych[1]; [1]ORNL, United States; [2]Arizona State University, United States

Resistive switching in thin films phenomena have by now been widely reported throughout an enormous range of material classes, almost making them a generic property of field and current induced [MM1] material response. However, the mechanisms behind resistive switching have been persistently difficult to control, not in a small part due to its non-equilibrium nature. Moreover, from a practical side, the need for “controlled breakdown” to initiate resistive switching, is undesired due to significant power dissipation, stochasticity as well as dramatic restructuring of the material. Such structural changes are the major reason why the structure-function paradigm for resistive switching materials is difficult to develop.
In present work we have advanced both the measurement and the conditioning of the resistive switching phenomena utilizing TaOx as a model system. On one hand, we introduced two microscopy techniques – microwave impedance microscopy and cathodoluminescence – for the characterization of electroresistive phenomena. The advantage of these methods is that they can directly probe the electronic structure and conductance of amorphous binary oxide materials down with nanoscale imaging resolution. Therefore, much more robust connection to theoretical methods can be established, that can then guide a design approach material optimization. Meanwhile, we utilized ion-beam irradiation as a path to activate conductivity of materials without the need for energy-intensive electroforming. Using model Ta2O5-x amorphous films we will demonstrate: (1) direct imaging of electronic structure and trap centers in thin amorphous TaOx films; (2) electronic, dielectric and conductive characterization of Ta2O5-x after He-ion irradiation. Although He-ions begin to modify the nature of the bond [MM2] centers even at the lowest doses, the films exhibit remarkable stability toward large displacive dose of He-ions and are driven to metallic state only at the limit of structural decomposition; (3) unexpected enhancement of luminescence yield with increasing damage of the binary oxide film. We attribute this effect to preferential injection of bright luminescing centers under the combined effects of He-irradiation and localized electric fields. Our techniques are directly compatible with device architectures, potentially allowing for a high-degree of on-demand tuning of neuromorphic circuitry and materials.

Materials and Technology Elements for Scaling Quantum Processors Ricardo Donaton; IBM Quantum, United States

Quantum computing has the potential to be a new computing paradigm. At IBM Quantum we have been scaling the number of qubits, improving coherence

times and gate fidelities as seen through the evolution of our quantum processors: Falcon 27 qubits, Hummingbird 65 qubits, Eagle 127 qubits, and we are on track to deliver Osprey 433 qubits and Condor 1121 qubits. Throughout this process we are learning about materials, process integration and yield, mechanical aspects, superconducting flexible cables, cryogenic infrastructure, control electronics and more. However, we cannot continue to simply increase the chip size to accommodate more and more qubits. Because of that, we are developing processes and architectures to connect processors into modular systems.
In this talk we will discuss the architectures and materials used in integrating new technology elements such as superconducting interconnects, through-substrate-vias and advanced packaging techniques that are enabling us to scale up our quantum processors. We will also touch on how we are planning to continue scaling up and deliver 4000+ qubit processors in the near future.

Materials and Integration for Quantum Computing in Silicon Mark A. Eriksson; Univ of Wisconsin-Madison, United States

As much as possible, qubits for quantum computers must be isolated from their environment in order to preserve phase coherence and maintain entanglement. Remarkably, the techniques used to make classical silicon CMOS devices can be used to make qubits with excellent performance. The operation of these devices, on the other hand – from the required temperatures to the number of electrons comprising a typical qubit – is very different from what is found in even the most advanced classical integrated circuits. In this talk, I will present two recent advances in materials – and the integration of those materials – for quantum computing in silicon. Recent results have begun to demonstrate the remarkable properties of silicon quantum wells containing short wavelength oscillations in the concentration of added germanium atoms. This highly engineered material, which has concentration oscillations on the 1-2 nanometer scale, changes the band structure in ways that provide better protection for quantum states, by increasing the energy gap to energy levels outside the qubit basis. It also is predicted by theory to introduce spin-orbit coupling, which can be used to enable all-electrical control of spin qubits. I will also discuss the role of integration, including 3D integration, which enables readout of quantum dot qubits in silicon by measuring the microwave transmission of a superconducting resonator on a separate substrate, flip-chip bonded to the first.

3:30 PM *EL19.06.07
Cryogenic Electronics for Quantum Computing: From Materials to Devices Cezar Zota, Eunjung Cha, Alberto Ferraris, Mridula Prathapan, Peter Mueller and Thomas Morf; IBM Research, Switzerland

The impact of an advanced quantum computing technology on society will be transformative [1]. To realize such a quantum technology, the entire quantum system must evolve, from the qubit chip to the supporting readout and control electronics [2]. Integration of cryogenic electronics inside the cryostat may become necessary to reduce system cost, increase speed and improve the input-output bottleneck [3]. Significant efforts have already been made to develop cryogenic integrated circuits for the generation of qubit control signals inside the cryostat. One of the main design constraints of such circuits and their subsequent integration is the low available cooling power, which is in the order of a few W at the 3 K stage, and significantly less at the lower stages. Advanced cryo-circuits demonstrated today show power dissipation in the order of 5 mW/qubit [4]. This means that even with such solutions, scalability will remain challenging for advanced quantum computers. An approach to address this power challenge is to develop not only tailored cryogenic circuits, but also tailored cryogenic devices that can leverage the unique and beneficial properties of materials at low temperatures.

In this work, we will demonstrate the design and operation of a cryogenic qubit control circuit, an RF arbitrary waveform generator, based on commercial 14 nm FinFET technology. The circuit exhibits exceptionally low power dissipation and excellent noise performance. To plot a path towards even further reduce power dissipation, we study and model the comprising transistor technology at 4 K. The results indicate that a tailored cryogenic CMOS technology, leveraging the reduced subthreshold swing and enhanced mobility of the transistors, could achieve orders of magnitude reduction of DC power dissipation. Finally, we demonstrate cryogenic circuits based on III-V materials, such as InGaAs and InP, and show how these leverage the extremely high electron mobility of cryogenic quantum wells towards even further enhanced circuit performance.

Characterizing Nanomagnets Used for Silicon Spin Qubit Operation Peter Rickhaus[1], Liza Zaper[1,2], Floris Braakman[2], Alexander Stark[1], Felipe Favaro de Oliveira[1], Mathieu Munsch[1], Patrick Maletinsky[2,1] and Martino Poggio[2]; [1]Qnami AG, Switzerland; [2]Universität Basel, Switzerland

Certain type of spin qubit implementations require the application of well-defined magnetic fields.[1] These are provided by nanomagnets. For the sake of reproducible qubit operation, it is key to ensure that the stray field, generated by the nanomagnets, has little variation caused by the nanofabrication technique. We use Scanning Nitrogen-Vacancy Magnetometry (SNVM) to map out the magnetic stray field generated by nanomagnets. Previously, we have successfully used this technique to characterize the very small stray fields that originate from CoFeB nanowires.[2] Here, we fabricate the nanomagnets using focused electron beam ion deposition (FEBID), a resist-free technique that potentially improves the magnetic homogeneity. We use the high sensitivity and spatial resolution of SNVM to characterize the magnetization, homogeneity and magnetic particles of the nanomagnets and to find improvements for the fabrication technique.[3]

5:00 PM EL19.07.03
Alternative Approaches to Purify As-Produced Boron Nitride Nanotubes from Thermal Induction Plasma Process Jingwen Guan, Yueying Li, Steven Walker, Robyn Iannitto, Liliana Gaburici, Keun Su Kim, Dean Ruth, Mark Plunkett, Christopher T. Kingston and Benoit Simard; Security and Disruptive Technologies Research Centre, Canada

Boron nitride nanotubes (BNNTs) are an engineered nanomaterial possessing a compelling set of intrinsic properties, including a stable broad band gap about 5.5 eV, therefore, being an electrical insulation material, excellent mechanical strength, high thermal conductivity, high oxidation resistance, and transparency in visible light. These properties make them perfect candidates for future nanocomposites in applications such as high-temperature and extreme environments, and transparent and protection materials. After the discovery of carbon nanotubes (CNTs), BNNTs were first theoretically predicted and then successfully synthesized in 1995 by an arc-discharge method. Subsequently, numerous other techniques for BNNT synthesis have been discovered, including the plasma-based Hydrogen Assisted BNNT Synthesis (HABS) method developed at the National Research Council Canada (NRC). Despite such advances in production, direct growth of highly pure BNNTs still remains challenging today, with most methods yielding varying mixtures of BNNTs, non-nanotube fragments and particles, and incompletely consumed feedstock. From the HABS method, the as-produced BNNT product consists of approximately 20 wt% elemental boron particles, and 25 wt% of non-nanotube B-N byproducts and unreacted h-BN feedstock. Removal of these impurities is essential to extract the full potential of BNNTs in nanocomposites. We will present three different approaches to post-synthesis purification of HABS-BNNT materials produced at the NRC, namely gas-phase halogen processing, non-covalent polymer extraction, and a three-stage solution process, and will discuss the advantages and disadvantages of each approach with respect to purity, efficiency and scalability.

5:00 PM EL19.07.04
Atomic Structure of Amorphous TiO_2 : GeO_2 Mixtures and its Evolution with Annealing Ruth Osovsky[1,2], Emmett Randel[1], Aaron Davenport[1], Samuel Castro Lucas[1], Michael Van Erdewyk[1], Justin B. Sambur[1] and Carmen S. Menoni[1]; [1]Colorado State University, United States; [2]Israel Institute for Biological research, Israel

Transparent amorphous oxide thin films are ubiquitous in photonics technologies. They are transparent over a broad wavelength range, from near ultraviolet to near infrared. Their refractive index in the near infrared offers high contrast with Si or among oxides, as is the case between (amorphous) *a*-Ta_2O_5 and *a*-SiO_2, which is exploited for light confinement in integrated Nano- and Si photonics devices. Amorphous oxide thin films are also extensively used in optical interference coatings for most demanding laser science applications. Tunable optical and mechanical properties are accessible by depositing mixtures of two or more cations. Recent research on ion beam sputtered (IBS) mixtures of 44% TiO_2 and 56% GeO_2 have been identified as prospective candidates for the high index layer in interference coatings for gravitational wave detectors, as their internal friction, when annealed to 600 °C for 100 hours, is ~4x lower than state-of-the art TiO_2 : Ta_2O_5 [1]. This work reports on a study of the evolution of atomic structure and bonding of mixtures of TiO_2 and GeO_2 through Raman and Infrared spectroscopies with annealing. Characteristic vibrational signatures of *a*-GeO_2 are altered in the mixtures, indicating the doping of Ti ions into the lattice of *a*-GeO_2 in substitutional mode, as evidenced by a larger distribution in inter-tetrahedral Ge-O-Ge bond angles and suggesting a more open and flexible network. Annealing causes structural reorganization on the TiO_2 : GeO_2 mixtures, as observed by the evolution in Ge-O-X (X=Ge, Ti) vibrational signatures in the mixture, which is more significant at temperatures ≥ 500°C. This work brings out a new understanding of the modifications in the atomic structure of TiO_2 : GeO_2 mixtures upon thermal treatment, which is critical to understand the mechanisms involved in affecting internal friction in this promising high refractive index materials for coatings of gravitational wave detectors [1].

5:00 PM EL19.07.06
Effects of Metal Diffusion on Electrical Performance and Reliability of Low Dielectric Constant Thin Films Fabricated by Plasma-Enhanced Chemical Deposition Method Under Thermal Stress Seonhee Jang, Rajib Chowdhury and Thomas Poche; University of Louisiana at Lafayette, United States

To reduce a resistance-capacitance (RC) time delay in the back-end-of-line (BEOL) interconnect is critical for advanced integrated circuit chips. Copper (Cu) and low-dielectric constant (low-*k*, *k*<4.0) interconnects can reduce the RC time delay by 30-50 %, compared to traditional aluminum (Al) and silicon oxide interconnects because Cu/low-*k* film combination provides lower metal line resistance and parasitic capacitance between metal lines. However, the migration and diffusion of metal into the low-*k* films become challenging during the integration of Cu/low-*k* film, resulting in degradation of electrical performance and reliability. One solution is to form metal barriers. With further scaling of technology node, the volume of Cu metal lines decreases and its resistance significantly increases because of Cu surface and grain boundary scattering and the metal barriers. The other solution is to employ different metals to reduce the surface and grain boundary scattering effect. Potential candidates to replace Cu can be determined by lower product value of bulk resistivity and electron mean free path than that of Cu. Based on this criteria, cobalt (Co) and molybdenum (Mo) were selected. In this study, the integration of Co or Mo with the low-*k* films was conducted and electrical characteristics and reliability of the low-*k* films were investigated.
In this study, low-*k* SiCOH thin films were fabricated on p-type Si (100) wafer by plasma-enhanced chemical vapor deposition (PECVD) of tetrakis(trimethylsilyloxy)silane (TTMSS, $C_{12}H_{36}O_4Si_5$) precursor at room temperature. The thickness of the low-*k* SiCOH film was in the range of 100-200 nm. Following, three different metals Cu, Co, and Mo were deposited on the low-*k* SiCOH film through a shadow mask using a DC sputtering method to fabricate metal-insulator-silicon (MIS) capacitors. All metal films were deposited at room temperature. The thickness of the films was approximately 50 nm. The fabricated MIS capacitors were then annealed in N_2 atmospheres at 400 °C for 2 h. The elemental composition changes were investigated by X-ray photoelectron spectroscopy (XPS). The electrical characteristics and reliability of the MIS structures were measured from capacitance-voltage (C-V) and current-voltage (I-V) curves using a semiconductor parameter analyzer.
The C-V curves of Cu-gate, Co-gate, and Mo-gate MIS capacitors were compared before and after thermal stress. The typical C-V curves were obtained with accumulation, transition, and depletion regions from the negative to positive bias application. Depending on the type of metal-gate, the accumulation capacitance was different, suggesting that the deposition of metal gate may affect the capacitance of the underlying low-*k* film. The thermal annealing reduced the accumulation capacitance of the MIS capacitors. The *k*-value was determined by the equation, $k=C_{acc}d/\varepsilon_0 A$, where C_{acc} is the accumulation capacitance, d is the thickness of the low-*k* film, ε_0 is he vacuum permittivity, and A is the gate area. An increase in the *k*-value suggests that the low-*k* thin film was damaged by plasma during metal sputtering deposition. After annealing, the *k*-values were reduced, indicating that plasma-induced damage to the film could be partially recovered by annealing process. A flatband voltage (V_{fb}) shift in the C-V curves could occur due to the presence of charges of fixed, interface, and mobile types. Another shift in the C-V curves was the evidence of the diffusion of metal ions into the low-*k* film by annealing process. An increased leakage current after annealing demonstrates that the diffusion of metal ions occurred in the low-*k* film. From the XPS elemental composition analysis, metal atoms diffused into the low-*k* film at the interface between the low-k film and each metal after annealing. A large V_{fb} shift was also

observed after annealing suggests that a thermal stress stimulated more metal ions to diffuse into the low-*k* film.

5:00 PM EL19.07.07
Colloidal Single Crystals Engineered with DNA in Lithographically Defined Microwells Alexa Wong[1,2], Kwanghwi Je[3], Cindy Zheng[1,3], Liban Jibril[1,2], Ziyi Miao[1,2], Sharon Glotzer[3] and Chad Mirkin[1,2]; [1]Northwestern University, United States; [2]International Institute for Nanotechnology, United States; [3]University of Michigan–Ann Arbor, United States

Lithographically-defined microwell templates are used to study DNA-guided colloidal crystal assembly parameters, including superlattice position, orientation, and size, in an effort to increase our understanding of the crystallization process. In addition to enabling the synthesis of arrays of individual superlattices in arbitrary pre-defined patterns, the technique allows one to study the growth pathways of the crystals via *ex situ* scanning electron microscopy. Importantly, a Volmer–Weber (VM) (island formation)-like growth mode is identified, which has been reproduced via simulations. Notably, both experiment and simulation reveal that the crystallites merge and reorient within the microwells that defined the crystal growth to form single-crystalline structures, an observation not common for VM pathways. The control afforded by this platform will facilitate efforts in constructing metamaterials from colloidal crystals as well as their integration into optical devices and applications.

5:00 PM EL19.07.09
Steady-State and Transient Electron Transport in the Two-Dimensional Electron Gas in Gallium-Aluminum-Nitride Heterojunctions with Gallium Nitride Yana Wang[1], Michael Shur[2], Walid A. Hadi[3] and Stephen K. O'Leary[1]; [1]University of British Columbia, Canada; [2]Rensselaer Polytechnic Institute, United States; [3]Florida State University, United States

At the interface of gallium-aluminum-nitride with gallium nitride, a two-dimensional electron gas will form. This electron gas can both enhance the low field mobility and influence the electron drift velocity for higher applied electric field strengths. Using a self-consistent Schrödinger-Poisson equation solver, we determine the concentration of electrons within such a two-dimensional electron gas as a function of the aluminum content. A comparison will then be made with results acquired using the analytical approach of Ambacher *et al.* [1]. The impact of this two-dimensional electron gas on the steady-state and transient electron transport that occurs within this material will then be critically examined. The device implications will be explored.

Flexible Hydrogenated Amorphous Carbon Thin Films Fabricated by Plasma-Enhanced Chemical Vapor Deposition of Cyclohexane Precursor Thomas Poche, Rajib Chowdhury and Seonhee Jang; University of Louisiana at Lafayette, United States

The characteristics of the hydrogenated amorphous carbon (HAC) films can be determined by the composition of sp^3, sp^2, and sp^1 hybridized structures depending on the bond type of four valence electrons. The C-C bonds with sp^3 and sp^2 correspond to diamond and graphite, respectively, and a mixture of sp^3 and sp^2 determines the material properties. The sp^3 bond shows some advantages including mechanical strength, wide band gap, and chemical and electrochemical inertness, however it is unfavorable for a strip process after etching. The HAC films by adding hydrogen to a sp^3/sp^2 could possibly present an etching resistance. The HAC films are characterized according to the composition ratios among a sp^3, sp^2, and hydrogen. When the hydrogen content is large, polymer-like HAC films can be formed with low film density due to high content of sp^3. When the hydrogen content is small, the content of sp^3 becomes low, resulting in a diamond-like HAC with high film density and hardness. When the hydrogen content becomes smaller, the content of sp^2 is high and a graphite-like HAC can be obtained. Depending on the deposition conditions, the sp^2/sp^3 hybridization ratio can vary over a wide range of values. Flexible HAC thin films were fabricated by plasma-enhanced chemical vapor deposition (PECVD) of cyclohexane (CHex, C_6H_{12}) precursor on the substrate of indium tin oxide on polyethylene naphthalate (ITO/PEN). The sheet resistance of ITO was about 12 Ω/square. The transparency of ITO was ≥ 75 % with a haze of 3 %. The PEN substrate was DuPont Teijin film. Thicknesses of ITO and PEN layers were >180 nm and 0.125 mm, respectively. Gas molecules vaporized from the CHex precursor were carried by argon (Ar) with a purity of 99.999 % gas and delivered to the reactor. A base pressure was 0.53 Pa before deposition. The HAC films were deposited at room temperature of 25 °C with an operating pressure of 26.7 Pa. The RF plasma power with 13.56 MHz was chosen from 20 to 100 W. To characterize etching properties of the HAC films, dry etching with $Ar+CF_4+O_2$-based gas chemistry was conducted in an inductively coupled plasma-reactive ion etching (ICP-RIE) system. Tetraethyl orthosilicate (TEOS) oxide was used as the reference for calculating the etch rate and etch selectivity. The etch selectivity of the HAC film was calculated by t_{TAC}/t_{TEOS}, where t_{TEOS} and t_{TAC} are the thicknesses of the TEOS and HAC removed after dry etching. The thickness and extinction coefficient of the HAC films were measured by ellipsometer. Surface morphology of the films was observed by atomic force microscopy (AFM). The functional groups of the films were identified using Fourier transform infrared (FTIR) spectroscopy. The chemical composition of the films was determined by X-ray photoelectron spectroscopy (XPS). The structural arrangement of the carbon bonds was analyzed by Raman spectroscopy.
The prominent IR absorption consists of C–H stretching modes at 3300-2800 cm^{-1} and C=C and C–H bending modes below 2000 cm^{-1}. The C–H stretching mode can be deconvoluted into three: $sp^1\equiv$C–H modes centered at 3300 cm^{-1}, sp^2=C–H$_n$ modes at 3085-2975 cm^{-1}, and sp^3–C–H$_n$ modes at 2955-2850 cm^{-1}. The structural transformation could occur from the sp^3 to sp^2 depending on deposition conditions. Two carbon allotropes – diamond and graphite – can be distinguished by their Raman spectra. Typical D and G peaks were observed around 1350 and 1590 cm^{-1} in the Raman spectra, respectively. The Raman spectra of disordered carbons can be classified by the intensity ratio of the D and G modes, I(D)/I(G). To quantify the chemical bonding status, the ratio R is introduced as the peak area ratios of C–C to C–H$_x$. The etch-durability represented as the inverse of the film loss is related to the ratio R. Etching properties were strongly affected by deposition conditions and etching parameters.

5:00 PM EL19.07.12
TEM Investigation of Resistive Switching mechanism of $PbSnO_3$ Perovskite Oxide RRAM Device Meng Hsuan Yang and Wen Wei Wu; National Yang Ming Chiao Tung University, Taiwan

Resistive memristors with high density and nonvolatile have the significant potential for long-term data storage and development of artificial neural computing. Among most filamentary-type resistive switching(RS) memories, conventional binary oxides (MO_x) are extensively studied as RS materials in memristors.[1] However, there are few studies on ternary oxides and lack of stoichiometry information.
In this study, we introduced novel material $PbSnO_3$(PSO) as switching layer, which epitaxially grew on $SrRuO_3$ (SRO) bottom electrode and $SrTiO_3$ (STO) substrate. This work revealed the resistive switching mechanism by means of the formation nanochannel in the $PbSnO_x$ (PSO) matrix and the effect of oxygen deficiencies on its characteristics. High-resolution transmission electron microscope (TEM) was utilized to achieve a clear visualization of conducting path. Furthermore, the components and structures were analyzed by electron energy loss spectroscopy (EELS) and energy dispersive spectroscopy (EDS) equipped in TEM. PSO-based RS memory exhibited superior performance including high ON/OFF ratio, long data retention time, narrow distribution of switching voltage, and stable device-to-device uniformity, which provide great potentialities on the application of novel RRAM devices.

5:00 PM EL19.07.13
Deformable Carbon Atomic Film-based Etching Mask Jiwoo Kim, Dong Hoon Moon and Gwan-Hyoung Lee; Seoul National University, Korea (the Republic of)

Carbon-based materials have been studied in the various field such as semiconductor industry as potential materials due to their superior properties such as high electrical and thermal conductivity, chemical stability, and mechanical strength. Carbon-based materials have great potential not only as channel and electrode materials with their outstanding electrical properties, but also as sacrificial masks , etch stop, and barrier materials with their high chemical stability and excellent mechanical strength. Chemically stable carbon-based thin film can be a key to overcoming the conventional technological limit of enabling complex 3D stacking structure and nano-fabrication. Here, we synthesize carbon atomic film on silicon substrates and show mechanical properties and etching behavior of the carbon mask. Deformation of the carbon thin film occurs during etching and unique 3D structures can be fabricated with the carbon mask. Also, the kirigami pattern allows the fabrication of more complex 3D structures which is not available with conventional mask materials. Our work paves the path for the etching and fabrication technique for complex 3D structures.

5:00 PM EL19.07.14
A Novel Electrical Characterization Method for Simultaneous Extraction of the Grain Size, Single-Crystalline Grain Sheet Resistance, and Grain Boundary Resistivity of Polycrystalline Monolayer Graphene Honghwi Park, Jiyeong Yun and Hongsik Park; Kyungpook National University, Korea (the Republic of)

Among many kinds of graphene grown or synthesized by various methods, graphene grown on metal catalysts by chemical vapor deposition (CVD) has been the most widely used for device applications because large-scale monolayer graphene can be produced with a relatively good material quality. However, CVD graphene is typically grown as polycrystalline composed of multiple single-crystalline grains stitched by grain boundaries (GBs), and carrier scattering at the GBs could severely degrade electrical performance and uniformity. For the design and fabrication of electrical devices utilizing CVD graphene, therefore, it is very important to know the electrical parameters of single-crystalline grains and GBs as well as the average grain size, as these directly correlate to electrical performance of CVD-graphene devices. Accordingly, many approaches to dealing with them have been studied over the past decade; however, extracting the grain-related parameters (*i.e.*, the average grain size, grain sheet resistance, and GB resistivity) through a simple characterization method still remains as a great challenge because of the difficulty in observing graphene GBs and evaluating the electrical properties of the GBs and single-crystalline grains separately.

Here, we report for the first time an electrical characterization method that can extract the average grain size, grain sheet resistance, and GB resistivity of monolayer CVD graphene simultaneously through a simple transmission-line model (TLM) measurement. We found out that the electrical property of polycrystalline graphene (*i.e.*, sheet resistance) depends significantly upon the device dimension and such the dependence results from the GB density within the device channel region. By statistically investigating the distribution of GB density depending on channel dimensions, we developed an analytical resistance model that can explain the relation between the sheet resistance of polycrystalline graphene and its grain parameters. With this resistance model, we confirmed that the three-grain parameters can be extracted simultaneously with high accuracy (> 99%) from the dependence of the sheet resistance on the channel dimension. Furthermore, the developed analytical resistance model and its applicability for parameter extraction were experimentally validated by characterizing TLM patterns fabricated on monolayer CVD graphene. The result showed that the average grain size, grain sheet resistance, and GB resistivity of CVD graphene can be extracted simultaneously with high accuracy. This method of simultaneous extraction of the grain-related parameters from the sheet-resistance dependence on the channel dimension obtained from simple TLM measurements will provide a useful tool for the electrical characterization of CVD graphene and other poly-crystalline 2D materials, and their efficient device applications.

5:00 PM EL19.07.15
Control of Threshold Voltage of AlGaN/GaN FinFET by Monolayer Doping Linh Chi T. Cao[1], Shu-Han Hsu[1] and Chun-Lin Chu[2]; [1]Sirindhorn International Institute of Technology, Thammasat University, Thailand; [2]Taiwan Semiconductor Research Institute National, Applied Research Laboratories, Taiwan

Abstract:
With the evolution of modern society and economy, the demand for network applications, broadband network systems have been gradually grabbing significant attention in the high-tech industry. To meet the requirements of smart life, smart city, and unmanned devices and vehicles in the future, the standard of 6G could include wireless communication between low-orbit satellites combined with 5G cellular communication systems. For 6G wireless communication, wide bandgap and high-electron-mobility transistors of AlGaN/GaN (HEMTs) are emerging as excellent candidates for radiofrequency (RF) and microwave power amplifiers due to their high-power-handling capabilities and ability of small-scale fabrication to obtain minor and cheaper chip size. The conventional AlGaN/GaN HEMTs such as depletion-mode transistors with a negative threshold voltage (Vth) can limit the device application and their stability against temperature. Therefore, it is important to convert the gate-controlled channel from depletion- to enhancement mode. Herein, this study presents a method that can accurately control threshold voltages of AlGaN/GaN by using monolayer doping with fluoride-containing molecules without any lattice damage that can be created from conventional methods such as implantation or dry-etching. First, epitaxy of GaN/AlGaN/GaN was introduced over SOI substrate sequentially in CVD chamber. TEM shows the corresponding thickness for each layer (Figure 2). Using a self-assembly technique, a uniform and reproducible monolayer of 1H,1H,2H,2H-Perfluorooctyltriethoxysilane (POTS), fluorine-containing molecules, was immobilized onto surface of AlGaN/GaN substates by covalent bond Ga-O-Si. The XPS measurement observed fluoride signal with 56.48 % of atomic percentage that confirmed the formation of fluoride- self assembled monolayer onto AlGaN/GaN substrate. The doped concentration of fluoride atoms can be controlled by self-assembled time and the doses of POTS for assembled reaction. After forming a fluoride-containing monolayer, the device is then capped with SiO_2, spike annealed under high temperature to complete monolayer doping process. The AlGaN/GaN FinFET device composed of the P-type and N-type high-mobility carrier channels will be fabricated to further verify the performance and reliability characteristics for the novel Vth turning process. This can open more process possibilities for next-generation high mobility AlGaN/GaN FinFET to serve future related 6G communication and low-orbit satellite circuit development.
Keywords: Fluoride monolayer doping, 6G communication, AlGaN/GaN FinFETs, self-assembled monolayers (SAMs).

Selectively Self-Healing, Stretchable and Wirelessly Operatedsensor System Based on a Rubber-Modified Epoxy with High Toughness Somin Kim and Jeong Sook Ha; Korea University, Korea (the Republic of)

There has been extensive research on self-healing materials for extending the lifespan of wearable devices and for environmental friendliness. However, it is still in progress to get selectively self-healing functionality by specific stimulus such as heat or light for prohibiting the unintentional merging of materials to ruining the devices.

In work, we report on the synthesis of thermo-responsive self-healing epoxy and its application to fabricating self-healing strain and temperature sensors. Thermo-responsive self-healing epoxy is synthesized by using poly(tetramethyl glycol), 1,4-butanediol diglycidyl ether, aminophenyl disulfide, and dimethylglyoxime. Dimethylglyoxime and aminophenyl disulfide are highly thermo-responsive whose triggering temperature can be tuned by molecular structures. By heating, the disulfide bond exchange reaction and the regeneration of the oxime-carbamate bond can be initiated, resulting in self-healing. In addition to self-healing performance, the synthesized polymer exhibits high toughness and stretchability owing to the ring-opening reaction of the epoxy group and packing of poly(tetramethyl glycol). Using the synthesized self-healing epoxy film as a substrate, individual temperature and strain sensor is fabricated based on a mixture of the self-healing polymer and conductive materials, and NFC coil was patterned on the polymer substrate to transmit energy wirelessly. Then, a multi-sensor patch of vertically assembled sensor layers and NFC coil layer are made using deformable and self-healing liquid metal galinstan interconnections. Here, the layer-by-layer assembly is attributed to interlayer self-healing without delamination. Such fabricated multi-sensor patch can monitor bio-signals and can be charged wirelessly after attachment onto human skin and it can be fully self-healed by heating to recover the sensitivity even after multiple cycles of damage and healing.

5:00 PM EL19.07.17
Comparative Study of NiO_x/β-Ga_2O_3 p-n Heterojunctions on (-201) and (001) Free-Standing β-Ga_2O_3 Substrates Dinusha Herath Mudiyanselage, Dawei Wang, Ziyi He and Houqiang Fu; Arizona State University, United States

β-Ga_2O_3 is a wide bandgap (WBG) semiconductor material that has been extensively studied for power, optical, and RF electronics due to its large bandgap of 4.9 eV and high breakdown field of ~ 8MV/cm. It is expected that β-Ga_2O_3 can outperform its GaN and SiC counterparts. However, most of the demonstrated β-Ga_2O_3 devices are unipolar due to the lack of p-type Ga_2O_3, such as high electron mobility transistors (HEMTs) and Schottky barrier diodes. This is primarily attributed to the absence of shallow acceptors and holes trapped in localized polarons. To overcome these constraints, other p-type materials, such as p-type NiO_x, have been utilized to produce β-Ga_2O_3 based p-n heterojunctions. Several NiO_x/β-Ga_2O_3 devices, such as p-n diodes and junction barrier Schottky (JBS) diodes have been demonstrated so far. These devices show excellent properties, such as low on-resistance and high breakdown voltages. Moreover, due to its highly asymmetric monoclinic crystal structure, β-Ga_2O_3 exhibits anisotropic properties along different crystal orientations. However, the impacts of different β-Ga_2O_3 crystal orientations on NiO_x/β-Ga_2O_3 p-n heterojunction are still not clear.
In this work, we perform a comparative study of NiO_x/β-Ga_2O_3 p-n heterojunctions on (-201) and (001) crystal orientations. The edge-defined film-fed grown β-Ga_2O_3 substrates were acquired from Novel Crystal Technology, Inc Japan with a similar n-type doping concentration of [Sn] = 5 × 10^{18} cm^{-3} and thickness. First, the substrates were cleaned using acetone, isopropyl alcohol (IPA), and DI water. The Ti/Au (20/130 nm) back contacts were deposited by electron beam (E-beam) evaporation followed by rapid thermal annealing at 500 °C in N_2 environment. Then, standard photolithography was performed to define patterns for deposition of NiO_x and the anode. 200 nm NiO_x and the anode Ni/Ti/Au (20/15/100 nm) were deposited using E-beam evaporation, followed by a liftoff process to isolate individual devices. I-V and C-V measurements were performed using a 4200 SCS semiconductor parameter analyzer. Both devices show an excellent rectification with ON/OFF ratio of 10^{10}. The I-V measurements indicate a turn-on voltage of 1.9 and 2.6 V, an ideality factor of 1.3 and 2.5, and an on-resistance of 3.7 and 5.4 mΩ.cm^2 for (-201) and (001) devices, respectively. The (-201) device exhibited better performance compared with the (001) device in terms of low turn-on voltage, near ideality, and low on-resistance. C-V measurements indicated a doping concentration of 1.6 ×10^{18} cm^{-3} and 1.7×10^{18} cm^{-3} for respective devices. This indicates both devices have similar hole concentrations in the NiO_x layer. These differences in the device electrical properties are attributed to the different atomic configurations, the density of dangling bonds, and conductivity modulated hole injection into β-Ga_2O_3. Further investigation through annealing and temperature-dependent measurements will reveal more information about the anisotropic nature of NiO_x/β-Ga_2O_3 p-n heterojunctions. This work can be an importance reference for understanding the anisotropic electrical behavior of β-Ga_2O_3 heterojunction based bipolar devices.

5:00 PM EL19.07.18
Study on Switching Voltage of Silver Telluride Nanoparticle-Based Resistive Random Access Memory Won-Yong Lee and Jaewon Jang; Kyungpook National University, Korea (the Republic of)

In this study, we report on the change of the switching voltage of a silver telluride nanoparticle-based resistive random access memory (RRAM) device in accordance with the annealing temperature. Solution-processed Ag/silver telluride/Au RRAM was fabricated using synthesized silver telluride NPs. According to the annealing temperature, the change in the properties of the silver telluride thin-film was observed, and the change in the electrical properties of the RRAM devices was also observed. The fabricated silver telluride-based RRAMs have complementary resistive switching characteristics regardless of the annealing temperature. However, it was confirmed that the reset switching voltage was decresed according to the change of the thin-film as the annealing temperature increased. The reset voltage of the device annealed at room temperature was ±3~4V, whereas reset voltage of the device annealed at 200°C decreased to ±1V. This change in switching voltage is due to the change in the crystallinity and surface morphology of the thin-film.

5:00 PM EL19.07.19
Investigating Resistive Switching Mechanism in $PbHfO_3$ Based RRAM Device Che-Hung Wang and Wen Wei Wu; National Yang Ming Chiao Tung University, Taiwan

Recently, binary metal-oxide based resistive random access memory (RRAM) has become one of the popular candidate for future application in memory system due to its excellent characteristics, such as high switching speed, and trusting stability. In this work, the dielectric layer $PbHfO_3$ (PHO) films of 100 nm thickness have been epitaxially deposited on $SrRuO_3$ bottom electrode and then deposited Au as top electrode. PHO shows great electrical properties, which performs high cycling endurance (up to 400 cycles), uniform distribution of both low resistant state (LRS) and high resistant state (HRS), and long retention time (over 10^4 s). The high resolution TEM and STEM images demonstrate the PHO structure before and after the switching behavior. These results strengthen the switching mechanism and the detailed discussion of this switching behavior provide a novel aspect of the RRAM switching mechanism.

5:00 PM EL19.07.20
Atomic-scale Investigation of Structural evolution and Resistive Switching Behaviors in Lanthanum cobaltite -Based Resistive Random-Access Memory Yen Jung Chen and Wen Wei Wu; National Yang Ming Chiao Tung University, Taiwan

Resistive random-access memory (RRAM) is considered for next-generation non-volatile memory (NVM) owing to its simple devices, low cost and high storage density. Resistive switching occurs in a wide range of materials among the transition metal oxides (TMO). In this work, we utilize epitaxial ternary metal oxides layer, LaCoOx (LCO), which grows on Nb-doped SrTiO3 (Nb-STO) substrate as RRAM device. We deposited Au/Ti metal as the top electrode, and measured the SET and RESET process with more than 900 cycles. To reveal the resistive switching behaviors, we use the high-resolution transmission electron microscope (TEM) and Atomic-scale scanning transmission electron microscopy (STEM) to observe the structural evolution and oxygen-ion migration in LaCoOx. From the TEM results and the corresponding Fast-Fourier-Transform Diffraction pattern (FFT-DP), the functionalities of LaCoOx films can be manipulated by distinct voltage. It is clearly demonstrated that the structure changes from monocrystalline to polycrystalline. Further demonstrate structural evolution, we change the top electrode to Pt/Ag. According to previous study, we know that the topotactic phase transformation between perovskite and brownmillerite phases can be performed for epitaxial LaCoOx films. In recent years, topotactic phase transformation has attracted much attention owing to their potential physical and electronical properties for RRAM devices. Under negative bias, the

Pt/Ag/LCO /Nb-STO RRAM device can switch from the pristine high resistance state (HRS) to the LRS, which is known as the SET process. As we continuously applied voltages sweep cycles, the structure will transform from LaCoO2.67 to brownmillerite LaCoO2.5 with perovskite LaCoO3 regions. Additionally, we use X-ray photoelectron spectroscopy (XPS) to demonstrate the Co valence changed for further studying micro-structural evolution and the resistive switching behaviors. This study not only revealed the oxygen-ion migration of LaCoOx but also proved it to be the promising candidate for RRAM application.

5:00 PM EL19.07.21
High Figure of Merit Indium-Tin Oxide (ITO) Electrodes Based on Metal-Polymer Composites without Counter Anions Dongbeom Kim, Wonjeong Suh, Jaehyun Kim, Yebin Park and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

In solution-based polymer-assisted deposition (PAD), high performance transparent conducting oxides (TCO) have been rarely reported compared to multicomponent inorganic thin films (metal-oxides, -carbides, -nitrides, and -chalcogenides). TCO fabrication requires i) removal of impurities, ii) high-density oxide film, iii) homogeneity in crystal structures and film morphology, and iv) controllable elemental doping. This study carries out a systematic investigation into preparation of stable multicomponent metal-polymer complex solutions by removing the counter anions in the solution. This study also performs accurate acid-base titration for each metal species in order to optimize the amount of PEI, thus maximize the density of the film. As a representative TCO, Sn-doped In_2O_3 (ITO) films have been fabricated. The ITO film has an excellent sheet resistance (24.5 Ω/sq), high transparency (93%), and a figure of merit of $2.1 \times 10^{-2}\ \Omega^{-1}$, which are comparable to the best.

5:00 PM EL19.07.22
Single-Acceptor Grain-Boundary Segregation for DC-Bias-Insensitive High Effective Permittivity and Ultralow Dissipation in Ceramic Capacitors Ji-Sang An and Sung-Yoon Chung; KAIST, Korea (the Republic of)

Class-II multilayer ceramic capacitors, a necessary component in many microelectronic and automobile devices, are based on polycrystalline $BaTiO_3$ with chemically heterogeneous core−shell-type grains with multiple dopants. Instead of using this conventional duplex grain structure, we utilize nonequilibrium atomic-scale grain-boundary segregation of an appropriate single acceptor additive in nanocrystalline $BaTiO_3$ to achieve unprecedented dielectric functionality. Composition analyses directly demonstrate that the distribution of each additive is strongly confined to grain boundaries within several unit-cell width together with no chemical heterogeneity in the bulk grains. The resulting dielectric loss is identified to be <1% up to 100 MHz and, in particular, the nominal high relative permittivity of a 10^3 order with exceptional temperature stability is preserved even under a large DC bias field. The present study emphasizes that the suppression of grain growth and the control of additive segregation at the atomic level are key approaches toward achieving better ceramic capacitors.

5:00 PM EL19.07.24
Tunneling Field-Effect Transistors Based on $MoS_2/MoTe_2$ and MoS_2/WSe_2 Heterostructures with Ion-Gel Dielectrics GuenHyung Oh[1], JinGi An[1], JaeCheol Shin[2], Jonghoo Park[3] and TaeWan Kim[1]; [1]Jeonbuk National University, Korea (the Republic of); [2]Dongguk University-Seoul, Korea (the Republic of); [3]Kyungpook National University, Korea (the Republic of)

Two-dimensional (2D) transition-metal dichalcogenide semiconductors have the potential to scale down for future electronics due to their atomically thin layer and sharp interface. The band-to-band tunneling (BTBT) carrier injection process in tunneling field-effect transistor (TFET) is a promising approach to solve the fundamental thermionic limit of subthreshold swing (SS) of 60 mV/dec at room temperature. In this study, we investigated the van der Waals 2D/2D vertical heterostructures grown by the metal-organic chemical vapor deposition (MOCVD) and CVD-grown. Molybdenum disulfide (MoS_2) was used n-channel materials, whereas molybdenum ditelluride ($MoTe_2$) and tungsten diselenide (WSe_2) were used p-channel materials. Those heterostructures exhibit the staggered gap type (type II), which was suitable for TFET applications. The electrical transport properties of the $MoS_2/MoTe_2$ (or WSe_2) heterostructures using an ion-gel top gate dielectric exhibit the minimum SS values as low as 9.1 (7.5) mV/dec. The BTBT process was confirmed by the negative differential transconductance, negative differential resistance behavior, and temperature *I-V* characteristics. This work demonstrates considerable promise for wafer-scale production of next-generation low-power consumption electronic devices.

5:00 PM EL19.07.25
Low-Temperature ALD Silicon Nitride for NAND Flash Memory with a Very High Frequency (60 MHz) Plasma Source Minjeong Rhee and Il-Kwon Oh; Ajou University, Korea (the Republic of)

Silicon nitride (SiN_x) thin film has been used as a charge trap layer in NAND flash memory devices. As the NAND flash memory devices are more nanoscale and more complex structures, SiN_x is mainly studied through atomic layer deposition (ALD) with a high step coverage, low deposition temperature, and thickness control as the atomic level.[1] Since thermal ALD requires a relatively high deposition temperature for SiN deposition, so that plasma-enhanced ALD (PE-ALD) has been suggested for a relatively low deposition temperature with high film quality. However, PE-ALD has issues of low step coverage and damage to the bottom layer due to additional plasma energy. In particular, damage to the SiN_x bottom layer can cause tunnel oxide deterioration and cause a reliability issue in NAND flash memory. [2] Therefore, research on a process with higher step coverage and less damage to the bottom substrate while maintaining the advantages of low deposition temp and high growth rate is required.
In this study, we suggest a SiN_x process with better film quality, higher step coverage, and less damage. We used bis-diethylamino silane ($H_2Si((N(C_2H_5)_2)_2)$) as a precursor and N_2 plasma in radio frequency (RF) or very high frequency (VHF, 60 MHz) as a reactant. As the first in comparing the characteristics of SiN_x in RF PE-ALD and VHF PE-ALD, the saturation curve according to precursor feeding time and the linearity curve of the thickness according to the increase in ALD cycle were investigated using an ellipsometer to investigate the suitability of the process. The chemical composition ratio and impurity content of the thin films were comparatively analyzed through X-ray photoelectron spectroscopy (XPS). In addition, to check the step coverage in each process, a cross-sectional transmission electron microscope (TEM) after focused ion beam (FIB) treatment was checked after depositing SiN_x on a substrate that has a 1:5 aspect ratio. The damage to the substrate was measured through the average lattice constant change rate of the lower substrate before and after SiN_x deposition, which was calculated through TEM measurement. Through the above analysis, we analyzed that VHF PE-ALD has better characteristics than RF PE-ALD in terms of thin film quality, damage, and step coverage, showing its applicability in NAND flash memory. To analyze the characteristics of the device, after fabricating a metal-oxide-nitride-oxide-semiconductor (MONOS) capacitor with a control gate/gate oxide/floating gate/tunnel oxide/Si structure, the C-V curve was measured through a probe station. Through the electrical property measurement, the effect of SiN_x deposited with VHF PE-ALD as a charging trap was analyzed. By adjusting the frequency of PE-ALD from RF to VHF, this study showed applicability in NAND flash memory, which requires high step coverage, low damage, and high capacity.

Establishing Magneto-Elastic Coupling in a Spin-Crossover Molecular Network Grown on 2D Surfaces Shatabda Bhattacharya and Hirokazu Tada; Osaka University, Japan

Spin-crossover (SCO) complexes show bistability of spin states under various actuation parameters including temperature. This bistability along with hysteresis loop has potentiality of using them as binary units for information storage application. However, despite of cooperativity in SCO complexes, they remain non-magnetic. This is probably due to the reason that the microscopic origin of cooperativity has been primarily described by means of elastic interactions in pristine SCO. Apart from elastic coupling, long range magnetic interaction must be given equivalent importance. The spin-crossover phenomenon originates from the competition between the mean spin pairing energy (Δ), which favors the high-spin (HS) paramagnetic state and the ligand field parameter (10Dq), which favors the low-spin (LS) diamagnetic state. In addition to non-magnetic spin state transitions, the magnetic interaction can be alternatively introduced via substrate incorporation. In comparison to molecular crystals with isolated units, 3D molecular network are better candidates for extending the interaction through chemical bridges. Hybrid heterostructure based on SCO/2D surfaces remain a sensitive tool for detecting spin transitions. The fragility of SCO materials upon interfacing them on 2D surfaces is an unsolved issue. Hence, determining the ultimate scale limit with suitable 2D substrate at which cooperativity becomes effective is of major interest. Here, we showcase an easily processable, robust SCO/2D hybrid heterostructures that show long range magnetic ordering through exchange interactions. Fe-Triazole based SCO complex has been chosen for this types and chemically synthesized reduced graphene oxide (rGO) was used as the 2D substrate. Due to presence of large number of functional groups on the surface of rGO, it is a promising candidate for anchoring SCO molecular network epitaxially on rGO. Theoretically, it has been found that energy stabilization of SCO/rGO is better than Graphene/SCO. After formation of the heterostructure, interfacial charge transfer (CT) between SCO and rGO has been evidenced by means of various characterization techniques. The CT changes the high spin (HS) and low spin (LS) transition states of the molecular network which is of fundamental importance. With enough number of HS states and via superexchange interaction between the Fe-centers, a long-range magnetic ordering has been established during the spin state transition which favors like spin pairings (HS-HS or LS-LS). We have found that hysteresis width (ΔK) and transition temperatures ($T_{1/2}^{up}$, $T_{1/2}^{down}$) can also be controlled in a vast way by tuning the thickness of the SCO molecular network on rGO surface. Depending on layer number, ferromagnetic (cooperative) to antiferromagnetic (anti-cooperative) ordering has been evolved. This makes a magnetically ordered SCO/2D hybrid which could perform plethora of applications in nanomagnetics. Apart from magnetic characterization, the spin state dependence of electrical conductivity in SCO is also arrested through transport measurement due to the presence of highly delocalized π-surface electrons of 2D rGO. While pristine SCO remain insulating ($\sim 10^{-11}$ S) due to weak intermolecular interaction of van der waals nature, after attachment to highly conducting rGO surface, the conductance enhances in many folds ($\sim 10^{-5}$ S). While the overall transport is mediated via rGO surface, the epitaxial SCO network acts as scattering potential with the itinerant conduction electrons. Since the LS/HS states of SCO also depend on magnetic field in this case, the SCO/2D heterostructure shows magnetoresistance which is the main prototype for magnetoresistive- switching application. The conductance changing along with enhanced magnetic coupling could be utilized for switching application in spintronics using SCO/2D material.

High-Performance Junction-Free Field-Effect Transistor Based on Blue Phosphorene Shubham Tyagi, Paresh C. Rout and Udo Schwingenschlögl; King Abdullah University of Science and Technology, Saudi Arabia

Two-dimensional semiconductors have great potential in high-performance electronic devices. However, the common way of contacting them with metals to inject charge carriers results in contact resistance (leading to poor current delivering capability) and remains a bottleneck in the scaling of modern devices. We will discuss a junction-free field-effect transistor consisting of semiconducting monolayer blue phosphorene as channel material (with high carrier mobility) and metallic bilayer blue phosphorene as electrodes. The junction-free design minimizes contact resistance. Employing first-principles calculations along with the non-equilibrium Green's function method, we demonstrate an ultra-low contact resistance, a high I_{on}/I_{off} ratio of up to 2.6×10^4 and a remarkable transconductance of up to 811 μS/μm.

Acknowledgement: This research was supported by funding from King Abdullah University of Science and Technology (KAUST). For computer time, this research used the resources of the Supercomputing Laboratory at KAUST.

Graphene-Enabled Practical Molecular Electronics—Charge Transport in Junctions Between Molecules and 2D Materials Bhartendu Papnai[1,2] and Mario Hofmann[3]; [1]Academia Sinica, Taiwan; [2]National Tsing Hua University, Taiwan; [3]National Taiwan University, Taiwan

The idea of producing functional elements on atomic length scales has become a recent focus of research since the scaling of conventional electronics is reaching the molecular domain. The tailoring of individual molecules to impose electronic functionality has the promise of large-scale production of high-performance structures with novel properties. Devices can be created by using molecules in such a way that a new property emerges.
The concept to build a device within a molecular scale by exploring the properties of 2D materials is one of our primary goals. This work demonstrates the fabrication of the Vertical Molecular Field-Effect transistor in which the molecular layer of desired thickness is been used to form a junction. The thickness of the molecular film can be tuned by the use of Langmuir Blodgett techniques which we have used for making a homogeneous and uniform film of the molecule over graphene. The study of layer formation and deposition of tunable thickness (i.e. 1nm to several nm) molecular layers is achieved in this project. The Brewster Angle microscopy technique for imagining the Langmuir Blodgett film during its different stages has been used. The study of molecular junction formation was confirmed by electrochemical impedance spectroscopy. The characteristics of molecular field-effect transistors have been studied in this project and it has been observed that the current-voltage measurements of the devices show a decrease in current on further increase in voltage in a device. This is termed Negative Differential Resistance (NDR) and NDR peak are observed at 0.15V and 0.11V respectively with 5.2nA and 2.6nA are the Peak-to-Valley Current Ratio (PVCR) for the devices. Hundreds of molecular vertical FET devices have been measured and the device performance was assessed according to output and transfer characteristics. The formation of a junction between graphene-molecule and graphene-SiO2 was also observed. As NDR has been observed in devices of different channel lengths which shows that our devices have a significant NDR and this can be further used for various applications in logic gates and memory devices.
The discovery of graphene in 2004 gave birth to a new arena of 2D materials having exciting optical and electrical properties. Graphene having a honeycomb monolayer structure is interesting because of its excellent flexibility and mechanical strength. Graphene with excellent electronic properties that can be synthesized into large-area, flexible and conductive films suitable for electrodes. In molecular junctions, graphene film can be used as an interlayer electrode. which showed that the device has a high yield and long-term stability has been fabricated. In recent years the use of graphene as electrodes in molecular devices provides a high yield and stability because of their unique electronic structure and transport characteristics. We here

combine graphene's enabling properties with robust self-limiting deposition techniques to achieve the ultimate scaling of vertical graphene transistors to atomic dimensions.

Integration of Free-Standing Ultrathin High-κ Native Oxide for High-Performance Two-Dimensional Transistors Kongyang Yi and Zheng Liu; Nanyang Technological University, Singapore

As the current semiconductor technology based on silicon is facing increasing challenges below 5 nm nodes, the emerging two-dimensional (2D) transistors based on 2D semiconductors such as 2D transition-metal dichalcogenides (TMDCs) are attracting more and more attention. However, despite the variety of channel materials, the dielectric materials, which are equally important to the fabrication of high-performance 2D transistors, are still limited. So far, the majority of preparation methods of dielectric materials are realized through deposition, where the requirement of nucleation points is intrinsically contradictory to the high-quality dangling-bond-free surface of 2D semiconductors. Alternatively, native oxides of 2D semiconductors are being studied, but the performance is far below expectation compared with silicon dioxide (SiO_2) for Si, and the dielectric is restricted by the category of the parent semiconductors. Here, an ultrathin high-κ native oxide is integrated in 2D transistors as a free-standing dielectric material. Subthreshold swing down to 60 mV/dec at room temperature and on-off ratio over 10^8 is obtained in top-gated molybdenum disulfide (MoS_2) transistors. This work thus highlight the successful integration of a native oxide with desired dielectric properties in a non-native system.

9:30 AM *EL19.08.05
The Role of Native Defects in Ultra-Scaled h-BN Devices Mario Lanza; King Abdullah University of Science and Technology, Saudi Arabia

Two-dimensional (2D) layered hexagonal boron nitride (h-BN) might have multiple applications in electronics, such as anti-scattering substrate, passivation film, gate dielectric, and lateral thermal heat spreader (in-plane) or blocker (out-of-plane). However, when the h-BN is synthesized at the wafer scale with industry-compatible techniques, such as chemical vapour deposition (CVD), the presence of local defects impoverish its dielectric properties, as well as the figures-of-merit of the devices. In this talk I will discuss the role of native defects in CVD h-BN as observed via cross-sectional transmission electron microscopy (TEM) and conductive atomic force microscopy (CAFM). I will present data gathered in samples from the companies Graphene Supermarket and Grolltex and compare them with home-made CVD h-BN. We will also benchmark the data by comparing with additional measurements conducted in mechanically exfoliated h-BN from the National Institute for Materials Science (NIMS), which is the state-of-the-art in terms of crystallinity quality.

Bringing 2D-Materials from Lab to Fab - Maturing Processes to Enable Upscaling Inge Asselberghs; IMEC, Belgium

It turned into a never-ending success story, the discoveries with layered 2D-materials have led to a good understanding of the material properties and the identification of a broad range of potential application zones like sensors, photonics, spintronics and electronics [1, 2]. One of the most challenging approaches of having 2D-based circuits for high-performance logic is considered [3, 4]. While the list of material options keeps increasing, the request to demonstrate manufacturability is ramping up fast. The performance gap between synthetic materials and natural crystals is decreasing rapidly. Recently, a paper by Liu et al. [5] shows the mobility improvement up to 120 cm2/Vs for bilayer MoS2. This emphasis the urge to enable pathfinding experiments to close the gaps associated to identified process challenges [3, 6] and conduct pathfinding integration exercises in a 300 mm fab environment [7].

Therefore, a simplified single transistor test vehicle in a 300mm fab is required to allow the exploration of material selection and process condition identification at single device level. Here, wafer scale assessment provides insights in device-to-device, die-to-die and wafer-to-wafer variability. Combined with inline metrology, a unique insight can be given on the individual process steps and their impact on the channel properties. For example, acoustic wafer maps provide a unique way to reveal adhesion related effects. Once this exploration is done, a more elaborated integration route can be conducted.

11:00 AM EL19.08.07
Damage-Free Deposition of Aluminum-Based High-κ Dielectrics on Graphene by PEALD Ardeshir Esteki[1], Alwin Daus[1], Sarah Riazimehr[2], Harm Knoops[2,3], Federico Fabrizi[4,1], Maryam Mohammadi[4], Martin Otto[4], Gordon Rinke[4] and Max C. Lemme[1,4]; [1]RWTH Aachen, Germany; [2]Oxford Instruments Plasma Technology UK, United Kingdom; [3]Technische Universiteit Eindhoven, Netherlands; [4]AMO GmbH, Germany

Graphene has great potential for heterogeneous integration with modern electronics [1]. One of the remaining challenges is the damage-free deposition of dielectrics on graphene and control of its doping level [2]. Plasma-enhanced atomic layer deposition (PEALD) is a production-ready technique for depositing high-κ dielectrics, but it often damages graphene due to highly reactive and energetic species formed during plasma activation. This problem has been circumvented by using thin interlayers such as hexagonal boron nitride to protect graphene [3], with the drawback of complicating fabrication by adding a second 2D material. In this work, we investigate a direct PEALD process using an Oxford Instruments Atomfab™ PEALD system. Our process provides a high-κ dielectric directly deposited onto graphene without detectable damage. Furthermore, we can systematically tune the doping level of graphene by varying the dielectric thickness.
Pd bottom contacts were deposited onto Si substrates with 90 nm thermally grown SiO_2 and structured by lift-off. Graphene was dry-transferred onto the samples and patterned by reactive ion etching. Aluminum-based dielectric layers with thicknesses of $t_{de} \approx 7$, 12 and 17 nm were deposited by PEALD at 200 °C in a low-power nitrogen plasma process employing trimethylaluminium as the precursor. Ti/Pd top-gates were fabricated by electron-beam evaporation and lift-off.
The effect of dielectric deposition onto graphene was investigated by Raman spectroscopy. A statistical analysis of the D to G peak intensity ratios and the full-width-half-maxima of the 2D peaks indicate no measurable process damage, in contrast to the standard Al_2O_3 plasma deposition process performed as a control experiment.

A “doping” effect of the graphene channel is observed in back-gate voltage-dependent drain current measurements (I_D vs. V_{BG}) in a four-point (4p) configuration. Measurements in air performed for ten devices show strong p-doping of graphene before deposition, with Dirac voltages of V_D ~30 V. After dielectric deposition, V_D shifts in a negative direction by ~25, ~35 and ~44 V for t_{de} of 7, 12 and 17 nm, respectively. The maximum electron and hole mobilities were extracted using the direct transconductance method [4], which excludes contact resistance effects due to the 4p configuration. The dielectric capping layer increases the maximum hole mobility from ~1500 to ~2300 cm^{2}V^{-1}s^{-1} and the maximum electron mobility from ~150 to ~1600 cm^{2}V^{-1}s^{-1}. After depositing top-gates, we performed double-gate current-voltage measurements and extracted a dielectric constant of ~35 for the PEALD dielectric [5]. This high value was further verified through separately fabricated metal-insulator-metal structures suitable for capacitance-voltage measurements. The top-gate 4p measurements (I_D-V_{TG}) yielded V_D of ~0.6 V and hysteresis below ~1% of the gate-source voltage sweep range. We further investigated the origin of the high dielectric constant in our PEALD dielectrics through material and structural analysis such as transmission electron microscopy, atomic force microscopy, energy dispersive x-ray spectroscopy and x-ray diffraction.

In summary, we demonstrate a scalable, low-damage PEALD process for direct deposition of high-κ dielectric films on graphene which can be used to tune V_D. This work opens new pathways for heterogeneous integration of devices with two-dimensional materials preserving material quality and controlling their doping.

Atomic Layer Deposition of Conformal Wafer-scale WS$_2$ Films: a Promising Liner and Barrier Alternative for Back-end-of-Line Applications

Muhammed Juvaid Mangattuchali[1], Tan Hao[1], Hippolyte P. Astier[1], Soumyadeep Sinha[1], Chandan Das[2], John Sudijono[2] and Silvija Gradečak[1]; [1]NUS Singapore, Singapore; [2]Applied Materials, Inc., Singapore

The continued scaling of silicon integrated circuits makes it crucial to find substitute materials for both the front-end-of-line (FEOL, transistors) and back-end-of-line (BEOL, interconnects) applications. Currently, approximately 4-nm thickness is required for conventional liners and barriers to be effective. In forthcoming sub-5 nm technology nodes, these would occupy a substantial share of the interconnect cross-section and consequently increase the resistivity of Cu interconnects. Conversely, downscaling the thickness of the liner and barrier layers would result in poor Cu blocking efficiency. Two-dimensional (2D) transition metal dichalcogenides (TMDs) have been recently identified as promising candidates for Cu diffusion barrier and liner applications at the sub-nm scale. However, most 2D TMDs are grown using chemical vapor deposition processes at high temperatures (>800°C), making them incompatible with BEOL applications. Plasma-assisted growth can reduce growth temperatures, but poor conformality and plasma-induced defects remain challenges. Here, we report a complete thermal (no plasma assistance) atomic layer deposition (ALD) process for the deposition of crystalline WS$_2$ growth at <450 °C, suitable for BEOL integration. The process yields layer-controlled conformal (>95%) growth of WS$_2$ on an 8-inch wafer scale. Raman spectroscopy and transmission electron microscopy measurements were used to elucidate the quality and number of layers in WS$_2$, whereas x-ray photoelectron spectroscopy and energy dispersive x-ray spectroscopy were used to assess the stoichiometry and compositional uniformity, respectively. We further show that as-grown single and multilayer WS$_2$ grown *via* ALD are promising candidates as a liner layer: Cu interconnects with thickness of 10—20 nm show 50% reduction in resistivity when deposited on WS$_2$ compared to the reference SiO$_2$/Si substrate. In addition, thermal stress measurements of Cu/WS$_2$ layers show that WS$_2$ is a potential diffusion barrier alternative as it effectively blocks the diffusion of Cu into the surrounding dielectric. Our results demonstrate that 2D TMDs grown *via* thermal ALD are promising building blocks for BEOL applications beyond the 5 nm nodes.

Large-Area Synthesis of 2D Transition Metal Dichalcogenides Using Plasma-Enhanced Atomic Layer Deposition Ageeth A. Bol; University of Michigan, United States

2D materials have been the focus of intense research in the last decade due to their unique physical properties. This presentation will highlight our recent progress on the large-area synthesis of two-dimensional transition metal chalcogenides for nanoelectronics using plasma-enhanced atomic layer deposition (PEALD). In particular, we demonstrate wafer-scale deposition of polycrystalline MoS2 thin films at very low temperatures down to 100 °C using PEALD. ALD is a scalable, semiconductor industry compatible gas-phase method producing uniform, high-quality thin films with accurately controlled thickness. Our PEALD process is based on self-limiting, alternating surface reactions of a metalorganic molybdenum precursor Mo(NtBu)2(NMe2)2 and mixed H2S/H2/Ar plasma. We have identified the critical role of hydrogen during the plasma step in controlling the composition and properties of molybdenum sulfide films. By increasing the H2/H2S ratio, we are able to deposit polycrystalline MoS2 films at temperatures as low as 100 °C. To the best of our knowledge, this represents the lowest temperature for crystalline MoS2 films prepared by any chemical gas-phase method.[1]

ALD-grown 2D films typically exhibit a high density of out-of-plane 3D structures in addition to 2D horizontal layers. While the out-of-plane 3D structures are ideal for catalysis applications, the presence of such 3D structures can hinder charge transport, which hampers device applications. In this presentation I will show how we used mechanistic insight obtained by HRTEM to tune the shape and density of the 3D structures during plasma-enhanced ALD. The obtained morphology control was further confirmed by electrical measurements.[2]

Earlier [3] we have shown that ALD is an excellent technique to make MoxW1-xS2 alloys with precise control over the alloy composition. Here, I will focus on how (plasma-enhanced) atomic layer deposition can aid in synthesizing p-doped 2DTMCs with precise control over the doping concentration, which is an asset for 2D TMD based device applications.

SESSION EL19.09: 3D Integration
Session Chairs: Supratik Guha, Francesca Iacopi and Ehrenfried Zschech
Thursday Afternoon, April 13, 2023
Moscone West, Level 3, Room 3020

1:45 PM EL19.09.01
High-performance and CMOS-BEOL compatible AlScN/MoS$_2$ FE-FET array KwanHo Kim, Jeffrey Zheng, Roy H. Olsson and Deep M. Jariwala; University of Pennsylvania, United States

3D Monolithic integration of memory/storage devices with front-end-of-line (FEOL) logic transistors has been a critical issue in computer hardware. This integration is important for reducing computational power consumption simultanously with improved energy efficiency in big-data and Internet of things (IoT) applications such as artificial intelligence. Despite decades of effort, it is still highly challengeing to demonstrate reliable, compact, back-end-of-line (BEOL)-compatible, energy-efficient, and scalable memory/storage devices. Ferroelectric Field Effect Transistors (FE-FETs) are one of the most promising candidates that can meet the strict requirements. Recent advances in CMOS-compatible ferroelectric materials such as Zr-doped HfO$_2$ (HZO) have attracted more attention to FE-FET as a promising candidate for small energy-efficient nonvolatile memory. Over a decade, while HZO-based FE-FETs have made great advances, highly notable ferroelectric properties have recently been discovered in aluminum scandium nitride (AlScN) in 2019. AlScN shows a high remnant polarization (P_r) of > 110 µC/cm2, which is two to three times higher than that of HZO, and has a BEOL-compatible deposition temperature of 350 °C. These merits make AlScN a very promising candidate for BEOL-compatible FE-FETs. However, despite these remarkable ferroelectric properties, scalable FE-FETs using thin AlScN ferroelectric have not yet been demonstrated. Here, scalable BEOL-compatible FE-FETs based on CVD grown two-dimensional (2D) MoS$_2$ channel and 20, 45 and 100 nm ferroelectric AlScN are presented. The large array of FE-FETs statistically showed very large memory windows of >7.8 V, ON/OFF ratios of $>10^7$, and ON current density >250 µA/um, all at highly scaled ~80 nm channel lengths. In addition, the FE-FET shows a stable retention measured up to 10^5 seconds and 10 years by extension, and endurance up to 2×10^4 cycles. Finally, due to the large memory window, the FE-FETs shows multi-bit (2, 4 and 7-bit) pulse programmable threshold and conductance states, opening a path towards scalable 3D hetero-integration of 2D channel/AlScN memory device with Si CMOS logic.

3D MOSAIC of N3XT Chips—Domain-Specific Technology for Future Systems H.S. Philip Wong; Stanford University, United States

Future electronic systems will continue to rely on, and increasingly benefit from, the advances in semiconductor technology as they have had for more than five decades.

Three dimensional integration is one of the major technology directions for integrated circuits. A key technology direction is CMOS + X, where X can be memory, photonics, spintronics, power electronics, nanomechanics, sensors and actuators, RF/mm-wave, and even quantum computing. Nanosystems of 3D integrated “X” technology (N3XT) is a key concept at the chip level. We must also go beyond a single chip from a wafer and focus on integrating chips into systems using MOSAIC (MOnolithic Stacked Assembled IC).

MOSAIC systems may enable a wide spectrum of compute throughput, energy efficiency, and memory capacity to be simultaneously realized within the same hardware to support emerging workloads for edge machine intelligence. Accelerators addressing a variety of workloads can be reconfigured for application-level flexibility. Intelligently partitioning and co-designing the logic, memory, and interconnect with new design space made possible by CMOS + X can be key to such new capability.

I will give an overview of the new materials, device technologies, and design concepts that may need to be developed to realize this vision.

Challenge Of 3D Stacking Technology For Advanced System Integration Masaaki Niwa[1,2]; [1]The University of Tokyo, Japan; [2]Research Association for Advanced Systems (RaaS), Japan

Cloud and MEC servers in post-5G information communication systems are required to realize advanced and diverse computational processing. On the other hand, it is becoming more difficult year by year to improve the performance of semiconductor devices due to the demise of Moore's Law, which has long supported technological innovation as a development index for semiconductor devices. To achieve even higher performance, miniaturization technology must be combined with cutting-edge packaging technology that integrates peripheral devices such as chiplets (memory, sensors, AI chips, RF, etc.) into a single package.
To materialize this, 3D integrated semiconductor devices, which are further miniaturized and consume less power, are expected to become a mainstream that will meet the requirements of many applications in the future. And it is necessary not only to develop the package designs that meet the demands of applications, but also to develop the consistent semiconductor manufacturing technology from materials to processes and devices to a level that can be mass-produced, while further advancing system and technology co-optimization (STCO).
Along with the changes and new creations in semiconductor manufacturing process due to the evolution of advanced packaging, the distinction between front- and back-end processes tends to disappear. System integration using 3D integrated packages and chiplets will be a mainstream in the future. Under such circumstances, the 3D integrated package will become a choke point for future semiconductor supply.
This time, the technological trends of advanced packaging as well as its manufacturing (including equipment) and material technology will be reviewed, focusing on advanced 3D hybrid direct bonding which is a potential candidate for ultra-fine devices.
In order to bond two wafers, the following two types of bonding must be achieved with high alignment accuracy.
1. Low resistance connection between Cu in TSV (Through Si Via) and Cu pad
2. Strong bond of each Si area other than Cu area.
For the hybrid bonding, it is necessary to realize these bonds at the same time.
A hybrid bonding method currently in practical use is a fusion bond that forms hydroxyl groups on the Si surface. However, this has an unfavorable problem of requiring high temperatures for the Cu atoms to break through the oxide layer on the Cu surface to inter-diffuse during the Cu–Cu bonding process in addition to achieve hydrophilic bonding in the Si region. One of the important issues in directly bonded hybrid bonding is the state control of Cu-Cu and Si-Si interfaces during bonding. And the surface activation [1] before the bonding is essential to achieve this.
At Research Association for Advanced Systems (RaaS), as a national project, wafer-on-wafer (WoW) and chip-on-wafer (CoW) technologies by means of low-temperature surface activation [2] are under development with Japanese companies and national research institute.
In this presentation, technologies for the hybrid bonded 3D system integration by WoW, CoW will be discussed including the studies under the national project/NEDO* performed at RaaS.

4:00 PM *EL19.09.04
Advanced Logic Scaling Using Monolithic 3D Integration Marko Radosavljevic; Intel Corporation, United States

Transistor scaling has been one of the key engines driving semiconductor industry for many decades now. Beyond traditional (Dennard) scaling of physical dimensions and supply voltages, innovations such as new materials and new architectures are being constantly and regularly deployed to enabled introduction of new technology nodes.
Main new architectural changes revolve around moving from planar device geometries to more 3D – first finFETs and most recently gate-all-around (GAA). These changes provide significant opportunities for scaling both due to (1) enabling gate pitch scaling because of improved short channel effects and (2) higher performance because device width is decoupled from planar area. To enable these architectures, technology teams delivered many materials and process innovations due to increased physical aspect ratios as well as need for very conformal depositions.
Extending further into this third dimension, researchers in academia, consortia and industry are very interested in exploring device stacking as means of increasing both functionality and logic scaling. While this appears as a natural next step, it also provides an open wide space ripe for new materials, integration approaches and applications. As such much of the early work has been focused on both (1) design technology co-optimization (DTCO) to identify needed ingredients to enable scaling and (2) demonstrating those ingredients into physical implementations in Si.
In this presentation, I will provide general overview of monolithic 3D integration options, will focusing on material centric aspects of this approach by highlighting experimental status and challenges.

SESSION EL19.10: Poster Session II

Session Chairs: Paul Berger and Pei-Wen Li
Thursday Afternoon, April 13, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM EL19.10.01
How Changes in the Crystal Temperature and Doping Concentration Impact Upon the Steady-State and Transient Electron Transport Within Gallium-Aluminum-Nitride/Gallium Nitride Heterojunctions Yana Wang[1], Michael Shur[2], Walid A. Hadi[3] and Stephen K. O'Leary[1]; [1]University of British Columbia, Canada; [2]Rensselaer Polytechnic Institute, United States; [3]Florida State University, United States

Noting that at the interface of gallium-aluminum-nitride with gallium nitride, a two-dimensional electron gas will form, we examine how the electron transport characteristics within such a gas vary in response to changes in the crystal temperature and the doping concentration. For the purposes of this analysis, Monte Carlo electron transport simulations are pursued. A critical comparison with results corresponding to bulk gallium nitride is considered. The device implications of these results then will be explored.

5:00 PM EL19.10.02
Testing the Compatibility of Photothermal Lithography with Commercial Lithography Equipment Meghna Jha, Joaquin Mogollon Santiana, Aliyah Jacob, Kathleen Light, Michael Lau, Megan Hong and Adam J. Moule; University of California, Davis, United States

Semiconducting Polymers (SPs) have received widespread attention due to their promising qualities like superior absorbance/emission, easy chemical tunablity, low-temperature solution processing, lightweight and flexible substrates, and low environmental toxicity. A significant obstacle for the industrial development of SPs is the lack of a patterning technology that is inexpensive, rapid, and viable and capable of producing sub-micron features. Photomask lithography is impossible because the SPs cannot withstand the processing steps. The Moule group recently developed a new photopatterning concept that enables micropatterning of SPs. We present a novel solution based optical patterning method that is compatible with any non-cross-linked SP, termed Photothermal Lithography. Selective polymer domains are removed as a photo-induced temperature gradient enables selective dissolution in a combination of solvents. In this study we test the compatibility of this technique with the Alvéole PRIMO. Alvéole PRIMO is a commercially available cleanroom equipment that enables Micropatterning, hydrogel polymerization and microfabrication, all in a single device. We were able to use this equipment to enable and test out Photothermal patterning technique on P3HT at various solvent concentrations and laser fluences. In this study we analyze the effect of depth of field, solvent concentrations, and laser fluences that effect the pattern size and resolution. This proves that Photothermal Patterning is compatible with available commercial Lithography equipment and this can be the way forward to fabricate patterned electronic devices with SPs.

5:00 PM EL19.10.03
Single Crystalline Ge Thin Film Grown on C-Plane Sapphire by Molecular Beam Epitaxy Emmanuel Wangila, Calbi Gunder, Subhashis Das, Nirosh Eldose, Hryhorii Stanchu, Fernando Oliveira, Chen Li, Shui-Quing Yu and Gregory Salamo; University of Arkansas, Fayettiville, United States

Germanium (Ge) film was grown on c-plane sapphire with and without a 10 nm AlAs buffer layer using molecular beam epitaxy. The samples were characterized using high-resolution X-ray diffraction (HRXRD) and atomic force microscopy (AFM). The samples grown directly on sapphire exhibits 2 germanium orientations, the (111) and (220) while samples grown using the AlAs buffer layer had only (111) orientation at 27.5 degrees. Samples that were grown with the AlAs buffer were investigated further and at different temperatures were observed to relax the compressive strain as the temperature was increased. From the Phi scan, the peaks with high intensity appear after every 60 degrees while lower intensity peaks can be seen at 30 degrees between the high intensity peaks. We also investigate the impact of different the thickness (50nm, 100nm,150nm and 200 nm) of the Ge layer. In this case the ratio of the high to low intensity Phi scan peaks was less with 100 nm thick Ge sample. This sample also had the lowest XRD rocking curve linewidth of 633 arcsec. This sample is prepared for epitaxy growth of SiGe and GeSn and we will discuss initial efforts at these growths.

5:00 PM EL19.10.04
Cubic Boron Nitride's Electron Transport John Chilleri[1], Poppy Siddiqua[2], Michael Shur[3] and Stephen K. O'Leary[2]; [1]New Mexico Institute of Mining and Technology, United States; [2]University of British Columbia, Canada; [3]Rensselaer Polytechnic Institute, United States

Through the use of a semi-classical three-valley Monte Carlo electron transport simulation analysis, the character of the electron transport that occurs within the cubic phase of boron nitride is examined. For the purposes of this particular analysis, both steady-state and transient electron transport processes are examined. For the steady-state analysis, the dependence of the electron drift velocity on the applied electric field strength is examined. For the transient electron analysis, however, we study how an ensemble of electrons, initially in thermal equilibrium, i.e., zero-field, responds to the sudden application of a constant and uniform applied electric field. A critical comparison, of these electron transport results with those corresponding to a variety of other semiconductor materials, is offered. The device implications of these results are explored.

5:00 PM EL19.10.05
Ultrawide Bandgap BN based Vertical Power Diodes via TCAD Simulation Ziyi He[1], Kai Fu[2], Mingfei Xu[3], Jingan Zhou[3], Tao Li[3], Yuji Zhao[3] and Houqiang Fu[1]; [1]Arizona State University, United States; [2]The University of Utah, United States; [3]Rice University, United States

Boron nitride (BN) material is an emerging ultrawide bandgap (UWBG) semiconductor with great promise for applications in power electronics, ultraviolet (UV) photonics, and quantum photonics. The current most mature phase of BN, hexagonal BN, has a large bandgap of 6.0 eV and has attracted a lot of interest owing to its unique physical properties. Due to its high thermal conductivity of 390 W/(K●m), high breakdown electric field of ~12 MV/cm, and high carrier mobilities, h-BN is also an attractive candidate for high-performance high power high voltage power electronic devices. However, it is still very challenging to produce high quality thick h-BN layers due to the technical difficulties in materials epitaxy and doping, which has hindered the development of BN devices. Furthermore, vertical architecture is usually adopted in high voltage power devices due to high current and voltage handling capability, immunity to surface issues and degradation and excellent heat dissipation. However, there are very few reports on BN vertical power devices and the performance limit of these devices is still not clear.
In this work, we use technology computer-aided design (TCAD) simulation to theoretically investigate the electrical performance of ultrawide bandgap BN-based vertical power diodes. Three configurations of h-BN power diodes were investigated, including vertical h-BN Schottky barrier diode (SBD), vertical h-BN PN diode, and vertical h-BN/AlN PN diode. The electrical properties of the three diodes were comprehensively investigated, including the band diagrams, forward and reverse characteristics for different doping concentrations and layer thicknesses. The h-BN material properties were defined in Silvaco Atlas, including bandgap, effective masses of electron and hole, permittivity, impact ionization coefficient, electron affinity, mobilities, carrier lifetimes, donor and acceptor activation energies from the previous reports of h-BN. All the substrates' doping concentrations were set to be 5×10^{18} cm^{-3} as ohmic contact layers for P-type and N-type. The h-BN power diodes showed excellent performance, especially for breakdown behaviors. The h-BN SBDs with a 5 µm drift layer showed a turn-on voltage of 0.5 V for Pt Schottky contact and breakdown voltages over 450 V. The h-BN PN diode with a 2.5 µm drift layer showed a turn-on voltage of 6.2 V and a breakdown voltage over 3 kV, the critical electric field is calculated to be 13.6 MV/cm. The h-BN/AlN heterojunction PN diode with a 2.5 µm AlN drift layer showed a turn-on voltage of 5.8 V and breakdown voltages over 2 kV. This work provides a theoretical understanding on the device principles of vertical BN power diodes, which can serve as a useful reference for the future development of efficient and robust BN power electronics.

5:00 PM EL19.10.07
Design and Fabrication of AlGaN/GaN Multiple p-Channel Schottky Barrier Diodes Dawei Wang, Dinusha Herath Mudiyanselage and Houqiang Fu; Arizona State University, United States

Wide bandgap GaN holds great promises for high-efficiency power conversion systems. To realize GaN power integrated circuits (ICs), peripheral logic circuits based on GaN are necessary, such as controllers, drivers, protection circuits. By using the AlGaN/GaN high electron mobility transistors (HEMTs) platform, all these components can be integrated on a single chip, dramatically reducing parasitic effects, such as gate ringing and false turn-on of power transistors. Currently, most GaN logic circuits still rely on only n-channel devices. This is because it is challenging to realize high-performance GaN p-channel devices due to much lower hole mobilities and sheet carrier density. Recently, multi-channel heterostructure is proposed to address the tradeoff between carrier mobility and density. But there are still few reports on GaN multi-channel p-type devices partly due to the difficulty in buried p-GaN activation, unknown doping concentration and thickness of the inserted p-GaN layers, and the acceptor-holes separation process.

In this work, we perform the design, modeling and fabrication of GaN-based vertically stacked 2DHG (two-dimensional hole gas) multiple p-channel Schottky barrier diodes (SBDs). The device epilayers were grown by metal-organic chemical vapor deposition (MOCVD) on a sapphire substrate, consisting of a thick GaN buffer layer, a 300 nm UID-GaN layer, and multiple layers for p-channels that are composed of a 40 nm p^+-GaN layer, a 20 nm UID-GaN layer, and a 15 nm $Al_{0.2}Ga_{0.8}N$ layer. In order to effectively activate the buried p-GaN layers, trenches with different geometric patterns between the anode and cathode were etched by 400 nm of depth. The devices were then annealed at 800 °C for 1 hour to break the Mg-H bond and allowed the [H] to diffuse to the ambient through the etched sidewall. Moreover, these trenches are also geometrically designed as edge terminations that can eliminate high electric field crowding at reverse bias, which is necessary due to the vulnerability of the etched trenches. Finally, the two electrodes and passivation layer were deposited on top of the devices. The distance between the anode and the cathode is from 15 um to 25 um. The device's electrical properties will be measured. For the simulation, the impacts of doping concentration and thickness of p-GaN layers and the thickness of UID-GaN layers of the multi-channel heterostructure will be comprehensively investigated. And the ionization energy of [Mg] in GaN was set to be 300 mV. 3-D simulation will be also introduced to design the structure of the trenches. It is shown that the ON-current densities at an anode voltage of -3.5 V for the SBDs with 1, 3, and 5 p-channels were extracted as 0.12, 0.26, and 0.365 mA/mm, respectively. With the doping concentration of acceptor increasing from 1×10^{19} to 3×10^{19} and 6×10^{19} cm^{-3} in each p-GaN layer, the ON-current has a slight increase from 0.35 to 0.365 and 0.38 mA/mm at an anode voltage of -3.5 V, indicating that the doping concentration of p-GaN is not critical dominant in the sheet carrier density of 2DHG channels. With the thickness of each UID-GaN between p-GaN and AlGaN increasing from 2 to 5, 10, and 20 nm, the ON-current is also increased from 0.24 to 0.265, 0.3, and 0.365 mA/mm. These results can provide critical references for the future development of GaN multiple p-channel devices such as multiple p-channel diodes and FETs for integrated power and logic circuits.

5:00 PM EL19.10.08
Growth of Germanium on GaAs (001) Substrates via Molecular Beam Epitaxy (MBE) Calbi Gunder, Emmanuel Wangila, Hryhorii Stanchu, Solomon Ojo, Sudip Acharya, Mohammad Z. Alavijeh, Shui-Quing Yu and Gregory Salamo; University of Arkansas, United States

In this report the growth of Germanium (Ge) has been investigated on GaAs (001) substrates via molecular beam epitaxy (MBE). Ge was grown both on GaAs and AlAs buffer layers to compare the difference in film quality, surface morphology and optical characteristics via photoluminescence (PL). From this investigation we were able to achieve higher-quality Ge layers when grown on a 30 nm AlAs buffer. In addition to this we have observed atomic steps of Ge when the growth temperature is between 500-600°C. Developing a high-quality Ge layer on III-V opens the possibility of it being used as an additional surface to investigate the growth of high tin content GeSn and or SiGeSn systems which are of significant interest in the study of microwave photonic applications.

5:00 PM EL19.10.10
Memory Characteristic of Organic/Inorganic Hybrid Synaptic Transistor with Silk Fibroin Gate Insulator Hyunjoo Hwang, Wonwoo Kho and

Seung Eon Ahn; Tech University of Korea, Korea (the Republic of)

According to the development of the 4th industry such as Artificial Intelligence (AI) and Internet of Things (IoT), needs to process large amounts of data is exploded. The conventional Von Neumann computing system is facing challenges of a bottleneck between data processing and memory unit. To overcome this issue, a neuromorphic computing system inspired by the human brain using parallel processing has appeared. Therefore, neuromorphic devices have been introduced based on various materials. Also, flexible and biocompatible organic synapse devices is studied a lot for wearable artificial intelligence systems.
In this study, we introduce organic/inorganic hybrid synaptic transistor with Silk fibroin from *Bombyx mori* cocoon as gate insulator. Silk fibroin is an electronic biomaterial that has light transmittance, good bio-compatibility and high mechanical flexibility. The dielectric constant (k) of silk fibroin is around 6, which is higher than SiO_2's. The potentiation and depression characteristics of hybrid synaptic transistor were investigated based on various pulse scheme. Artificial neural network (ANN) simulation with experimental results of silk fibroin synaptic device shows high recognition accuracy (>95%) for handwritten digit database in MNIST. It will be discussed working mechanism of synaptic transistor with silk fibroin and the possibility of the application of silk fibroin for synaptic devices.

5:00 PM EL19.10.11
ALD-prepared Metal Nitrides with Tunable (Super)conductivity by Ion Energy Control Erwin Kessels[1], Silke Peeters[1], Marc Merkx[1], Mariadriana Creatore[1], Adrie Mackus[1] and Harm Knoops[1,2]; [1]Eindhoven Univ of Technology, Netherlands; [2]Oxford Instruments Plasma Technology, United Kingdom

Metal nitrides find applications in numerous devices ranging from state-of-the-art field-effect transistors in logic to superconducting qubits in emerging quantum circuits. In many cases these metal nitrides need to be closed films with thicknesses < 10 nm which makes atomic layer deposition (ALD) often the method of choice. There are also increasingly strict demands on the (super)conductivity of these films, which makes it necessary to explore novel approaches to control their properties. In addition, there is growing interest to prepare the films with a selectivity towards specific materials and surface orientations.

In this contribution we will report on the preparation of conductive metal nitrides using plasma-enhanced ALD with precise ion energy control through rf substrate biasing. From results on TiN_x, HfN_x and TaC_xN_y, it is demonstrated that the conductivity can be accurately tuned by controlling the energy of the ions. The highest conductivities, approaching the values of the bulk materials, can be reached by increasing the ion energy to ~100-150 eV whereas higher energies lead to deterioration of the film properties though ion damage. A similar maximum in the critical temperature T_c is observed when evaluating the superconductivity. The conductivity results are correlated with compositional and structural properties of the films demonstrating the important role of energetic ions in reducing the O incorporation in the films and enlarging the polycrystalline grain sizes. Given the directional nature of the ions, the conformality of the films on 3D structured surface is also addressed. Moreover area-selectivity on prepatterned surfaces with different materials is demonstrated when employing ALD cycles with small molecule inhibitor dosing. These and other features enabled by ion energy control during ALD will allow for an extended set of applications of metal nitrides in next generation electronic devices.

5:00 PM EL19.10.12
Universal Ligands for Dispersion of Two-Dimensional MXene in Organic Solvents Tae Yun Ko[1], Daesin Kim[1], Arun Nissimagoudar[1], Seung-Cheol Lee[1], Xiaobo Lin[2], Peter Cummings[2], Yury Gogotsi[3], Insik In[4], Chong Min Koo[5] and Tufail Hassan[5]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Vanderbilt University, United States; [3]Drexel University, United States; [4]Korea National University of Transportation, Korea (the Republic of); [5]Sungkyunkwan University, Korea (the Republic of)

Ligands can control the surface chemistry, physicochemical properties, processing, and applications of nanomaterials. MXenes are the fastest growing family of two-dimensional (2D) nanomaterials showing promise for energy, electronic, and environmental applications. However, complex oxidation states, surface terminal groups, and interaction with the environment have hindered the development of organic ligands suitable for MXenes. Here, we demonstrate a simple, fast, scalable, and universally applicable ligand chemistry for MXenes using alkylated 3,4-dihydroxy-L-phenylalanine (ADOPA). Owing to the strong hydrogen bonding and π electron interactions between the catechol head and surface terminal groups of MXenes and the presence of hydrophobic fluorinated alkyl tail compatible with organic solvents, the ADOPA ligands functionalize MXene surfaces under mild reaction conditions without sacrificing their properties. Stable colloidal solutions and highly concentrated liquid crystals of various MXenes, including Ti_2CT_x, Nb_2CT_x, V_2CT_x, Mo_2CT_x, $Ti_3C_2T_x$, Ti_3CNT_x, $Mo_2TiC_2T_x$, $Mo_2Ti_2C_3T_x$, and $Ti_4N_3T_x$, have been produced in various organic solvents. Such products offer excellent electrical conductivity, improved oxidation stability, and excellent processability, enabling applications in flexible electrodes and electromagnetic interference shielding.

5:00 PM EL19.10.13
Magnetic Edge Doping of Chalcogenide-based Topological Insulators via Solvothermal Methods for Intrinsic Time Reversal Symmetry Breaking Gabriel Marcus, David Carroll and Timothy W. Carlson; Wake Forest University, United States

Topological insulators (TIs) represent an intriguing class of materials that possess time symmetry- protected spin currents at their edge. Application of a magnetic field to such systems causes symmetry breaking and establishes a persistent charge current that circulates around the TI perimeter. Although external magnetic fields are typically discussed in the context of TI time reversal symmetry breaking, doping with magnetic materials might generate intrinsic fields that yield symmetry collapse while simultaneously allowing for donation of carriers that strengthen the charge current. Here, we present our work undertaken to produce chalcogenide-based TIs and subsequently achieve edge modulation doping with magnetic metals like iron or nickel. A versatile and straightforward solvothermal wet chemistry approach was used to synthesize high yields of bismuth telluride (Bi_2Te_3) platelets which have the potential for nanoparticle growth at reactive edge sites. Different concentrations of iron and nickel dopants were added to solutions of Bi_2Te_3 and the resultant materials were characterized to assess the extent of magnetic edge doping. A variety of techniques including electron microscopy (TEM, SEM, SAED), spectroscopy (XPS, EDS, XRD), Hall Effect measurements, and magnetic force microscopy were used to visualize nanoparticle formation, quantitatively assess material composition, confirm host material doping, and determine magnetic response. Preliminary results indicate that edge nanoparticle formation is taking place; experiments to optimize dopant growth, verify carrier injection from dopant to host and understand the influence of such dopants on the host material's properties are ongoing. If magnetically doped chalcogenide TIs become a reality, they may play significant roles in quantum device and quantum information applications thanks to enhanced persistent charge currents that could maintain entanglement at relatively high temperatures.

Ultra-thin Hafnia-based Ferroelectric Tunnel Junction Synaptic Device for Neuromorphic Computing Application Wonwoo Kho, Hyunjoo Hwang and Seung Eon Ahn; Tech University of Korea, Korea (the Republic of)

IDC, a U.S. market intelligence firm, predicts that the global digital information volume to be 80 ZB (1 ZB equals 1 trillion GB) as of 2022. This massive information has a high proportion of unstructured data such as voice and video. Current serial von Neumann computing has limitations in processing and storing a large amount of unstructured data produced. The solution to this issue may be found in neuromorphic computing, a parallel processing technique. An efficient spike-based artificial neural network is needed for neuromorphic computing. Accordingly, a synapse device capable of spike-based learning is attracting attention, and studies to reduce the size of the synapse device are becoming active.

HZO-based ferroelectric tunnel junction (FTJ) is a simple MFM structure optimized for scaling down. It is also a promising memristor device that can be used as an analog synapse device for neuromorphic computing. The synapse device corresponds to ~10^{15} biological synapses in an artificial neural network that mimics the neural network of the human brain, hence miniaturization is essential. In addition, as it has recently been experimentally found that the learning method of biological synapse is Spike Timing Dependent Plastics (STDP), many studies are being conducted on this. However, research on STDP learning of ferroelectric-based synaptic devices is lacking.

We effectively implemented Long-term Potentiation (LTP) and Long-term Depression (LTD) with STDP learning methods by fabricating HZO FTJs with ultra-thin films of 3 nm level. Using the Cross-sim simulator and extracted LTP and LTD, the accuracy of pattern recognition of a handwriting image was assessed. In conclusion, we propose that our 3 nm extreme thin film HZO FTJ might be applied to artificial neural networks for implementing neuromorphic computing.

5:00 PM EL19.10.15

Redesigning Micro-Electromechanical Systems for Additive Manufacturing Emily Huntley[1], Kyler Kunzler[2], Georgia Kaufman[1], Michael Gallegos[1], Tim Dallas[2] and Bryan Kaehr[1,3]; [1]Sandia National Laboratories, United States; [2]Texas Tech University, United States; [3]Center for Integrated Nanotechnologies, United States

Micro-electromechanical systems (MEMS) are devices that sense and actuate at the microscale. Typically, MEMS devices are fabricated using multi-step, clean-room techniques that are time consuming in both design and fabrication and thus cost prohibitive for prototyping or small-lot production. Recently, simple MEMS actuators have been fabricated in a single-step approach using the micro-scale 3D printing technique of multi-photon lithography. Subsequent thin-film metal deposition produced dynamic MEMS that move through applied electrical power. In our work, we aim to adapt tried-and-true MEMS devices such as chevron actuators—traditionally fabricated using, for example, the SUMMiT V process—to be compatible with additive manufacturing, and ultimately develop complex multicomponent systems and functions. The design for additive manufacturing approach employed here required many iterative design/test cycles to adapt planar, multi-level assemblies into more 3D free form fabricated objects. Following this iterative process, we demonstrate rotation of a 300-micron, 100-toothed gear via a linear thermal actuator coupled to a long-spanning cantilever. Overall, this work extends the capabilities and knowledge surrounding the use of microscale 3D printed structures for producing dynamic MEMS and has the potential to displace traditional microfabrication techniques that require dozens of process steps.

5:00 PM EL19.10.16

Optimizing the Contact Structure for Scaled 50 nm-Channel MoS_2 and IGZO Field Effect Transistors Yuchen Zhou, Chankeun Yoon, Kelly Liang and Ananth Dodabalapur; The University of Texas at Austin, United States

A novel idea of replacing conventional flat-edge electrodes with an array of spike-shaped electrodes has been implemented and proved useful for overcoming short-channel effects and improving charge injection. 50 nm-channel MoS_2 field effect transistors (FETs) with nanospike array electrodes demonstrated improved gate control relative to flat edge electrode devices. By using the nanospike array electrodes with 5 nanospikes and a 1:3 spike-to-spacing ratio, a high on/off ratio (~10^7), negligible drain-induced barrier lowering (0.1 V/V), and a steep subthreshold swing can be achieved. While this design has worked well for amorphous metal oxide and organic semiconducting materials, the physics behind the nanospike electrodes is material dependent. Therefore, the structure of the nanospike needs to be optimized to realize the full potential for 2D materials such as MoS_2. We also hypothesize that the optimized nanospike electrodes work well for CVD grown MoS_2, which is more suitable for industrial-scale fabrication.

The nanospike array electrodes were patterned onto 90 nm of SiO_2 using electron beam lithography and 17 nm of Cr and Au were thermally evaporated. 3 nm and 20 nm of MoS_2 and hBN flakes were mechanically exfoliated respectively and transferred onto the patterned contacts. The top gate with a width of 3 mm was patterned with 100 nm thick Cr and Au. The tips of the nanospike are 200 nm wide equilateral triangles with a 1mm long rectangular base protruding vertically between the conventional flat electrodes. The channel length between the tips of the source/drain nanospikes is 50 nm.

Ideally, charge nanoribbons are formed at high drain biases between the spikes of the source and drain, resulting in the higher charge injection in a narrower semiconducting channel for each pair of the nanospikes. However, the spacing between each nanospike on the source/drain electrodes can have different effect on the formation of charge nanoribbons. We have examined various ratios of the nanospike vs. spacing including 1:2, 1:4, and 1:5 and compared with the established 1:3 ratio. As expected, the current magnitude is at its highest for 1:5 ratio (~ 70 mA vs. 20 mA for $V_d = 1$ V) due to larger channel width, but the subthreshold swing degradation was observed as well. Another configuration of the nanospike array electrodes that has worked well for organic materials is the one-sided nanospike electrodes. In this configuration, instead of using the nanospike electrodes for both the source and drain, the nanospikes are implemented on the source side only. The highest current magnitude (~160 mA), on/off ratio (~10^9), and the steepest subthreshold swing (~100 mV/dec) were achieved in this configuration with a 1:3 spike-to-spacing ratio. Since the source electrode plays the main role of charge injection, having the nanospikes on the source side facilitates charge injection, while more charges are received by the drain side compared to the double-sided nanospike configuration, resulting in a higher drain current. A optimized structure for the nanospike array electrodes can be carefully selected by pairing the single-sided nanospike electrodes with the best spike-to-spacing ratio. The two-dimensional charge nanoribbons formed by this structure provides an alternative to the three-dimensional nanowire semiconducting channels that are currently being investigated by industry.

Nanospike electrodes are also useful in flexible and printed electronics in which the contact metallization can be defined with nanoimprint lithography resulting in small channel lengths. Results with IGZO indicate that excellent transistor performance can be achieved with nanospike electrode devices even when the channel length is less than the gate insulator thickness, which is common in flexible and printed electronics.

5:00 PM EL19.10.17

1D Transition Metal Chalcogenides: Novel van der Waals Metals for Microelectronic Applications Jing Jin, Danial Coyle, Thomas Empante, Michelle Wurch and Ludwig Bartels; University of California, Riverside, United States

Micron-scale single-crystal nanowires of metallic $TaSe_3$, a material that forms -Ta-Se_3-Ta-Se_3- stacks separated from one another by a tubular van der Waals (vdW) gap, have been synthesized using chemical vapor deposition (CVD) on a SiO_2/Si substrate, in a process compatible with semiconductor industry requirements. Their electrical resistivity was found unaffected by downscaling from the bulk to as little as 7 nm in nanowire width and height, in striking contrast to the resistivity of copper for the same dimensions. While the bulk resistivity of $TaSe_3$ is substantially higher than that of bulk copper, at the nanometer scale the $TaSe_3$ wires become competitive to similar-sized copper ones. Moreover, we find that the vdW $TaSe_3$ nanowires sustain current densities in excess of 10^8 A/cm^2, an order of magnitude more than copper, and feature an electromigration energy barrier twice that of copper. The results highlight the promise of quasi-one-dimensional transition metal trichalcogenides for electronic interconnect applications and the potential of van der Waals materials for downscaled electronics.

Recent work has extended the preparation strategies to $ZrTe_3$ and related materials. Patterning of the substrate prior to CVD growth can encode the location and alignment of the CVD-grown nanowires resulting in a network of connections on the substrate.

5:00 PM EL19.10.18
Evolution of Electronic States During *In Situ* Transformation of Lanthanide Intermetallic $Pr_2Co_3Ge_5$ Ellis Kennedy[1], Trent Kyrk[2], Mary Scott[1,3] and Julia Chan[2]; [1]University of California, Berkeley, United States; [2]Baylor University, United States; [3]Lawrence Berkeley National Laboratory, United States

Recently identified low-dimensional intermetallic homologous series with the formula $A_nB_{n+1}X_{3n+1}$ consisting of rare-earth (A), transition metal (B), and tetrels (X) have potential as novel quantum materials [1]. Members of the series exhibit strongly correlated electron behavior, including superconductivity [2], Kondo lattice behavior [3], and vying antiferromagnetic and ferromagnetic states [4]. One member of the series, $Pr_2Co_3Ge_5$, exists in multiple polymorphs, each with unique magnetic and electronic properties. Single-crystal monoclinic m-$Pr_2Co_3Ge_5$ was grown using the flux growth method with tin as a metallic non-reactive flux. XRD confirmed the monoclinic structure and *C2/c* space group.

Electron-transparent lamellae prepared from the bulk *m*-Pr2Co3Ge5 were analyzed using monochromated probe-corrected electron energy-loss spectroscopy (EELS) and a direct electron detector. EELS provides information about the atomic coordination, electron interactions, and elemental identification [5]. The Co and Pr ionization edges were recorded from an edge portion of the lamella, approximately 50 nm thick. The lamella was tilted off-zone to avoid channeling effects in the EEL spectra and the energy resolution was 0.24 eV based on the zero-loss peak. The bulk average Pr valency is dominated by the Pr^{4+} cation, with the M_4 ($3d_{3/2} \rightarrow 4f_{5/2}$) edge exhibiting a lower energy shoulder on the main peak. A bulk in situ heating holder was used to increase the sample temperature from room temperature (20C) to 80 °C to induce a transformation from the monoclinic to orthorhombic *o*-Pr2Co3Ge5 (*Ibam*) phase in 10 °C steps. The temperature range was selected based on a previous in situ XRD study that placed the transformation between 40 and 60 °C. A change in the ionization edges began around 55 °C (with potential calibration error of a few degrees) as the Pr edges changed to reflect a 3+ dominant state in which the M_5 ($3d_{5/2} \rightarrow 4f_{7/2}$) edge developed a high energy shoulder and the M_4 edge split into two peaks separated by 3.3 eV. The Pr and Co EEL spectra of the lamella after heating was compared to a *o*-Pr2Co3Ge5 standard to confirm it had undergone a full structural transformation. Ionization edges captured between the initial and final structures show a mixed Pr valency, falling between the +4 state of the monoclinic phase and +3 state of the orthorhombic phase.

The use of dual EELS enabled analysis of the Co edges in tandem with the Pr edges during heating. The Co L_3 edge onset shifted to a higher energy between the *m*-Pr2Co3Ge5 and *o*-Pr2Co3Ge5 phases; however, the $L_{2,3}$ maximum peak positions are downshifted by 1 eV. Changes in both the Pr and Co edges indicate compensating electron behavior between the two cations.

The change in Pr valency and the observation of intermediate valencies suggests an instability of the *f*-electron valence that is possibly advantageous in materials with strong electronic correlations. Understanding the behavior of the *4f*-electrons and their relation to the Co *3d*-electrons that are largely responsible for the complex magnetic properties of materials in the series will improve their use as quantum materials [6].

Feature Size Dependence of Semiconducting Polymer Films Based on Molecular Weight Distribution Joaquin Mogollon Santiana, Adam J. Moule and Meghna Jha; University of California - Davis, United States

Semiconducting Polymers (SPs) have received widespread attention due to their promising qualities like superior absorbance/emission, easy chemical tunability, low-temperature solution processing, lightweight, and flexible substrates, and low environmental toxicity. A major obstacle to the development of SPs devices is the lack of patterning processes, most traditional lithography methods done for inorganic semiconductors damage the SPs. Recently the Moule group developed a process named Projection Photothermal Lithography (PPL) that enables patterning in SPs films based on solubility compatible with non-crosslinked polymers. The method works by placing a thin SP film inside a cell with a semi-poor solvent, a binary mixture of a strong and weak solvent that will not dissolve the film at room temperature but will spontaneously dissolve as the temperature rises. Light is projected onto an area which will generate heat. The local temperature will increase until it surpasses the dissolution temperature (DT) causing the polymer to dissolve allowing us to pattern the film. Previous work was done using P3HT where it was found that tunning the semi-poor solvent ratio had a direct relationship with the DT. Using PPL with a homemade microscope set up rapid (~ $4cm^2hr^{-1}$), large single exposure area (0.21 mm^2), sub-µm patterns can be obtained optically In order to generalize this concept a different semiconducting polymer (PDPP3T) was used. It was determined that the PDI for this polymer is much broader than P3HT resulting in a significant difference in dissolution temperature for smaller and larger chains of polymers in the film. Knowing this our goal was to determine how PDI distribution and molecular weight affect the size of features made using the PPL method. With the PDPP3T data, it was determined that a larger molecular weight and small PDI are ideal for this patterning technique, as dissolution will occur more uniformly, which agrees with the P3HT results.

5:00 PM EL19.10.20
Direct Laser-Induced Hierarchical Mesoporous Copper Oxide on Copper Surface for Electrochemical Sensing Sotoudeh Sedaghat, Sina Nejati and Rahim Rahimi; Purdue University, United States

In this work, we demonstrate a novel a one-step rapid laser-processing approach for the fabrication of electrochemically active copper oxide mesoporous structures directly on copper metal surfaces. The effect of laser processing power on the composition, crystallinity, microstructure, wettability and color of the laser-induced oxide on the copper surface was systematically studied using optical microscopy, scanning electron microscopy (SEM), grazing incidence X-ray diffraction, Raman spectroscopy, and water contact angle measurements. The created ratio and percentage of crystalline Cu2O [111] and amorphous CuO with different laser processing conditions was confirmed by GI-XRD and Raman spectroscopy. Results of these studies confirmed clear decrease in size of created copper oxide nanostructures and increase in overall crystallinity of the final surface with increase in laser power processing conditions. The optimized copper oxide electrodes with the highest surface area and crystallinity showed the ability to be used for nonenzymatic glucose and hydrogen peroxide sensing with a unique ultrahigh sensitivity, fast response/recovery time, and selectivity. This rapid laser-induced oxidation technique can be potentially applied for scalable fabrication of wide range of electrochemically active metal oxide micro/nanostructures directly onto different metal surfaces for potential used in other electrochemical and biochemical sensing applications.

5:00 PM EL19.10.21

Understanding Oxygen Migration due to Contacts and Gate Bias-Stress in Indium Tin Oxide Transistors Sumaiya Wahid[1], Mahnaz Islam[1], Christopher Perez[1], Timothy D. Brown[2], Michelle Chen[1], Matthew Marcus[3], Hendrik Ohldag[3], Suhas Kumar[2] and Eric Pop[1]; [1]Stanford University, United States; [2]Sandia National Laboratories, United States; [3]Lawrence Berkeley National Laboratory, United States

Field-effect transistors with semiconducting oxide channels are promising candidates in several applications due to their low-temperature deposition, ultralow leakage current, as well as processing compatibility with silicon technology [1-3]. However, their stability is under question and their performance can degrade after long-term operation, an effect which is poorly understood. In this work, for the first time, we use *in-situ* x-ray absorption spectroscopy to probe the instability of indium tin oxide (ITO) transistors by looking into oxygen migration in metal-insulator-semiconductor-metal (MISM) test structures. To fabricate the MISM devices, we e-beam evaporate ~30 nm Pd as the back (gate-like) contact, followed by ~13 nm Si_3N_4 (as the insulator) with conductively-coupled plasma-enhanced chemical vapor deposition at 350 °C. This nitride is used to avoid interference from any oxygen species other than in the ITO. Next, we deposit ~4 nm thick ITO (as the semiconductor channel), using radio-frequency magnetron sputtering at room temperature, 100 W power and 5 mTorr pressure. Finally, the ~30 nm top metal contact (four types of samples with Ti/Pt, Ni, Pd, or Pt) is deposited using e-beam evaporation. To utilize *in-situ* scanning transmission x-ray microscopy, these MISM devices are fabricated on SiN_x membranes.

From the spectral absorption measurement of samples with four different workfunction metals, we demonstrate, for the first time, that metal contacts scavenge oxygen from ITO according to a trend consistent with their reactivity. Such oxygen scavenging from the ITO channel in a transistor creates more oxygen vacancies, which in turn generate more carriers in the channel, causing a negative threshold voltage shift, especially at short channel lengths [4] where the contacts are closer together. The observed trend with metal reactivity agrees well with our previous reports of ITO transistors with Ni *vs.* Pd contacts, where Ni contacts caused a more negative threshold voltage shift at shorter channel lengths *vs.* Pd contacts [5,6].

To investigate the microscopic physics during device operation and understand the gate bias-stress effect in ITO transistors, we perform *in-situ* x-ray absorption spectroscopy while applying voltage bias to the MISM structures with Ni contacts, and observe oxygen migration near both the ITO/dielectric and ITO/Ni interfaces. To correlate this effect with transistor behavior, we fabricate transistors using the same composition as the MISM structure and observe a similar trend. Notably, the device behavior upon gate-bias stressing is different with Si_3N_4 dielectric from our previously reported works with Al_2O_3 or HfO_2 dielectrics [7], which reinforces the impact of dielectric material on the stability of ITO transistors.

In short, our results provide new insight of device operation and threshold voltage (in)stability of ITO transistors using *in-situ* x-ray characterization. Both metal contacts and the gate insulator play major roles in oxygen migration, and are therefore instrumental for optimizing transistor performance and reliability.

This work is partly supported by the Stanford Graduate Fellowship (S.W., M.I.) and the SystemX Alliance.

Ultrafast Colorimetric Humidity Sensors with Mesoporous Titania Microspheres Nutpaphat Jarulertwathana, Syazwani Mohd-Noor and Jerome Hyun; Ewha Womans University, Korea (the Republic of)

Fast humidity monitoring is becoming increasingly important for a wide range of applications including emerging healthcare solutions and fuel cell engineering. However, most commercially available sensors suffer from slow response times ranging from seconds to minutes, limiting their use. Herein, we propose mesoporous solid and yolk-shell titania microspheres as ultrafast colorimetric humidity sensors. Different microsphere morphologies were synthesized through a solvothermal process with varying reaction times, and their performances were compared to determine the optimal structure for humidity sensing. We found that the pore volume, pore diameter and crystallinity, respectively, determine the responsive RH range, response time and stability of the materials. The optimal mesoporous solid microsphere had a fast response time of 20 ms and was structurally-stable for at least 180 days, which was the duration of this study. These microspheres were integrated into a prototype sensor system, consisting of a pair of LEDs and a photodiode. The system was sensitive and fast enough to detect unique humidity profiles generated from human speech, demonstrating an alternative approach to speech recognition. These results suggest that mesoporous titania microspheres are promising for ultrafast humidity detection.

Transparent and Flexible Memristor Utilizing Copper-Iodide Based on Low Temperature Solution Processing Yongin Cho, Arindam Bala and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

This study proceeds with the utilization and process of binary halides, which is a representative candidates, to discover an active layer suitable for memristors. Herein, the solution-based Copper Iodide (CuI) thin film is used an active layer of the memristor which shows high performance of memory device from the point of endurance and retention. To implement of a transparent memristor, indium tin oxide (ITO) is deposited as a bottom electrode on the polyethylene terephtalate (PET) substrates. The CuI thin film is formed by dissolution-recrystallization solution-treatment at 80°C and silver electrode is deposited thereon to have a sandwich structure. The memristor having a high transparency of 90% or more has a current difference of 10 times between a low-resistive state (LRS) and high-resistive state (HRS). The memristor has a steady endurance of 100 cycles at low voltage range (-2.5V to 2.5V) and a constant read voltage of -0.5V, and the CuI-based memory remains stable for 10^4s in rentention characteristic. Additionally, the device also exhibits the same level of resistance state difference and current under bending stress. The CuI film is used as the active layer of a stable memristor introduced with transparent and flexible memory applications.

5:00 PM EL19.10.24

Two-Dimensional Field-Effect Transistors with a Reconfigurable Floating Gate for Logic-in-Memory June-Chul Shin, Hyun Young Choi and Gwan-Hyoung Lee; Seoul national University, Korea (the Republic of)

Recently, machine learning applications, such as artificial intelligence, neuromorphic computing, and autonomous vehicles, are attracting extensive attention. However, the von Neumann architecture consisting of the separated parts of data processing and data storage has weaknesses in real-time processing and consumes large power. Therefore, there has been a need for energy-efficient electronic hardware without data transport between logic and memory units. In this regard, two-dimensional (2D) materials are considered promising candidates for logic-in-memory. Owing to the atomic thickness and electrostatic controllability, the conductance of 2D field-effect transistors (FETs) can be precisely modulated so that they can be used for reconfigurable logic circuits. However, the logic-in-memory in previous works still shows a large power loss because the used 2D memory devices have only n-type transport. Therefore, it has been required to develop a CMOS-based circuit consisting of p-type and n-type memory devices, which have a low static power consumption and high noise margin. Here, we demonstrate 2D FETs with a reconfigurable floating gate based on the van der Waals heterostructure. By using WSe_2 as an ambipolar channel, the WSe_2 FETs exhibit not only reconfigurable memory operation of n- and p-type polarity but also multiple conductance states. The inverters and circuits based on the WSe_2 FETs show multi-functionality in logic operation with low power consumption. Our work highlights the great potential of atomically thin semiconductors for next-generation low-power electronics.

SESSION EL19.11: Low-Dimensional Materials II
Session Chairs: Ageeth Bol and Supratik Guha

8:30 AM *EL19.11.01
Dielectric, Magnetic, and Contact Properties of Two-Dimensional Materials William Vandenberghe[1], Madhuchhanda Brahma[1], Emeric Deylgat[1], Massimo Fischetti[1], Akash Laturia[1], Mehrdad Rostami Osanloo[1], Bart Sorée[2,3,4], Sabyasachi Tiwari[1] and Maarten Van de Put[1]; [1]The University of Texas at Dallas, United States; [2]imec, Belgium; [3]KU Leuven, Belgium; [4]University of Antwerp, Belgium

Two-Dimensional (2D) Materials have received an enormous amount of attention in the past decade. Modeling and simulation have also advanced dramatically and many materials properties can be determined from first-principles. Here, we present an overview of our recent progress in modeling dielectric, magnetic, and contact properties of 2D materials.
We first highlight how the dielectric properties can be calculated in a robust way. We show that in hexagonal boron-nitride, the out-of-plane dielectric constant changes minimally when going from monolayer to bulk. We show how leveraging materials databases, 32 novel candidate 2D dielectrics with a large band gap can be identified. For practical applications as an insulating dielectric, the band alignment with adjacent materials must be determined as well. Calculating the electron affinity and bandgap of all 32 materials, we estimate the leakage current and identify oxyhalides like LaOBr and LaOCl as promising 2D “high-k” future dielectrics.
Next, we show how magnetic properties can be determined from first principles while accounting for long-range interactions and the anisotropy of the exchange interaction. We apply our method on known 2D ferromagnets like CrI_3, and $CrGeTe_3$ to verify good agreement with experiments. We subsequently study the magnetic order of doped transition-metal dichalcogenides (TMDs) and identify V-doped $MoSe_2$ as the most promising doped TMD-based 2D ferromagnet. We also present how magnetic switching can be simulated atomistically by coupling quantum transport with Monte Carlo simulations. We further show how we can screen materials databases for the most promising 2D magnets.
Finally, we show our progress in understanding electrical contacts to semiconducting 2D materials like TMDs. We compute image-force barrier lowering in a 2D material surrounded by a dielectric. Calculating the current flowing from the metal to the semiconductor, we show that when the 2D material is surrounded by a “low-k” dielectric, the contact resistance is dramatically improved. The recipe we identify for making low-resistance contacts is: low Schottky barrier, high doping concentration, and low dielectric constant of the surrounding dielectric.

Enhancing the Nucleation of Dielectrics on MoS_2 by Atomic Layer Deposition Alexander Shearer, Jung-Soo Ko, Eric Pop and Stacey F. Bent; Stanford University, United States

Recently, 2D transition metal dichalcogenides (TMDCs) have received significant attention due to their unique optical and electrical properties, lending themselves to exciting applications such as microelectronics, sensing, catalysis, photonics, and more. In order to be used in these applications, TMDCs generally must be incorporated into nanoscale material stacks composed of other 2D materials or more often 3D materials including metals or metal oxides. Due to the uniformity and angstrom-level thickness control that it provides, as well as its widespread use in the semiconductor industry, atomic layer deposition (ALD) has become a promising candidate for depositing those metals and metal oxides on the TMDCs to form the requisite stacks. However, because of both the inert nature and low surface energy of the basal plane of TMDCs, it is difficult to deposit thin films upon these materials using techniques like ALD – often leading to films of poor quality with pinholes, voids, and rough surfaces.

Numerous techniques have been employed to improve ALD nucleation onto 2D materials: pretreatment of the surface with various absorbates, addition of both metal and molecular seed layers, and use of physisorption-assisted ALD by means of low temperature processing. The latter technique is particularly interesting because it still provides the benefits of ALD – namely the thickness control – and is a non-destructive mild treatment that does not lead to the incorporation of impurities from chemical pretreatments. While it has been employed before, little is known about how the approach can be further leveraged to lead to the growth of better films.

In this work, we investigate how various ALD parameters – such as temperature, purge time, and precursor – impact nucleation behavior and film quality of dielectrics, like Al_2O_3 and HfO_2, on MoS_2, a prevalent TMDC. Using atomic force microscopy (AFM), we study film nucleation and continuity as a function of ALD cycle number to better understand the impact of each ALD parameter. Additionally, using x-ray photoelectron spectroscopy (XPS) and reflection electron energy loss spectroscopy (REELS), we investigate the interfacial properties of the dielectric on MoS_2. Our results show that by selecting a low temperature, short purge process, with as few as 15 cycles of Al_2O_3 ALD, we can create a seed layer upon which high temperature ALD can be performed – resulting in a continuous, smooth film. Furthermore, according to AFM and Auger electron spectroscopy data, under the same operating conditions, different ALD Al_2O_3 and HfO_2 precursors exhibit distinct nucleation and growth behavior on MoS_2, indicating varied wetting of the TMDC surface and altered reaction kinetics by the precursors. The dependence of the deposited film properties on the ALD precursor choice and the process parameters will be discussed.

9:15 AM EL19.11.03
Anti-Ambipolar Phototransistors Based on 1D GaAsSb/2D MoS_2 Heterojunctions Wei Wang and Johnny C. Ho; City University of Hong Kong, Hong Kong

The incapability of modulating the photoresponse of the assembled heterostructure devices has remained a challenge for developing optoelectronics with multi-functionality. In this presentation, we report a gate-tunable and anti-ambipolar phototransistor based on 1D GaAsSb nanowire/2D MoS_2 nanoflake mixed-dimensional van der Waals (vdW) heterojunctions.[1] The resulting heterojunction shows asymmetric control over the anti-ambipolar transfer characteristics, possessing the potential to implement electronic functions in logic circuits. Meanwhile, the anti-ambipolar device allows the synchronous adjustment of band slope and depletion regions by gating in both components, thereby giving rise to the gate-tunability of the photoresponse. Coupled with the synergistic effect of the materials in different dimensionality, the hybrid heterojunction can be readily modulated by the external gate to achieve a high-performance photodetector exhibiting a remarkable on/off current ratio of 4×10^4, fast response of 50 μs and high detectivity of 1.64×10^{11} Jones. Due to the formation of type-II band alignment and strong interfacial coupling, a prominent photovoltaic response is also explored in the heterojunction. Finally, a visible image sensor based on this hybrid device is demonstrated with excellent imaging capability, suggesting promising applications in future optoelectronic systems.

Advanced Epitaxial Si/SiGe Stacks for Nanowire Applications Andriy Hikavyy, Roger Loo, Yosuke Shimura and Naoto Horiguchi; imec, Belgium

A decade has passed since semiconductor industry had a major shift in the design paradigm of the field effect transistor (FET) moving from the so-called planar transistors to fin FETs or 3D transistors. Since then, this technology was perfected and currently reaching its limits. As scaling progresses the next shift is around the corner. After many years of R&D by many research groups, last year the major semiconductor players introduced a move from fin FET to gate all around (GAA) or nanosheet transistors in their scaling roadmaps. Looking further downstream, at VLSI 2021, imec introduced the forksheet and complementary FET (CFET) device architectures to extend the scalability of the nanosheet transistor family towards 1nm and beyond logic nodes.

In a CFET architecture, n- and p-MOS devices are formed on top of each other, removing the n-p spacing, allowing further maximization of the effective channel width and, hence, the drive current. This architecture can be realized in two ways: a monolitic and a sequential approach. In the first one both n- and p-MOS transistors are built on the same wafer. In the sequential approach the bottom device is built up to the contacts, next, a blanket semiconductor layer is bonded and top devices are formed. Both approaches have their pros and contras and are being currently intensively investigated.

One of the main building blocks of a GAA (nanosheet) transistor is a SiGe/Si stack with multiple SiGe and Si layers which act as active or sacrificial layers in the further processing. Growth of SiGe/Si stacks with relatively low Ge concentrations (<30%) is very well known for Group IV epi community which works with such stacks for decades. The situation changes significantly when we move to CFET architecture. One of the difficulties of the monolitic CFET is the integration of bottom and middle dielectric isolation (BDI and MDI) in order to cut-off a parasitic channel of the bottom device and to physically separate bottom and top devices. This complicates the initial SiGe/Si epi stack considerably and makes the final epi growth challenging.

In this contribution we will present typical schemes for manufacturing nanosheet devices and motivate SiGe/Si stacks needed in each case. Next, we will discuss strategies for epitaxial growth, choice of precursors and temperature ranges. Finally examples of the devices with integrated SiGe/Si stackes will be demonstrated.

Area-Selective Atomic-Layer Deposition of Carborane Thiols on Copper for Patterning and Interconnect Applications Sai Siva Kumar Pinnepalli[1], Raja Sekhar Bale[1], Rupak Thapa[2,1], Vamseedhara Vemuri[3], Nathan A. Oyler[1], Nicholas Strandwitz[3], Sean King[2] and Michelle M. Paquette[1]; [1]University of Missouri Kansas City, United States; [2]Intel Corporation, United States; [3]Lehigh University, United States

Miniaturization of components in an integrated chip follows Moore's law to advance computing capabilities for future technological needs. In the grand scheme of chip manufacturing, complex fabrication methods involving atomic-layer deposition (ALD) with precise control over atomic or molecular dimensions are envisioned to realize more than Moore's vision. Advanced chip-making further requires robust materials to develop miniaturized and scalable patterning processes. Boron carbide compliments silicon-based materials with its distinct chemical and physical properties and has potential applications as dielectric layers, hard masks, diffusion barriers, etch-stop, and patterning-assist layers. Carboranes are unique ALD precursors for boron carbide due to their three-dimensional icosahedral structure that produces densely packed, defect-tolerant, and cross-linkable monolayers over high-aspect ratio surfaces. Specifically, thiol-derivates of carboranes show intrinsic substrate selectivity towards copper and can assist in patterning processes.

The current study explores the vapor-phase ALD of the *ortho*-carborane-9,12-dithiol (9O12) and *meta*-carborane-1-thiol (M1) on copper surfaces. The process conditions for the 9O12 and M1 precursors—substrate temperature, precursor dose, and pressure—are optimized to obtain a higher substrate coverage. The films are characterized by X-ray photoelectron spectroscopy (XPS) and dynamic in-situ ellipsometry to gain insights into the kinetics of deposition mechanisms. Stability and structural changes as a function of temperature are evaluated to understand the robustness of the films. An overview of the 9O12 and M1 monolayer deposition and their applications to patterning will be presented at the eminent gathering.

10:45 AM EL19.12.02

Electrical Resistivity Evolution of Electrodeposited Ruthenium- and Molybdenum-based Nanowires for Interconnect Application Jun Hwan Moon, Seunghyun Kim, Taesoon Kim and Young Keun Kim; Korea University, Korea (the Republic of)

It is challenging to achieve historically anticipated improvements in the performance of integrated circuits (ICs) because the cost and complexity of the associated technology increase with each generation. As downscaling accelerates, the electrical resistance and diffusion to low-k dielectrics of conventional Cu/Ta/TaN interconnect become a major problem [1]. The reduction in the cross-sectional area of the interconnect causes an increase in the resistance of the interconnection structure, which causes RC delay and energy consumption. A liner/barrier whose thickness cannot be reduced any further drastically reduces the volume of the conductor in the trench structure, accelerating RC delay and making the process difficult [2]. Consequently, the demand for advanced interconnect metallization has increased. Therefore, the microelectronics industry is searching for new materials and processes [3].

This study investigates the electrical properties and microstructural evolution of nanoscale Ruthenium (Ru) and Molybdenum (Mo)-based metallic nanowires prepared via template-assisted electrodeposition. Most previous studies on advanced interconnect materials were carried out based on thin films. However, the actual structure and scale of interconnects, including vias and trenches, are nanowires with a high aspect ratio; thus, they exhibit properties significantly different from those of thin films owing to the confinement of low-dimensional systems.

In addition to material properties, nanopore engineering is required to fill the confined pores at the nanoscale with metallic materials. We provide an electrochemical strategy for synthesizing Ru- and Mo-based nanowires in nanopores and characterize the effects of microstructure and phase differences on the electrical properties of nanowires in situ. We find that the electrical resistivity was affected by the composition and microstructural changes, such as the diameter of nanowires, crystallite size, and phase. Properly designed alloys of advanced interconnect materials (e.g., Co, Ru, and Mo) show superior characteristics to existing materials in various characteristics that interconnect will have. We investigate the degree of thermal diffusion into a low-dielectric material by imitating a structure similar to an actual interconnect structure. First-principles calculations show that a corresponding liner/barrier is required as a new central conductor emerges.

A Highly Efficient and the Smallest AAA Battery-Powered Pocket X-Ray System Based on Carbon Nanotube Amar P. Gupta[1,2], Taewon Kim[2], Jinho Choi[1], Mrinal Bhusal Sharma[2], Seung Jun Yeo[2,1], Jeung Sun Ahn[1] and Jehwang Ryu[1,2]; [1]Kyung Hee University, Korea (the Republic of); [2]CAT Beam Tech Co., Ltd, Korea (the Republic of)

One of the most common types of radiological device on earth is the X-ray machine. From the airport to the hospital, X-rays are used at least once on both the person and their belongings. Even though X-ray machines are used a lot, they are among the least efficient machines, with a ratio of less than 1%. In conventional hot cathode filament-based portable X-ray machines, 75% of the energy is used to accelerate electrons, and 20% is used to heat the filament (cathode) to generate electrons inside the vacuum tubes. Thus, there are two types of electrical power sources needed: a) a low-voltage, high-ampere source to heat the filament and make electrons, and b) a high-voltage, low-ampere source to speed up the electrons and make X-rays. However, we have made the first X-ray system that fits in a pocket and is smaller than our palm. It doesn't use a filament and has a high-voltage module that can be used for both making electrons and accelerate them up. This is possible because the X-ray system uses a Carbon Nanotube (CNT) cold cathode digital X-ray tube, it doesn't make any heat, doesn't have a complicated structure for filament feedthroughs, and can be powered by 2 AAA batteries. Our X-ray system is one of the smallest in the world. It weighs about 80 grams and is about 40 mm X 30 mm X 25 mm. An X-ray survey meter can detect a soft X-ray with a voltage of up to 7 kV. It gives off 50 mSv/hr of radiation dose at a distance of 10 cm from the X-ray source, proving that this smallest X-ray system can be used for cell irradiation experiments and possibly as an alternative to all the hazardous radioactive materials used for QC testing and calibration of X-ray survey meters. It can also take X-ray pictures of soft things like plant leaves when it is powered by a Lithium ion battery that is smaller than an AAA battery. We are certain that this new Nanotube innovation will assist researchers all around the globe in making the X-ray machine more compact, portable, energy efficient, and environmentally friendly.

11:15 AM EL19.12.04
Multi-Dimensional Driven Verification Platform of Chemical Vapor Compositions Yun Ji Hwang, Iman Shackery and Seong Chan Jun; Yonsei University, Korea (the Republic of)

Since gas molecules do not exist in a single state in nature, future gas sensing technology will have to move toward predicting and determining the state of the gas mixture itself, rather than being limited to a specific single gas in the air. In this study, we propose a platform that detects gas in a mixed gas state under humidity conditions like human exhaled gas and predicts the type and mixture state of the gas. Our subminiature sensor is a multi-dimensional nano-electrode sensor. For each channel, six different ssDNA functionalized graphene are arranged, enabling multi-dimensional sensing at the same time. Our sensor confirmed the reactivity to the chemical vapor composition under the mixing conditions of various ratios of NO, NO_2, NH_3, and H_2S gases under low and high humidity conditions, and showed high reactivity even under high humidity conditions. Chemical vapor in a mixed state is simultaneously detected in multiple dimensions by our sensors, and the data is input in the form of electrical signals to our artificial intelligence model. Our convolutional neural network-based deep learning model is a very fast and efficient model that can process multi-dimensional data simultaneously and is trained and optimized through experimental data. Our artificial intelligence model can recognize the detected electrical signal, determine the type and ratio of gas included in the chemical vapor composition at the time of detection, and determine the status of harmful gases in the air. Our chemical vapor composition determination platform has verified its performance by achieving a recognition rate of over 99% in both low and high humidity conditions. Our research results are not limited to human expiratory gas diagnosis but are expected to serve as an excellent research background in various fields such as manufacturing, aerospace, and personal air management systems that require detection of harmful gases in real environments.

11:30 AM EL19.12.05
Area-Selective Atomic Layer Deposition using Aminosilane Precursors to Confer Oxide versus Nitride Selectivity Jinseon Lee[1], Jeong-Min Lee[1], Hongjun Oh[2], Bonggeun Shong[2], Tae Joo Park[1] and Woo-Hee Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Hongik University, Korea (the Republic of)

Area-selective atomic layer deposition (AS-ALD) offers tremendous advantages in comparison with conventional top-down patterning processes in that atomic-level selective deposition can achieve in a bottom-up fashion on pre-defined areas in multi-dimensional structures. Inherent AS-ALD of oxide thin films on SiO_2 versus SiN surfaces is highly relevant to manufacturing of 3D-structured memory devices, but little is known about inherent AS-ALD on such surfaces. For example, in accordance with the continuous demand for higher memory density, the number of stacked SiO_2/SiN layers in 3D V-NANDs is increasing, resulting in an increased aspect ratio and decreased SiO_2/SiN tier size in the vertical direction. Accordingly, when NAND cells with an information storage layer are formed by a conventional top-down lithography/etching process, inter-cell non-uniformity and interference problems inevitably occur. This suggests that AS-ALD of SiO_2 thin film as an interlayer dielectric is required only on SiO_2, not on SiN, for NAND cell formation with discontinuous SiN CTL to prevent crosstalk between adjacent cells. For this purpose, AS-ALD of SiO_2 thin films on SiO_2 versus SiN substrates are investigated. Theoretical screening based on density functional theory (DFT) calculation is performed to identify Si precursors which maximize adsorption selectivity, results indicate that an aminosilane has the potential to function as a highly chemo-selective precursor as compared with a halosilane. Application of the aminosilane precursor to SiN and SiO_2 substrates result in inherent deposition selectivity of ≈4 nm without the aid of surface inhibitors. Furthermore, deposition selectivity is enhanced using an ALD-etch supercycle in which an etching step inserts periodically after a certain number of ALD SiO_2 cycles. Thereby, enlarged deposition selectivity greater than ≈10 nm is successfully achieved on both blanket-and SiO_2/SiN-patterned substrates. Therefore, this approach for performing inherent AS-ALD expands the potential utility of bottom-up nanofabrication techniques for next-generation nanoelectronic applications.

Template-Mediated Well-Defined Nanostructures for Optical, Optoelectrical, and Magnetic Applications Rui Xu[1], Yong Lei[2] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf (HZ, Germany; [2]Ilmenau University of Technology, Germany

Advanced devices play a critical role for sustaining the ever-growing demands of our society for energy, information, health care, etc. To achieve high performance, devices with nanoscaled features are attracting more and more attentions by virtue of their unique and promising effects emerging at nanoscale. Structural design and engineering of materials provides a verstile platform to optimize the device performance and improve the commercial competitivity[1]. Regarding the structural engineering, controlling the geometrical parameters (i.e., size, shape, hetero-architecture, and spatial arrangement) of nanostructures have been the central aspects of investigations and practical applications. By using anodic aluminum oxide template, we realized well-defined controlling of nanostructures over the size, in-plane/out-of-plane shape, hetero-architecture, and spatial arrangement[2]. With such well-defined nanostructures, the optical, optoelectrical, and magnetic performance of nanodevices can be obviously enhanced.

Supply Chain Challenges to Advancing BEOL Scaling and Materials Development Sean King; Intel Corp, United States

Innovations in back-end-of-line (BEOL) interconnects over the past several decades have been driven primarily by both Moore's law mandated dimensional scaling of Cu wiring and permittivity scaling of low dielectric constant (i.e. low-k) interlayer dielectrics (ILDs) to mitigate increased resistance-capacitance (RC) delays. While the need for both dimensional scaling and RC delay mitigation has not diminished, the physical limits of ILD dielectric permittivity scaling has now been reached with the introduction of air-gap technologies, and the industry now instead faces limitations in thickness scaling for the Cu barrier materials needed for yield and reliability considerations. The latter combined with Cu resistivity size effects has led to an exponential increase in interconnect metal line resistance and created an intense interest for identifying alternate materials and fabrication methods for BEOL metallization.

In this address, we overview some of the new materials and processes of current interest for BEOL metallization with a focus on supply chain considerations that may limit or prohibit implementation. We will specifically examine technical considerations and supply chain challenges for the consideration of platinum group metals (PGM) as Cu replacement conductors, PGM recovery and recycling, and supply chain challenges for novel precursors for flowable and area-selective deposition (ASD) of low-k dielectric materials.

1:45 PM *EL19.13.03
The Electromigration Characteristics of Copper Pillars with Increased Solder Christine Hau-Riege, Kevin Caffey and Dongming He; Qualcomm Technologies, Inc., United States

Copper pillars are the interconnect of choice for first-level connections for high density flip-chip packaging and second-level connections for 2.5D/3D packages due to fine pitch capabilities, leading to smaller devices and lower costs. However, the presence of Cu-Sn intermetallic compounds is a reliability concern due to its increased brittleness relative to copper and solder, which has been well-studied through various aging tests. To mitigate mechanical failure, two approaches have been reported: the inclusion of a Ni barrier layer to slow down the formation of intermetallic as well as an increase in solder volume to reduce fracture. This paper focuses on the implications of increased solder on electromigration reliability. Full transformation of the solder is not achieved in these copper pillars, so that Cu-Sn continually forms through prolonged electrical and thermal acceleration. This paper will report the electromigration performance of such interconnects in terms of current direction and pillar configuration as well as examines electromigration-induced failure mechanism and failure criteria selection.

2:15 PM *EL19.13.04
Epitaxial Growth of Transition Metal Dichalcogenide Monolayers and Heterostructures for Large Area Device Applications Joan M. Redwing; The Pennsylvania State University, United States

Wafer-scale epitaxial growth of semiconducting transition metal dichalcogenide (TMD) monolayers such as MoS_2, WS_2 and WSe_2 is of significant interest for device applications to circumvent size limitations associated with the use of exfoliated flakes. Epitaxy is required to achieve single crystal films over large areas via coalescence of TMD domains with the same crystallographic direction.

The prospects and challenges associated with the epitaxial growth of wafer-scale TMD monolayers and heterostructures for the development of large area 2D devices will be discussed. Metalorganic chemical vapor deposition (MOCVD) has emerged as an enabling growth technology for TMDs due to its ability to achieve a combination of high growth temperatures (>700ºC) and large chalcogen overpressures which are needed to obtain stoichiometric epitaxial films. The unique aspects of van der Waals epitaxy of TMDs on sapphire substrates will be presented including the effects of crystallographic orientation of the substrate on nucleation density and domain orientation and the role of surface passivation and steps on domain alignment and defects. Techniques for wafer-scale 2D layer transfer for device integration will be reviewed and applications for wafer-scale TMD monolayers in nanoelectronics, sensing and photonics will be presented.

2:45 PM EL19.13.05
Impact of Impurities and Annealing Conditions on Structural and Optical Properties of Hafnia-Based Thin Films Manuel Alejandro Garcia Andrade[1], Tetyana v. Torchynska[1], Georgiy Polupan[1], Larysa Khomenkova[2,3] and Fabris Gourbilleau[4]; [1]Instituto Politecnico Nacional, Mexico; [2]V. Lashkaryov Institute of Semiconductor Physics at NASU, Ukraine; [3]National University "Kyiv-Mohyla Academy",, Ukraine; [4]CIMAP, UMR CNRS/CEA/ENSICAEN/UNICAEN, France

HfO_2 based materials offer high refractive index and high transparency in UV-NIR spectral ranges that are promising for photonic applications. For this purpose, the stabilization of HfO_2 structure is required to minimize the optical losses in the HfO_2 based optical materials. It is known that stabilization of tetragonal/cubic structure can be achieved via HfO_2 doping with trivalent atoms, such as rare-earth (RE) elements. In this case, the electrical neutrality is achieved via formation of oxygen vacancies, i.e. one vacancy for two dopant atoms. At the same time, the interaction between different ions and their redistribution upon high temperature annealing were not well addressed.
In this report structural transformation of HfO_2 thin films co-doped with silicon and lanthanides (Pr) is considered in terms of the evolution of optical and light emitting properties of these materials. The films were grown on Si substrates by radio frequency magnetron sputtering in argon plasma and annealed at T_A=1000ºC for t_A=15-60 min in inert atmosphere. The transformation of film properties was studied by means of SEM, EDS, XRD, XPS, Raman scattering and photoluminescence (PL) techniques. For HfO_2 films doped with Pr ions, the stabilization of the tetragonal HfO_2 phase in annealed films was observed contrary to the monoclinic structure of pure HfO_2 films. The main reason responsible for this phenomenon is the formation of oxygen vacancies. For Pr-doped HfSiOx films, the phase separation between SiOx and HfO_2 occurs upon annealing and the Pr ions appeared in the HfO_2 phase. The shape of RE-related PL spectra followed the structural transformation. Narrow RE-related PL peaks were detected in the samples annealed at 1000 fr 30-60 min that

confirms the location of RE ions in the phase with a high crystal field. The peculiarities of PL spectra and the mechanism of PL excitation and its changes with the phase separation for different films are discussed.

2:50 PM EL19.13.06
Structural, Magnetic, and Magnetocaloric Study of Rare-Earth Doped $Pr_{0.5}RE_{0.1}Ca_{0.4}MnO_3$ (PRECMO) (*x*=0.1; RE = Y, Nd, Sm, Eu, and Gd) Manganite Nanoparticles Synthesized via Autocombution Method Jolaikha Sultana[1,2]; [1]The University of Memphis, United States; [2]The University of Arkansas, United States

Perovskite manganites having the general formula, $R_{1-x}A_xMnO_3$ (where R is a rare-earth ion and A is an alkaline-earth ion) have been considered as potential candidates for magnetic refrigeration based on MCE because of the large magnetic entropy change at moderate fields. Also their extraordinary chemical stability and tunable phase transitions are also added advantages to choose manganites for magnetic refrigeration applications. The study reports the structural, magnetic, and magnetocaloric effect in rare-earth-doped Perovskite manganite $Pr_{0.5}RE_{0.1}Ca_{0.4}MnO_3$(*x*=0.1; RE=Y,Nd, Sm, Eu,Gd), PRECMO. The powder samples were prepared by a facile autocombution method followed by annealing at 1100 degree celsius for 12 hours. Structural characterization was done through XRD, SEM, and FTIR analysis. XRD pattern reveals that all the PRECMO samples crystallize in the perovskite phase with an orthorhombic structure (space group Pnma). The lattice parameter of the powder samples was calculated from the XRD pattern refinement, which showed a decrease in lattice parameter and volume upon rare-earth substitution in Nd<Sm<Eu<Gd<Y order. This systemic change in the lattice volume is the result of the lanthanide contraction of RE ionic radii. FTIR spectra identify the characteristic Mn–O bond stretching vibration mode near 600 cm^{-1}which shifts toward high wavenumbers due to distortion of the MnO6 octahedron with RE substitution. Field-cooled (FC) and zero-field cooled (ZFC) magnetization were measured at 100 Oe. The magnetic phase transition temperature for all RE^{3+} doped manganite lies below 100 K. Isothermal magnetization curves were investigated in the temperature range of 5-300 K in fields up to 5T. All RE^{3+} doped samples showed paramagnetic behavior at RT and ferromagnetic behavior at 5K. Nd-doped PRECMO showed maximum magnetization of 65 emu/g, followed by Eu, Gd, Y, and Sm. The purpose of this work is to investigate the magnetocaloric effect for low-temperature magnetic refrigeration applications. The magnetic isotherms are being investigated to derive the compound's maximum entropy change and relative cooling power.

Advanced 3D Printing Techniques for Future Electronics Yang Yang; University of Technology Sydney, Australia

The race to develop next-generation wireless electronics is accelerating at a rapid pace. Thanks to additively manufactured electronics (AME) technology, fast-prototyping, low-entry-cost, and in-house short-run manufacturing empower millions of start-ups and companies with demanding confidentiality and accelerated innovation. We aim to build a new class of multi-beam packaged antennas and miniaturized circuit designs to advance the knowledge for next-generation (5G) mobile devices. Compact and low-cost 3D printed antennas and circuits will be delivered to circumvent the limitations of today's mobile antennas, which are usually bulky and not compatible with future ultrafast wireless communications. The proposed AME antennas and microwave circuits should be easily integrated into mobile devices linking billions of high-speed wireless systems in a dynamic environment. New antenna prototypes with multiple dynamic beams will be created for emerging intelligent and immersive technologies, e.g. unmanned vehicles, ultra-low latency virtual reality, smart cities, and seamless telepresence on the move.

Threshold Voltage and Memory Window Engineering of Surface Modified $Ti_3C_2T_x$ Mxene Memristor for Memory and Neuromorphic Computing Navaj B. Mullani and Jun Hong Park; Gyeongsang National University, Korea (the Republic of)

Mxenes, a new type of two-dimensional material, have attracted extensive interest in memory and artificial synaptic device application because of its excellent electrical and chemical properties. In this work, the conductivity of Mxenes is engineered to enhance the switching of the device with addition of functional groups, via the etching and oxidation processes. The exceptional properties of partially oxidized MXene ($Ti_3C_2T_x$) memristors have shown a large memory window and decreased threshold bias; on the nanosecond scale, we emulated the complex spike time-dependent plasticity-dependent synaptic rules using electrical pulses. The low threshold voltage, steady retention time (10^4 s), clearly distinguishable resistance states and high ON/OFF rate ($>10^6$) are the main memory-related attributes of this device. Furthermore, the physical origin of electronic transport in this device is found to occur by a filamentary resistive switching mechanism, as determined by analyzing the atomic/kelvin probe force microscopy and modelled electrical fittings. The image edge detection ability of the synaptic device is also revealed by using a convolutional neural network. Therefore, the present functionalization method for Mxene memristors can facilitate the essential manufacturing complexity of high-density non-volatile memory storage and artificial synapse system.

Enhancing Functionalities of 2D and 2D/3D Hybrid Perovskite Films as Ionizing Radiation Detectors Beatrice Fraboni[1,2]; [1]Univ of Bologna, Italy; [2]INFN, Italy

The demand for large area, low cost and flexible high-energy radiation detection systems for medical imaging and public security, has pushed the research to develop novel detectors combining high sensitivity and low-cost fabrication processes. Recently, lead-halide perovskites emerged as a very promising novel class of materials for X- and gamma-ray detection. Their success can be attributed to the excellent perovskite optoelectronic properties. The presence of heavy elements like Pb, Br or I inside the lead-halide perovskite structure ensures a high effective atomic number, resulting in a high absorption coefficient in the ionizing radiation energy range. For efficient detection, high absorption is not enough, the charge transport properties of the material also play a crucial role. Diffusion length of over 1µm and long lifetime of carriers have been attributed to perovskite even in polycrystalline form. Moreover, perovskites can be fabricated also in thin-film form at low temperature from solution opening the possibility to low-cost, large-area and flexible detectors. Flexible detectors are extremely appealing because they open completely new and unexplored functionalities and markets such as wearable electronics, smart walls, and nuclear waste pipe testing for industrial and citizens' security, cultural heritage, and space applications.

We discuss how to improve the functionality as ionizing radiation detection of high-performing metal halide perovskites, targeting in both cases tens of microns perovskite active layer thickness and easily assembling onto flexible substrates: i) 3D perovskites, methylammonium lead triiodide (MAPbI3) and methylammonium lead tribromide (MAPbBr3), pure or in blends; ii) 2D/3D blends obtained by mixing 3D MAPbBr3 and 2D (based on larger organic ammonium cations) structure perovskites such as (PEA)2PbBr4; iii) 2D layered perovskites, (PEA)2PbBr4. Simple planar devices were fabricated on flexible substrates with the above detailed materials and their performances as ionizing radiation detectors have been tested under 40-150kVp X-ray beams and under MeV proton irradiation, also assessing their behaviour and stability for continuous operation at constant irradiation and bias.
We report on a detailed study on the relation between composition and electronic transport at the nanoscale, a key factor in polycrystalline thin films, carried out by comparing simultaneously acquired XRF (X-Ray Fluorescence spectroscopy) and XBIC (X-Ray Beam Induced Current). Finally we will discuss preliminary results on deep electronic levels in 2D (PEA)2PbBr4 obtained by Photo-Induced Current Transient (PICTS) analyses, a powerful tool to understand the role of electrically active defects in optoelectronic grade materials

11:00 AM EL20.01.02
Highly Efficient Organic Metal Halide Hybrid Scintillator Tunde B. Shonde[1], Maya Chaaban[1], He Liu[1], Oluwadara J. Olasupo[1], Azza Ben-Akacha[1], Fabiola G. Gonzalez[1], Kerri Julevich[1], Xinsong Lin[1], J.S. Raaj V. Winfred[1], Luis M. Stand[2], Mariya Zhuravleva[3] and Biwu Ma[1,1]; [1]Florida State University, United States; [2]The University of Tennessee, Knoxville, United States; [3]University of Tennessee, Knoxville, United States

Scintillators, which could convert high energy ionizing radiations to visible light photons, have recently seen surges of applications in various areas, ranging from nuclear substance monitoring to medical imaging and many industrial control systems. While a variety of materials, including inorganic single crystals, organic molecules, and plastics, have been developed for radiation scintillation, all of them have their own drawbacks and there is not yet a single material that possesses a combination of high radiation absorption, high light yield, fast responsivity with short decay lifetimes, and low cost of mass production.
In this talk, I will introduce a new design concept for the development of organic-inorganic hybrid scintillation materials that could be facilely prepared via low-temperature processes and exhibit high light yields with short decay lifetimes. For the proof of concept, a zero-dimensional (0D) organic metal halide (4-(4-(diphenylamino) phenyl)-1-(propyl)-pyrindin-1ium zinc bromide (TPA-P)$_2$ZnBr$_4$) exhibiting yellowish-green emission peaked at around 550 nm has been designed, synthesized, and fully characterized. Unlike previously reported organic metal halide hybrids with metal halides as emitter, (TPA-P)$_2$ZnBr$_4$ has high Z metal halides acting as X-ray sensitizer and aggregation-induced emission (AIE) organic cations as emitter. As a result, dramatically enhanced X-ray scintillation of TPA-P$^+$ is achieved via sensitization by ZnBr$_4^{2-}$. A light yield of 36,200 Photons/MeV is achieved for this 0D hybrid material, which is significantly higher than that of anthracene (~15,000 Photons/MeV) and comparable to those of inorganic scintillators, while the photoluminescence and radioluminescence decay lifetimes of 3.56 ns and 9.96 ns respectively are similar to those of pure organic scintillators. Moreover, the high light yield to decay time ratio of 3,634 Photons/MeV×ns and low detection limit of 21.3 nGy$_{air}$s^{-1} are among the best values achieved to date for all kinds of scintillation materials. Our work provides a new strategy to achieve molecular sensitization in ionically bonded organic-inorganic hybrid systems and expands the utility and tunability of functional organic molecules in these hybrid systems for useful optoelectronic applications.

11:15 AM *EL20.01.03
Evaluation of Perovskite for MeV Neutron Detection Wyatt Panaccione[1], Zhifang Shi[2], Praneeth Kandlakunta[1], Jinsong Huang[2] and Lei R. Cao[1]; [1]Ohio State Univ, United States; [2]University of North Carolina at Chapel Hill, United States

The detection of thermal neutrons or neutrons with energy in the order of eV is relatively easy because of their high interaction cross-sections with a few conversion elements (e.g., boron, lithium, cadmium of gadolinium, etc). But neutrons are produced in the MeV range in the most commonly used reactions. To take advantage of high cross-section, they have to be slowed down through the neutron-hydrogen scattering process in a bucky moderator. This work explores the direct detection of fast neutrons by neutron-hydrogen scattering reaction in perovskite. We firstly tried the experimental characterization of the electric current response of perovskite solar cells using a MeV fast neutron beam at the Ohio State University Nuclear Research Reactor. We then fabricated the Methyl-hydrazinium Lead Chloride (CH3NH2NH2PbCl3, MHyPbCl3) with a high atomic loading of hydrogens for their transient current response to a time modulated fast neutron beam with 1E7 neutron per cm^2 per second. Additionally, we studied the mechanism of X-ray induced damage in the hybrid halide perovskites where self-healing effect was observed. The threshold electron energies from X-ray interactions to cause the displacement of I- is in a range of 4.6 - 34.6 keV, which is far exceeding its activation energy (0.08 to 0.62 eV).

11:45 AM EL20.01.04
X-Ray Detectors with Ultrahigh Sensitivity Based on High Performance Printed Organic Field Effect Transistors Laura Basiricò[1,2], Ilaria Fratelli[1,2], Andrea Ciavatti[1,2], Adrián Tamayo[3], Carme Martinez-Domingo[3], Paolo Branchini[2], Elisabetta Colantoni[2], Zachary Lamport[4], Stefania De Rosa[2], Luca Tortora[2], Adriano Contillo[5], Raul Santiago[6], Stefan T. Bromley[7], John Anthony[8], Ioannis Kymissis[4] and Beatrice Fraboni[1,2]; [1]University of Bologna, Italy; [2]National institute for nuclear physics, Italy; [3]Campus de la Universitat Autònoma de Barcelona, Spain; [4]Columbia University, United States; [5]Elettra-Sincrotrone Trieste, Italy; [6]Universitat de Barcelona, Spain; [7]Institució Catalana de Recerca i Estudis Avançats, Spain; [8]University of Kentucky, United States

In the last decade organic semiconductors have demonstrated to be excellent candidates for the development of a new class of X-Ray detectors able to fulfil important emerging requirements such as the mechanical flexibility, the possibility to cover large and curved surfaces, low-cost, and low-bias operation. Moreover, they are the only material platform that can offer human tissue equivalence, i.e. due to their chemical composition (i.e. low-Z elements) organic materials have radiation absorption comparable to that of human organs and tissues. This is a highly desirable property for a dosimeter to be employed in the medical field since it avoids complex calibration procedures and the perturbation of the radiation beam when the detector is placed between the radiation source and the patient. In this study we propose a double strategy to achieve ultrahigh sensitivity to X-rays by fully organic direct X-ray detectors. We exploited two different advanced printing techniques to deposit the active layer of the organic X-Ray detectors in a fully controlled way obtaining highly performant Organic Field Effect Transistors (OFETs). This approach allowed us to boost the detecting efficiency by means of both the improvement of the collection/transport properties of the devices and the deep comprehension, identification and control of the active trap states ruling the photoconductive gain mechanism of the thin film-based detectors. We deposited blends of polystyrene (PS) with the organic semiconducting small molecule 1,4,8,11-tetramethyl-6,13-triethylsilylethynyl pentacene (TMTES) by Bar Assisted Meniscus Shearing technique.[1] The molecular structure of this material is similar to TIPS-Pn ((6,13-bis(triisopropylsilylethynyl)-pentacene)), however, the BAMS deposited thin films crystallize in a totally different, and more efficient, crystal packing (i.e., herringbone packing motif). This resulted in OFETs that reached very high mobilities of up to 2.5 cm^{2}V^{-1}s^{-1} and showed a reduced density of interfacial hole traps thanks to vertical segregation of the polystyrene at the semiconductor/dielectric interface and the consequent passivation of defects. In the second case [2] we deposited organic thin films of TIPS-Pn and TIPG-Pn (analogous molecule where the two Si atoms have been substituted with two Ge atoms) by Pneumatic Nozzle Printing. This printing procedure allowed to tune the morphology and packing of the film, to selectively vary key features related to trap states affecting the charge transport and collection and, ultimately, the detecting mechanism. We investigated electrically active traps for minority carriers by Photocurrent Spectroscopy with Optical Quenching. This technique allowed to identify the excitonic peaks which induce the inner amplification mechanism under X-ray exposure. Thanks to the activation of the photoconductive gain effect induced by the simultaneous presence of UV-vis and X-Ray photons, we experimentally assessed for the first time the presence and role of electrical traps for minority carriers responsible for this physical phenomenon. By these strategies, exceptional high sensitivities both for rigid and flexible devices ((4.10 ± 0.05) 10^{10} µC Gy^{-1} cm^{-3} and (9.0 ± 0.4) 10^{7} µC Gy^{-1} cm^{-3} respectively) for X-ray detection are achieved, which are the highest reported so far for direct X-ray detectors based on tissue equivalent full organic active layer, and higher than most perovskite film-based X-ray detectors. As a proof of concept to demonstrate the high potential of these devices, an X-ray image with sub-millimeter pixel size is recorded employing a 4-pixel array. This work highlights the potential exploitation of high performing OFETs for future innovative large-area and highly sensitive X-ray detectors for medical dosimetry and diagnostic applications.

Room Temperature γ-Rays and X-Ray Detection with CsPbBr$_3$ Perovskite Mercouri G. Kanatzidis; Northwestern University, United States

Highly sensitive hard radiation detectors operating at room temperature are in high need for a wide variety of applications. The perovskite semiconductor CsPbBr$_3$ exhibits a high spectral resolution of γ-rays at room temperature. CsPbBr$_3$ is air-stable, non-hygroscopic, and possesses high effective atomic number Z-eff of 65.9. An overview of the research progress on the bulk CsPbBr$_3$ crystals studied so far and detector fabrication and characterization of single crystals will be presented. Highly pure CsPbBr$_3$ single crystals with high quality can be grown using the Bridgman method. CsPbBr$_3$ perovskite's defect tolerance tends to screen electrically activated defects, enabling the carriers' remarkable transport properties. Our CsPbBr$_3$ detector has shown remarkable energy resolving capability under both X and γ rays, particularly in achieving 3.9% (4.8 keV, FWHM) energy resolution for 122 keV ^{57}Co γ-ray with good temporal stability. The hole carrier lifetime in CsPbBr$_3$ detector-grade single crystal was observed to be well over 25 µs. Pixelated devices can resolve ^{137}Cs 662-keV γ-rays with ~1% energy resolution. Results from synchrotron X-ray detection experiments with flux of 10^6 to 10^{12} photons/s/mm^2 at 58.61 keV, operating in current mode, will also be presented.

2:00 PM EL20.02.02
Halide Perovskite@Metal-Organic Frameworks Composites for Highly Stable, Low-Noise High Energy Direct X-ray Detectors Hayden Salway, Elena Avila, Ganbaatar Tumen-Ulzii, Oliver Moseley, Samuel D. Stranks, David Fairen-Jimenez and Miguel Anaya; University of Cambridge, United Kingdom

Halide perovskites one of the most promising materials for next-generation, highly sensitive, low-noise, direct high energy X-ray detectors due to their excellent optoelectronic properties including bandgap tunability, high photoluminescence quantum yields (PLQY), defect tolerance and chemical versatility. However, challenges for the successful commercialization of halide perovskites X-ray detectors remain. For example, processing halide perovskites into thick devices for optimal X-ray attenuation, without introducing defects via pressing, or mixing with polymer membranes represents one set of challenges. Further, to realize highly sensitive, low-noise detectors requires novel material choices to reduce dark currents, minimize current drift and enhance stability.

MOFs are another kind of materials which have started the gather attention as promising x-ray detectors, due to their ease of processing and chemical versatility enabling incorporation of high Z atoms and maximizing attenuation efficiencies.[1] Further, recent advancements in sol-gel MOF processing have enabled us to develop high-density MOF structures through advanced synthesis and densification, resulting in size controllable high-density materials with large attenuation efficiencies for high energy X-rays .[2] Recently, halide perovskite@metal-organic framework (PVKs@MOFs) composites have been successfully synthesized, which enhance perovskite stability and provides opportunities to harness the properties of multiple materials, overcoming the challenges of dark currents and thick film processing for highly stable X-ray detectors. [3]

In this work, we present the first of its kind PVK@MOF direct X-ray detector. Our unique synthesis approach formed halide perovskite nanocrystals via direct conversion from a sol-gel Pb MOF, resulting in a size and shape controllable PVK@MOF composite. This process can be tailored to the required X-ray energies for applications in radiography, CT, and PET scanning. The intrinsically insulating Pb MOF resulted in a composite with high resistivity and significant reduction in dark current. In addition, it maintained high current densities and sensitivity resulting from charge carriers generated upon X-ray excitation of perovskite nanocrystals within the composite. Moreover, reproducible medical imaging requires device resistance to current drift. In this regard, halide perovskites often see large dark current drifts due to strong ion migration effects, thus requiring long pre-biasing before optimally functioning. However, our PVK@MOF composite showed a significant reduction in dark current drift compared to the equivalent standalone perovskite detector, which we attribute to the rigid MOF structure limiting ion migration effects. We further present a full direct X-ray detector material characterisation framework using our PVK@MOF composite, demonstrating the full range of device performances which can be achieved by varying incident properties. The methodology of this work will lay the foundations for further device performance characterisation, removing ambiguity from current performance metrics and significantly advancing the application and commercialisation of halide perovskite X-ray detectors.

Quasi-2D Perovskite Photo-Diode for X-Ray Sensing Wanyi Nie; Los Alamos National Laboratory, United States

Polycrystalline perovskite film-based X-ray detector is an appealing technology for assembling large scale imager by printing methods. However, thick crystalline layer without trap and solvent residual is challenging to fabricate. First, I will introduce the solution method for the thick perovskite layer fabrication suitable for X-ray sensing. By introducing n-butylamine iodide into methylammonium lead iodide precursor and coating at elevated temperatures, compact and crystalline layers with exceptional uniformity are obtained on both rigid and flexible substrates. Photodiodes built with the quasi-2D layers exhibit low dark current and stable operation as well as a high X-ray sensing performance. Next, I will present our recent achievements in stabilizing the 2D perovskite photo-diode under electrical field stress. We found that the moisture in the environment can trigger voltage induced device failure. To circumvent this problem, we incorporated a hydrophobic interface layer to stabilize the device. As a result, the detector can stand for high electrical field stress that deliver high X-ray sensing efficiencies.

2:45 PM EL20.02.04
Thickness-Controlled Large Area (over 2500 cm^2) Perovskite Single Crystal for X-Ray Imaging Applications Youngseung Choi[1], Min Kyu Kim[1], Kang Heo[2], Dooho Kim[2] and Byungha Shin[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Vieworks, Korea (the Republic of)

In recent years, metal halide perovskite (MHP) has been actively studied in the fields of solar cells, light emitting diodes and X-ray detectors due to its excellent optical properties. In particular, large diffusion length, high resistivity, high attenuation coefficients and tunable band gap make MHP as an attractive candidate as a photon-absorber for direct x-ray detector application. Furthermore, MHP in the form of single crystal is attracting a lot of attention due to its lower defect density and higher mobility-lifetime product values than MHP thin films.

However, there still exist several issues to be addressed for MHP single crystal to be incorporated into commercial X-ray detectors. The primary issue is the synthesis of large-area single crystals while keeping its thickness on the order of mm—a thicker absorber will reduce charge collection efficiency and a thinner absorber causes insufficient X-ray absorption. In a conventional solution method of growing MHP single crystal, where a single crystal grows in free-standing configuration, the growth along the lateral dimensions is accompanied by the increase of the thickness. In order to utilize a free-standing single crystal for x-ray imaging, the crystal must be sliced or grinded into a smaller thickness, during which there is a high risk of crack formation or fracture due to highly brittle nature of MHP single crystal. In addition, a considerable amount of the material is wasted.

In this study, we designed a novel growth apparatus that allows us to grow MHP single crystals as large as 50 mm X 50 mm while limiting the thickness to 1 mm with no need for post-processing to reduce the thickness to apply for X-ray detectors. We fabricated X-ray detectors with our large-scale and thin single crystal and they exhibited an excellent sensitivity of 3.0x104 μC Gyair−1 cm−2. Thin film transistor panel integrated X-ray detector was also fabricated for large-scale imaging. The details of the synthesis of MHP single crystals as well as device characterizations will be discussed.

3:30 PM *EL20.03.01
Designs for Upconversion and Photomultiplication in Organic Shortwave Infrared Detectors Tse Nga Ng; University of California, San Diego, United States

The shortwave infrared spectral region is particularly powerful for a variety of applications including environmental monitoring and medical diagnosis, enabling greater penetration depth and improved resolution in comparison to visible light. Upconversion imagers that combine photosensing and display in a compact structure are attractive since they avoid the costly and complex process of pixilation. This talk will present the designs of polymeric upconversion imagers that combine photo-sensing and display in a compact structure, to enable visualization to 1300 nm. The photoresponse exhibited a high external quantum efficiency of 35% at a low bias of ≤ 3 V with –3 dB bandwidth of 10 kHz. The large active area of 2 cm^2 enabled demonstrations such as object inspection, imaging through smog, and concurrent recording of blood vessel location and blood flow pulses. The organic photodetectors are further improved by incorporating a new heterojunction interlayer to trigger trap-assisted photomultiplication. The interlayer served to suppress the dark current and enhance the photoresponse, leading to a detectivity of 10^10 Jones at -1.5 V and improves the contrast of an upconversion imager by 2x.

4:00 PM EL20.03.02
Photomultiplication Organic Photodetectors with High and Bias-Independent Specific Detectivity Shen Xing, Jonas Kublitski, Christian Hänisch, Louis C. Winkler, Hans Kleemann, Johannes Benduhn and Karl Leo; TU Dresden, Germany

Highly responsive organic photodetectors are of interest for imaging, health, and security monitoring applications. Photomultiplication organic photodetectors (PM-OPDs) are an ideal option due to the excellent sensitivity given by their internal amplification mechanism. However, for most PM-OPDs, the specific detectivity is likely to be sacrificed under reverse bias since a large operation voltage is usually required to obtain high sensitivity, but is usually accompanied by high shot noise. Here, we propose a fully vacuum-processed PM-OPD based on the low donor BDP-OMe:C_{60} material system. With the trap-induced interfacial bending of energy levels, the electrons can be efficiently injected via tunneling under only -1 V, leading to an external quantum efficiency of over 100% and a superior specific detectivity of $\sim 10^{13}$ Jones. More importantly, this high detectivity is almost independent of the increasing reverse voltage up to -10 V in the near-infrared spectral region. The bias-independent specific detectivity, high responsivity, and fast response speed prove the great potential of PM-OPDs.

4:15 PM *EL20.03.03
Molecular Switch-Embedded Organic Photodiode for Active Matrix Image Sensor Dae Sung Chung; POSTECH, Korea (the Republic of)

We suggest a strategy to artificially widen the linear dynamic range (LDR) of an organic photodiode (OPD) by introducing a light-intensity-dependent transition of its operation mode, such that a low saturation photocurrent can be overcome by additional operation mechanism. The active layer of OPD is doped with a strategically designed and synthesized molecular switch, which shows typical OPD performances with an EQE < 100% under low-intensity light illumination and photomultiplication behaviors with an EQE > 100% under high-intensity light illumination, resulting in an artificially extended LDR up to 225 dB. Such unique and reversible transition of the operation mode by light intensity self-recognition of molecular-switch-embedded OPDs can be explained by charge trapping/detrapping behavior of closed/open isomers of the molecular switch as well as the unbalanced quantum yield of the photocyclization/photocycloreversion of the molecular switch. To prove the suggested operation mechanism, various molecular switches with various functional groups are studied in conjunction with various photophysical analyses.
Regarding the suggested mechanism, we show that the fluorinated benzene group in the molecular switch is responsible for the formation of interfacial band bending at the interface between the semiconductor and itself, resulting in exciton quenching and electron trapping. In general, such unprecedented exciton quenching and electron trapping may degrade the performance of organic electrons, but in certain applications, these phenomena can be positively utilized. An example suitable for this application is a photomultiplication-type organic photodiode (PM-OPD). The operating mechanism of PM-OPD can be divided into two stages. First, photogenerated excitons are separated at the donor-receptor interface, electrons are trapped by spatially localized trap centers, and remaining holes are transited to the collecting electrode. Second, trapped electrons near the anode interface induce band bending, resulting in hole injection to generate photomultiplication. In other words, molecular switches embedded in OPD become such trapping centers under high-intensity light illumination and regains its original neutral properties under low- intensity light illumination.
After carefully optimizing dynamics of the light-intensity-dependent transition of operation mode of the suggested molecular-switch-embedded OPDs, these unique OPDs are integrated onto CMOS chip to demonstrate organic image sensors with superior sensitivity against strong light illumination.

SESSION EL20.04: Intrinsic Dark Current Limits

New Device Architectures and Performance Limiting Factors of Organic Near-Infrared Detectors Koen Vandewal; Hasselt University, Belgium

Organic photodetectors (OPDs) with a performance comparable to that of conventional inorganic ones have been demonstrated for the visible regime. However, near-infrared (NIR) photodetection has proven to be challenging and, to date, the true potential of organic semiconductors in this spectral range (800–2500 nm) remains largely unexplored. In this talk, I will introduce new device concepts for organic NIR detectors, based on resonant optical cavities and doped photo-active layers. Design rules and optimization strategies will be discussed, yielding wavelength selective devices (20 nm resolution) with a tunability of the detection wavelength over several hundreds of nanometers, allowing the printing of miniature NIR spectrometers. In a second part of the talk, we explore the performance limitations of organic NIR detectors: A relation between open-circuit voltage, dark current, and noise current is demonstrated for OPDs with detection wavelengths beyond 1100 nm. Based on these findings we estimate an upper limit of achievable specific detectivity values for organic photodiodes as a function of their longest NIR detection wavelength.

10:45 AM EL20.04.02
On the Role of Mid-Gap Trap States in Organic Photodetectors Stefan Zeiske[1], Oskar Sandberg[1], Nasim Zarrabi[1], Christina Kaiser[1], Sam Gielen[2], Wouter Maes[3], Koen Vandewal[2], Paul Meredith[1] and Ardalan Armin[1]; [1]Swansea University, United Kingdom; [2]Hasselt University, Belgium; [3]IMEC, Associated Lab IMOMEC, Belgium

Photodetectors derived from organic, semi-crystalline and amorphous semiconductors receive significant interest in the optoelectronic research community, industry, and consumer electronics. Their UV-to-NIR tuneable and narrow spectral responses, detectivities comparable with silicon and other crystalline semiconductors, and low embodied energy manufacturing with the potential of flexible application form factors offer great potential in next generation light sensing and imaging applications, such as wearable and building integrated electronics, or the internet of things. In any photodetector, the dark current is a critical parameter limiting the sensitivity at low light intensity and thus, defining the maximum achievable signal-to-noise. Organic photodetectors, in particular, are characterized by intrinsically high dark currents orders of magnitude higher than expected for thermally excited band-to-band transitions, the origins of which are still subject of current debate. Here, we find the dark current in organic semiconductor photodetectors to be universally mediated and thus limited by mid-gap trap states. We derive a diode equation based on Shockley-Read-Hall statistics and determine a revised upper limit for the specific detectivity of organic photodetectors. Finally, we present a method to overcome the limitations of those mid-gap trap states. Our results deliver new insight on the origin of performance- and sensitivity-limiting noise in organic light-harvesting applications, such as photodiodes and detectors.

11:00 AM EL20.04.03
Tuning Perovskite Composition for Low Dark Current and High Specific Detectivity Photodetectors Francesco Furlan, Davide Nodari, Matthew J. Fuchter and Nicola Gasparini; Imperial College London, United Kingdom

Organo-metal halide perovskites have gained attention for their remarkable optoelectronic properties, which made them an ideal material for photodetectors (PDs). In particular, modern PDs require to be cost-effective, self-powered, highly sensitive and flexible, all conditions that can be fulfilled by using a perovskite-based active layer.
The route to obtain highly sensitive sensors requires minimizing dark current (J_d) values, which limits the noise (i_n) in devices and maximizes light conversion. To date, few methods exist to reduce the dark current in perovskite PDs. They are based on the use of charge-blocking layers to minimize charge injection[1]. Other strategies are related to inclusion of additives or controlling film crystallization[2] to minimize backward charge injection at the electrodes. However, there is a deficit of efforts focused on understanding the role of perovskite composition and its correlation to device J_d.
In recent years, compositional engineering has played a fundamental role in developing perovskite solar cells, enabling higher device efficiencies, an adjustment of film defect densities and longer stabilities[3]. In this work[4], we study the effect of tuning the perovskite composition and report the performance of PDs fabricated with these active layers. We obtained ultra-low J_d values of 1.3×10^{-9} A cm^{-2} at –0.5 V with specific detectivity approaching 10^{13} Jones. Moreover, we observe for the first time a linear relationship between the J_d of devices and their V_{oc} over the 0-15 % Br range.
With a combination of optoelectronic measurements, transient analyses, impedance spectroscopy and morphological investigations, we attributed the low J_d of the of the 15% Br containing devices to the reduction of trap states, a better charge extraction of photogenerated carriers and an improvement in photoactive layer morphology and crystallinity.
Therefore, we demonstrate how compositional engineering of the active layer can be an alternative approach to conventional transport layer optimization to improve photodetector performances.

11:15 AM *EL20.04.04
Understanding and Reducing Dark Currents in Perovskite Photodetectors Rene A. Janssen; Eindhoven Univeristy of Technology, Netherlands

Perovskite semiconductors offer the possibility of spectral sensitivity from the visible to the near infrared and can be used in future photodetection applications like image sensing,[1] optical communication, environmental and health monitoring, or chemical and biological detection. Perovskite photodiodes, however, often suffer from relatively high dark current densities under reverse bias. Among the common strategies to reduce dark current density, the inclusion of charge-blocking layers between the electrodes and the perovskite layer has become popular. While these blocking layers are successful in increasing the energy barrier for charge injection, the lower limits of dark current density reached experimentally remain typically orders of magnitude higher than the expected intrinsic bulk thermal-generated dark current density. By determining the activation energy of the dark current in optimized perovskite photodiodes with different bandgaps and employing a series of electron-blocking layers, we find that the activation energy corresponds to the energy offset between the highest occupied molecular orbital of the electron blocking layer and the conduction band minimum of the perovskite.[2] Increasing this energy offset by using an appropriate blocking layer, a perovskite photodiode was fabricated that has a wavelength sensitivity up to 1050 nm, combined with an ultralow dark current density of 5×10^{-8} mA cm^{-2} and noise current of 2×10^{-14} A Hz$^{-1/2}$.[2]
To further increase performance we employ low-dimensional perovskites. Perovskite thin films with a vertical gradient in dimensionality result in graded electronic bandgap structures that are ideal for photodiode applications. Positioning low-dimensional, vertically-oriented perovskite phases at the interface with the electron blocking layer further increases the activation energy for thermal charge generation and thereby effectively lowers the dark current density to a record-low value of 5×10^{-9} mA cm^{-2} without compromising responsivity, resulting in a noise-current-based specific detectivity exceeding 7×10^{12} Jones at 600 nm.[3] These multidimensional perovskite photodiodes show promising air stability and a dynamic range over ten orders of magnitude, and thus represent a new generation of high-performance low-cost photodiodes.[3]

Chemical Fundamentals Defining The Intrinsic Detectivity Limits of Near-Infrared Organic Photodetectors Sam Gielen[1,2], Jochen Vanderspikken[1,2], Paul Meredith[3], Koen Vandewal[1,2], Ardalan Armin[3] and Wouter Maes[1,2]; [1]Hasselt University, Belgium; [2]imec, Belgium; [3]Swansea University, United Kingdom

Organic photodetectors (OPDs) with a performance comparable to that of the conventional inorganic ones have recently been demonstrated for the visible regime.[1] However, high performance near-infrared organic photodiodes are more challenging, as non-radiative recombination losses limit the specific detectivity (D^*), as well as the open-circuit voltage.[2] Besides, thermally excited transitions from mid-gap trap states further limit the dark current. Taking this into account, it can be concluded that OPDs have the potential to be a useful technology for wavelengths up to 2 μm, given that high external quantum efficiencies can be maintained at these low photon energies. To further elaborate on the fundamentals defining these limitations and investigate the (chemical) origin of mid-gap trap states, a next-generation of 'defect-free' organic semiconductors is synthesized. This allows to investigate the influence of specific material imperfections (end-capping, homocoupling defects, and metal impurities) on the material properties and device performance. In this contribution, we will give an overview of the synthetic approaches applied to produce the high performance near-infrared organic semiconductors, and show how defects and impurities have an impact on their intrinsic limits.

Highly Responsive 2D/2D TMDC/Perovskite Hetero-Photodetectors through Photo-Gating Leon Spee[1], Julius Konietzka[1], Annika Grundmann[2], Michael Heuken[2,3], Holger Kalisch[2], Andrei Vescan[2] and Franziska E. Muckel[1]; [1]University Duisburg-Essen, Germany; [2]Compound Semiconductor Technology, RWTH Aachen University, Germany; [3]Aixtron SE, Germany

Photoconducting photodetectors convert light to current through light absorption in a conducting channel, which changes resistivity or conductivity temporally. This kind of light detection is needed in a wide field of different applications like optical communication, optical sensing in healthcare and different lifestyle applications. For some applications special device attributes like e.g. flexibility or minimized weight and volume are needed. One highly promising material class for the realization of lightweight flexible photodetectors are 2D materials, especially semiconducting transition metal dichalcogenides (TMDCs). They offer high mechanical flexibility combined with large in plane conductivities and low intrinsic carrier concentrations, enabling low dark currents. However, due to their intrinsically limited light absorption, high responsivities and sensitivities are hard to achieve.
A great way to increase those measures in a photoconductive device is introducing a gain mechanism. For a gain the minority charge carriers are usually trapped, while the other type of charge carriers circle through the channel multiple times, generating multiple carriers by a single incident photon. In addition, in 2D materials, the trapped charges can act as localized floating gate and strongly modulate the conductivity.
Here we propose a combination of a TMDC and microscopically structured 2D perovskite in a heterostructure to achieve a high-responsivity photoconductor exhibiting a gain mechanism. 2D perovskites crystalize as inorganic perovskite layers which are intrinsically separated by insulating intercalated organic cations, forming natural grown multiple quantum wells. As channel material we use MOCVD grown MoS_2 monolayer, in which the MoS_2 layer completely covers the substrate. A liquid phase prepared $(BA)_2PbI_4$ layer on top of MoS_2 is intended to form trap states for minority carriers (holes) in order to achieve a gating mechanism. Electron transfer is blocked due to the organic cations acting as electron blocking layer [1]. To prevent the transferred holes from reaching the contacts, the $(BA)_2PbI_4$ is realized as a non-continuous layer. The optical quality of both material classes is preserved in the heterostructure architecture. We investigated the transfer mechanism by conducting photocurrent spectroscopy on devices with and without $(BA)_2PbI_4$ layer on top of MoS_2 and we demonstrate an increased responsivity in the heterostructure compared to the monolayer MoS_2, which we attribute to photo-gaiting through unidirectional charge carrier funnelling. We show that with an optimized device architecture responsivities up to 20 A/W are possible, which corresponds to a gain of 38.

Nanostructured and Hybrid Materials Enabled Photodetection Technologies for Biomedical Applications Guodong Zhou[1], Yuanzhe Li[1], Chuan Liu[2], Shih-Chi Chen[1] and Ni Zhao[1]; [1]Chinese University of Hong Kong, Hong Kong; [2]Sun Yat-sen University, China

Optical sensors for biomedical applications typically have to operate under very weak light intensity due to strong scattering of photons by tissues of biological objects. To optimize the sensing performance, the photodetector units of the optical sensors should possess high detectivity and mechanical flexibility, thus allowing for efficient collection of photons over curved skin/tissue surfaces and with high signal-to-noise ratio. In this talk, I will introduce our recent efforts in developing photodetector structures with self-amplification mechanisms, which are particularly suitable for weak light biomedical applications. I will first talk about organic bulk heterojunction (BHJ) phototransistors with a tri-layer gate dielectric design to realize high fabrication reproducibility and excellent light bias stability. Such devices enabled us to demonstrate, for the first time, portable functional near-infrared spectroscopy (fNIRS) for brain monitoring. In the second part, I will extend the discussion to the comparison between polymer/fullerene and polymer/non-fullerene BHJ systems and analyze how the recent material development in the organic photovoltaic community can be leveraged to enhance the performance of organic photodetectors. Finally, I will focus on the commonly seen gain – bandwidth trade-off problem of photodetectors and introduce a monolithically integrated photovoltaic transistor (PVT) design to solve this dilemma. The PVT exploiting a lead halide perovskite as the photoactive layer achieved a record high gain – bandwidth product of ~ 10^{11}. The unique advantage of such devices for fNIRS and other weak light detection applications will be discussed.

4:00 PM EL20.06.02
A Tetrathienopyrrole-Based Ladder-Type Donor Polymer for Wavelength-Selective Organic Near-Infrared Cavity Detectors. Kaat Valkeneers[1,2], Quan Liu[1,2], Jochen Vanderspikken[1,2], Sander Smeets[1,2], Koen Vandewal[1,2] and Wouter Maes[1,2]; [1]Hasselt University, Belgium; [2]IMO IMOMEC, Belgium

Incorporation of compact spectroscopic near-infrared (NIR) light detectors into various wearable and handheld devices opens up various new applications, such as on-the-spot medical diagnostics. To extend beyond the detection window of silicon, i.e., past 1000 nm, organic semiconductors are highly attractive because of their tunable absorption. In particular, organic NIR wavelength-selective detectors have been realized by incorporating donor:acceptor thin films, exhibiting weak intermolecular charge-transfer (CT) absorption, into an optical microcavity architecture. In this work, a new ladder-type donor polymer, based on an extended dithienopyrrole unit, is investigated in blends with PC61BM as the acceptor. It is shown that extending the rigid backbone enhances the CT absorption and extends the detection range further into the NIR. This results in a full-width-at-half-maximum of 32-40 nm at wavelengths between 920 and 1450 nm, yielding detectivities in the range of 1.07 × 10^12 to 1.82 × 10^10 Jones, thereby outperforming the state-of-the-art PBTTT-based devices, both in terms of absorption range as well as efficiency.

Defect Healing and Defect Metrology of WSe2 by Gate-Modulated Photoluminescence Doron Naveh; Bar-Ilan University, Israel

Defects in semiconductors have been at the focus of advanced materials research in the past century. Still, it is one of the most vibrant topics in materials research and particularly two-dimensional (2D) semiconductors. Spectroscopy and particularly photoluminescence is one of the main tools for inspecting 2D semiconductors, and in this work we have modulated the spectral measurements with a field effect potential in order to enhance the charge trapping and detrapping from point defects.
By performing gate modulated spectroscopy we determined a lower bound for the intrinsic defect density of CVD grown (and exfoliated WSe_2 samples. We demonstrated that a thin hBN buffer between the device and substrate eliminates hysteresis associated with injected holes.
Additionally, we performed a chemical healing process which replaces the oxygen defects with sulfur via adsorption of thiol molecules in solution and trimming of the carbon chains using rapid thermal treatment. We confirmed the efficiency of process in eliminating vacancy defects by XPS, cryogenic photoluminescence and by gate-modulated photoluminescence.
Lastly, we showed that the thermal detrapping process can be described as an activated reaction with an energy barrier of, which is an estimate for the defect states' electronic binding energy.

5:00 PM EL20.07.01
Boosting the Performance and Stability of All-Polymer Photomultiplication-Type Organic Photodiode: A Synthetic Approach Sangjun Lee[1], Gyeong Seok Lee[2], Mingyun Kang[1], Yeon Hee Ha[2], Yun-Hi Kim[2] and Dae Sung Chung[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Gyeongsang National University, Korea (the Republic of)

We demonstrate how achieving near-ideal spatial isolation of the polymer acceptor through a synthetic method can greatly improve not only the EQE but also the operational stability of an all-polymer photomultiplication-type organic photodiode (PM-OPD). Due to their extraordinarily high external quantum efficiency (EQE, often higher than 10,000%), photomultiplication-type organic photodiodes (PM-OPDs) have recently attracted a lot of attention and can be used as efficient self-amplifying photodiodes for the detection of weak light intensity. The trap-assisted photomultiplication mechanism in the PM-OPD is artificially activated, which sets it apart from traditional photovoltaic devices. The photoactive layer in a typical PM-OPD structure consists of a donor:acceptor (100:1, w:w) ratio to produce spatially segregated acceptor domains. Next, holes are gathered along the percolation pathway following the separation of photogenerated excitons at the donor/acceptor interface, and electrons are captured by the localized acceptor. Here, the Schottky barrier thins at the Al contact due to the trapped electrons, enabling hole injection through tunneling under reverse bias. Additional hole injection is necessary for current continuity; this is triggered by the narrowing of the Schottky barrier once a photogenerated hole is gathered by the counter electrode while the electron is still trapped. In order for PM-OPD to obtain a high EQE, "efficient electron trapping" is therefore a crucial requirement. In terms of effective electron trapping in PM-OPD, poly(3-hexylthiophene) (P3HT) as a donor and [6,6]-phenyl-C71-butyric acid methyl ester (PC71BM) as an acceptor have so far proven to be the most effective active layer combination. We hypothesize that this is mostly because the donor polymer semiconductors have better spatial distribution and localization of tiny molecule acceptors. We propose to address the simple phase separation of active layers with small molecular acceptors mixed with polymer donors during PM-OPD operation despite their high molecular diffusivity and the high operating voltage of a typical PM-OPD. To obtain not only a high EQE but also a high operational stability of PM-OPD, all-polymer bulk heterojunction (BHJ) should be researched in this regard, much like the organic photovoltaic field. Here, a series of naphthalenediimide (NDI)-based copolymers with variously alkylated benzenes are used in a synthetic method to examine the impacts of a polymer acceptor structure on PM-OPD performance. PNDI-Ph, PNDI-Tol, and PNDI-Xy were used as the polymer acceptors to create high-performance all-polymer PM-OPDs. PNDIs were subjected to systematic analyses using UV-vis absorption spectroscopy, density functional theory (DFT) calculations, and two-dimensional grazing-incidence X-ray diffraction (2D-GIXD). These analyses showed that structural features influence not only their optical, electrochemical, and microstructural properties but also their miscibility with donor polymers, and ultimately, the performance of the constructed all-polymer PM-OPD devices. This was demonstrated by effective Schottky barrier height measurement and drift-diffusion simulation. We showed that the crucial factor in the performance of an all-polymer PM-OPD device is spatial isolation of the acceptor domain inside the donor matrix, not high crystallinity or favorable electron transport characteristics. This led to the realization of an optimized PNDI-Xy based PM-OPD, which is greater than any previous all-polymer PM-OPD disclosed, with a high EQE of 770,000% and a high specific detectivity of 3.06 1013 Jones. We also discuss the improved operational stability of all-polymer PM-OPD devices against traditional small-molecule acceptor-based PM-OPD devices.

5:00 PM EL20.07.02
Imaging Carrier Redistribution in MoS_2 Photodetectors with Kelvin Probe Force Microscopy Woongbin Yim[1], Van Tu Nguyen[2] and Ji-Yong Park[1]; [1]Ajou University, Korea (the Republic of); [2]Vietnam Academy of Science and Technology, Viet Nam

The redistribution of charge carriers in monolayer MoS_2 photodetectors upon light illumination is investigated by surface photovoltaic measurements with

Kelvin probe force microscopy (KPFM). The surface potential changes with light illumination are related to the generation, diffusion, and recombination of photo-excited carriers in the photodetectors. It is found that photogenerated holes are trapped at the interface between MoS2 and the substrate, which is responsible for the device's photogating response. The photoresponse mechanism is further elucidated by temporal and spatial measurements of surface potential changes. The temporal response is consistent with the photogating mechanism as a major photoresponse mechanism in MoS2 photodetectors. The intensity-dependent measurements reveal the spatial distribution of defects in the devices. The result shows that KPFM is sensitive enough to probe in-plane as well as vertical charge carrier distribution in atomically thin materials.

5:00 PM EL20.07.04
High Responsivity Organic Phototransistors with Wide Absorption Spectrum for Underwater Optical Wireless Communication Lee Jeongmin and Kang-jun Baeg; Pukyong National University, Korea (the Republic of)

The technology of underwater communications can greatly enhance human's ability to study, monitor, and explore the ocean, as weall as to realize smart aqua farm, defense systems, and drone. Optical communication has the advantage of being able to communicate much faster than acoustic communication mainly used for underwater wireless communication and not being greatly affected by various noises. Therefore, optical communication is selected as an essential technology for underwater wireless communication. However, the unique characteristics under the surface of the sea present grand challenges to the development of wireless communication and networking system, including a harsh enviroment,severe attenuation, and multipath dispersion, and so on. Therefore, the photodetector must show high sensitivity even with weak light, and must be able to absorb light in a wide range. In this study, we aimed to manufacture a high-sensitivity organic phototransistor that showed high performance and high responsivity. Bulk hetero-junction organic phototransistors(OPTs) are fabricated from the profer combination of composite active layers consist of P-type electron donor organic semiconductor and an N-type non-fullerene electron acceptor. The bulk hetero-junction structure was used to maximize the separation efficiency of electrons and holes generated at the interfaces between the donor and the acceptor, indicating higher light response with light irradiation. This shows much higher excition dissociation efficiency than the layer-by-layer structure of the two materials. The bulk hetero-junction structure of the non-fullerene acceptor and the wide band-gap polymer material was well formed through AFM image by adjusting the donor and acceptor ratio. In addition, it was confirmed that the electrical characteristics of the Top-gate Bottom-contact TFT device showed high responsivity(>1A/W) even very weak light of 10μW(wavelength : 450nm~532nm) irradiation using a monochromator. The high sensitivity to light and the wide range of light absorption regions of the donor material showed high responsivity throughout the visible light region. It is expected that this high performance OPTs devices can be widely used like high-speed underwater optical communication fields such as underwater robots and drones, and is also expected to be used such as the marine defense industry and wide-area underwater communication network.

5:00 PM EL20.07.05
Dark Current Prevention and Fast Response of Efficient Injection Barrier Formation in Organic Photodetectors Woongsik Jang[1], Keum Hwan Park[2] and Dong Hwan Wang[1]; [1]Chung-Ang Univ, Korea (the Republic of); [2]Korea Electronics Technology Institute, Korea (the Republic of)

Complementary metal-oxide semiconductors (CMOS) image sensors include of photodetectors in pixel units. Organic photodetectors have in-built advantages in terms of chemically tailorable optical bandgap energy, lightweight components, solution and room temperature processable process via a specific molecular design. Specially, since the organic sensitive layers show excellent mechanical properties, curved and flexible design of photodetector is implemented. Despite many advantages of organic photodetectors, the dark current and noise current can induce degradation of detector performance. However, the source of dark current is unclear which of various contributions, such as electron flow through the junction, shunt leakage, thermionic emission, and tunnelling, are dominant.

In this research, we investigated source of dark current in organic photodetector structure consisting of photosensitive layers, interlayers, and electrodes. First, we introduce a non-fullerene acceptor to photodetector structure by comparing with a fullerene acceptor. The non-fullerene acceptor, eh-IDTBR leads to a high detectivity (1.61×10^{13} cm $Hz^{1/2}$/W) and a faster response time (2.7 μs) than those of fullerene acceptor ($PC_{71}BM$)-based photodetector. The eh-IDTBR can form higher injection barrier related with the excellent dark current suppression. In addition, the photodetector with eh-IDTBR shows excellent stability than the device with fullerene under continuous reverse bias and thermal stress.[1,2] Second, we apply carbon nanotubes as transparent anodic electrode. The carbon nanotubes reveal notable mechanical, optical, and electronic properties, which can realize curved and flexible organic photodetector structure with nearly 100% omnidirectional detection. The carbon nanotube electrode leads to a high detectivity of 2.07×10^{14} cm $Hz^{1/2}$/W, which is 100 times higher than that of device with the indium–tin oxide. The carbon nanotube electrode suppresses dark current to 9.62×10^{-13} A/cm^2 owing to its deep work function and high electron injection barrier. The flexible organic photodetectors are fabricated with the carbon nanotube electrode and operate stably after a bending test of 500 cycles.[2] Consequently, it is demonstrated the implementation of curved and flexible design by introducing the non-fullerene acceptor and the carbon nanotubes. This work sets a milestone in investigation of dark current and photo response for high-performance organic photodetectors.

Photomultiplication Type Organic Photodetectors with Fast Response Speed by Introducing $CsPbI_3$ Perovskite Quantum Dot Interlayer Minyoung Jeong, Se Gyo Han and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Organic photodetectors (OPDs) are promising optical sensor that detects color and brightness by converting light energy into electrical energy. Recently, many researches on photomultiplication (PM) type OPDs have been studied, which have an external quantum efficiency (EQE) over 100%, so that even weak light can be detected. Most of the reported PM type OPDs are operated by a trap-assisted charge carrier tunneling injection mechanism, which require a large external voltage and consequently have relatively slow response time. Here, we fabricated PM type OPDs with fast response and low operating voltages enabled by exploiting the ionic motion of $CsPbI_3$ perovskite quantum dots (QDs). A $CsPbI_3$ QD monolayer is inserted as a PM inducing layer on the photoactive layer composed of PM6:Y6 bulk heterojunction. Our PM type OPD has an EQE over 2000 % and 2.8 μs response time (f_{-3dB} = 125 kHz) at the 3 V, and yields a large EQE-bandwidth product of Hz. It also shows over the 10^{12} Jones of specific detectivity which value is comparable to the specific detectivity of commercial Si photodiode.

5:00 PM EL20.07.08
Tunable Photoluminescence from the Stoichiometry of $AgInS_2$ Nanoparticles with 2D WSe_2/h-BN Hybrid Photodetector Jae-Hyeon Ahn, Somi Lee, Min-Hye Jeong, Derrick Allan Taylor and Jong-Soo Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

The ternary I–III–VI nanoparticles, such as $AgInS_2$, $CuIn_S$, and $CuInS_2$, have been reported the future materials for optoelectronic devices. As one of these nanoparticles, environmentally benign silver indium sulfide nanoparticles (AIS NPs) have a significant absorption coefficient and strong photoluminescence quantum yield (PLQY) with a direct band gap. AIS NPs were synthesized by heating an Ag/In/S solution from 150 °C to 190 °C with various ratios to provide highly tunable photoluminescence (PL). The growth of crystal structure even at low temperatures (~80 °C) and the increased cation exchange of silver by indium at higher temperatures strongly influence the optical properties of the AIS NPs. The correlation between optical properties and synthesis parameters provided insights into the growth and stability of ternary NPs. Attempts to prepare stoichiometric and non-stoichiometric AIS NPs resulted in the tunable absorption and PL behavior as the hot-injection reaction product indicating that cation exchanges with Ag and In ions even when not directly incorporated in the initial reaction mixture. Control of the optical properties of these AIS NPs makes them potentially useful for applications in the photoelectric field, particularly in environmentally friendly electronics and wearable devices. In this study, we demonstrate that the photogenerated carriers formed from AIS NPs layers migrate to the WSe_2 layer and not only improve the photodetector performance but also enhance the photodoping effect of the WSe_2 layer with an ambipolar characteristic by holes injected from n-type AIS NPs. The results explain that the AIS NPs appeared to have high photosensitivity and stability under illumination. The high photosensitivity and stability of the hybrid photodetector indicate potential optoelectronic application.

5:00 PM EL20.07.10
Ab Initio Calculations of the Dielectric Function of $Eu_5In_2Sb_6$ for Light Dark Matter Detection Elizabeth Peterson, Priscila Rosa, Sean M. Thomas, Filip Ronning, Daniele Spier Moreira Alves, Christopher Lane and Jian-Xin Zhu; Los Alamos National Laboratory, United States

More than just answering an elusive question in fundamental physics, successful dark matter (DM) detection capabilities will have wide-ranging significance in the field of rare event detection, which makes this an exciting area of research for developing high-sensitivity detectors. Quantum materials with narrow meV-scale band gaps have recently emerged as promising targets for the detection of light DM in the largely unexplored mass range below MeV. The scattering and absorption rates of light DM with electrons in solid-state materials can be calculated with knowledge of the loss function, or the imaginary part of the inverse complex dielectric function, which in turn would enable prediction of the projected reach of a solid-state detector. To accomplish this from first-principles, it is critical to have accurate energy eigenvalues and the ability to calculate the dielectric function for finite momentum transfer q. Unlike visible light, DM may impart significant momentum transfer in the scattering process.

$Eu_5In_2Sb_6$, a narrow band gap material with complex antiferromagnetic ordering and potentially non-trivial band topology, is currently under investigation for DM detection, but many questions about its electronic structure remain open. Here, we present density functional theory based first-principles calculations of the electronic structure and complex dielectric function of $Eu_5In_2Sb_6$, which address the effects of magnetic ordering, spin-orbit coupling, and GW self-energy corrections. We will discuss the challenges of accurately calculating the electronic structure and dielectric function of narrow band gap quantum materials, such as $Eu_5In_2Sb_6$, and the implications this has for accurate prediction of the projected reach of light DM scattering and absorption.

5:00 PM EL20.07.11
A Novel Inkjet Printing Methodology to Form LiPCDA Radiochromic Films Paria Naderi[1], Rohith Kaiyum[1,2], Christopher W. Schruder[1], David F. Lewis[3], Ozzy Mermut[1], Alexandra Rink[2,4,4] and Gerd Grau[1]; [1]York University, Canada; [2]TECHNA, University Health Network, Canada; [3]RC Film Consulting, United States; [4]University of Toronto, Canada

Background & Objective:
In vivo dosimetry of the delivered radiation in cancer treatment is of utmost importance to ensure quality of care. Radiotherapy inaccuracies occur due to different factors such as organ motion, treatment setup errors, and complex energy delivery mechanisms. Radiochromic materials based on diacetylene monomers are good sensors for dose measurements, with several. advantages over the other dosimeters. Their effective atomic composition is close to that of water, making them suitable for in vivo radiotherapy measurements, and they can be engineered in a range of sensor area sizes and sensitivities. In radiochromic films, the monomers polymerize upon exposure to radiation. 10, 12-pentacosadiynoic acid (PCDA) is a common exemplar owing to its color transition upon polymerization. The films are initially colorless and spectral peaks in the red region of the visible region of the absorbance spectrum confirm the color change corresponding to the dose. The chromatic properties arise from highly conjugated (double-bond and triple-bond) backbones. With the substitution of lithium for hydrogen in the carboxylate group of the monomer, the sensitivity is markedly increased so that doses as low as 0.01 Gy are detectable. Both the sensitivity and morphology of the crystals are dependent on factors such as hydration, temperature, and Li^+ to PCDA molar ratio, with the most sensitive LiPCDA crystal in occurring in hydrated hair-like form.
Construction of commercial radiochromic films has been optimized for handling and use in two-dimensional dose measurements. However, using these materials for fibre-based *in vivo* dosimetry requires alternative deposition methods. Inkjet printing can enable fabricating compact sensor devices and may give more control over film thickness, which would help control the sensitivity of the deposited film. However, printing the most sensitive form of LiPCDA poses challenges due to the large size of the crystals (up to 20 µm in length), and viscosity of the gelatin. The objective of this work is to create LiPCDA crystals using ink-jet printing and separate components.
Materials & Methods:
LiPCDA was inkjet-printed onto a controlled area by separating the solution components: TEA.PCDA, LiCl, and gelatin.. Gelatin works as a binder while allowing lithium atoms to diffuse slowly into the tetraethyl ammonium/PCDA (TEA.PCDA) structure and form LiPCDA monomers, which is critical for proper crystal formation. A wet blade-coated bed of LiCl in gelatin was created. TEA.PCDA was inkjet-printed on the LiCl/gelatin bed using a custom-built inkjet printer and a 100-µm piezoelectric Microfab nozzle. The process was repeated while varying the molar ratio of Li^+ to PCDA. Dry films were then exposed to ionizing radiation using a UV lamp and were characterized by scanning electron microscopy (SEM) and UV-visible microscopy.
Results:

We could consistently form LiPCDA crystals using the above technique. At lower Li^+ to PCDA molar ratios the resulting form is hair-like composed of structures with a very high aspect ratio, and the absorption spectrum has a peak at ~ 630 nm. At higher ratios, the form is plate-like, and the absorption peak is at ~670 nm.

Conclusion:

With this inkjet printing methodology, LiPCDA radiochromic films are deposited while their morphology and absorption peaks are regulated by adding a precise amount of its components. The exact ratio of Li^+ to PCDA can be varied, resulting in films with two distinct forms and absorption peaks upon UV irradiation. This approach can later be applied to printing on the end of a thin fibre sensor.

Visible-Light-Driven Photocathodes Based on Mn-doped Colloidal Quantum Dots Ho Jin[1,2], Heeyoung Jung[1,2], Clement Livache[1] and Victor I. Klimov[1]; [1]Los Alamos National Laboratory, United States; [2]The University of New Mexico, United States

A typical photocathode is based on a photoelectric effect. It describes the ejection of electrons from the surface of a material when the photon energy is greater than the electron 'binding energy'.[1] Therefore, the quantum efficiency (QE) of a photocathode directly depends on the offset between the photon energy and the electron binding energy. For example, GaN photocathodes can reach QE = 70% at 10 eV, but their efficiency drops below 10^{-6} at 2 eV. There is considerable need for photocathodes that can be driven by low-energy photons.

A possible pathway to achieve photoemission with visible and even infrared photons is 'Auger ionization'. In this process, the energy released during electron-hole recombination is transferred to an 'acceptor' electron which thus is excited to a higher-energy state. However, for standard 'direct' Coulomb interactions, the efficiency of this process is low as the uphill Auger transitions are much slower than downhill transitions due to phonon-assisted cooling.[2] Recently, it was shown that the rate of uphill Auger-type energy transfer could be dramatically enhanced using spin-exchange interactions in Mn-doped colloidal quantum dots (CQDs).[3,4]

In the present study, we exploit this enhancement to demonstrate high-efficiency photocathodes driven by visible light. To prepare photocathodes, we deposit Mn-doped CQDs on top of a metal substrate with a thin insulating interlayer. The photocathode is placed into a home-made vacuum chamber and is biased with high voltage. To initiate photoemission, we illuminate the CQD film with 2.4 eV laser pulses. The ejected electrons are detected as a photocurrent which is measured as a function of incident laser power. We observe that the photoemission yield strongly depends on a Fermi-level of the metal substrates and the properties of the insulating layer. We find that both factors affect QEs primarily via the efficiency of re-neutralization of the CQDs following electron ejection. Without re-neutralization, the dot remains in the positively charged state which impedes photoemission due to electron-hole Coulombic attraction. After optimizing the photocathodes, we achieve ~0.2% internal photoemission QE with 2.4-eV visible-light excitation. This is about two orders of magnitude higher than for the undoped CQD films and ca. four orders of magnitude higher than for standard Cu photocathodes. The photocathodes show excellent stability for several hours of continuous operation.

Study of the Efficacy of a Perovskite Sensor-Based Non-Invasive Glucose Monitoring System Using Infrared Light Intensity Correlations�Towards the Development of Measurement Metrics Using Data Analytics David Ryman[1], Edgar Perez-Lopez[2], Saquib Ahmed[3,3] and Sankha Banerjee[1,4]; [1]California State University, Fresno, United States; [2]University of California, Merced, United States; [3]Buffalo State College, United States; [4]University of California, Davis, United States

The current work involves the use of perovskite oxide and halide interfaces toward the development of a non-invasive glucose monitoring device. A proof-of-concept glucose monitoring sensor circuit was embedded in an active polymer matrix with the goal of producing a correlation between the signal detected by a photodiode and a pulsed laser module using near-infrared light. Multiple modalities of the interaction are used for the detection of glucose concentrations in the control solution. The work involves the characterization of material electrical property characterization including the correlations between the heat generation in the LED/laser module, issues related to the dispersed nature of LEDs, precision of the perovskite photodiode module, alignment between the photodiode module and LED, and data from the continuous LED signal as compared to the pulsed laser signal. Correlations between these independent variables including the output voltage and the glucose concentrations are developed using machine learning methods. The active properties of the polymer matrix are also characterized using electrical impedance spectroscopy.

Improved Quality of Perovskite Materials Grown in Space and a Sustainable Business Model for Them Patrick Flowers and Jennifer Ruliffson; Redwire, United States

The push to privatize and commercialize space is gaining momentum in recent years. Indeed, a number of corporations now exist in the space sector who primarily focus on developing commercial products in space for terrestrial use. These space-enabled products take advantage of certain aspects of the space environment, like the lack of gravity, to manufacture higher quality products than could be made terrestrially. A great deal of research is currently underway, using platforms like the International Space Station, to identify viable space-enabled products.

Perovskite radiation detectors are one such class of materials that stand to benefit from space-based manufacturing. While their theoretical performance is quite promising, issues have persisted in real-world testing. Device performance suffers from the presence of dark currents several orders of magnitude higher than expected. This behavior is typically attributed to high defect density in the photosensitive perovskite material. Therefore, the quality of these perovskite materials is the performance limiting factor in radiation detector devices. It is expected that suppression of buoyancy effects during the growth process will significantly increase crystal quality.

One of the biggest challenges to successfully commercializing products manufactured in space is transportation costs. The cost per kilogram to launch materials to space and return them to earth is quite high. The sale price of commercially viable products made in space must be able to absorb these costs. This typically means that space-made products are much more expensive than their terrestrially produced counterparts. It can be difficult to convince consumers that the higher quality of space-made products justifies their higher costs.

Redwire, a leader in space enabled materials, addresses these challenges in a novel way. Redwire is the owner/operator of the Industrial Crystallization Facility (ICF), a payload designed for crystal growth experiments onboard the International Space Station. In this presentation, Redwire discusses the capabilities of ICF, and introduces a new paradigm for commercialization of crystalline space-enabled materials wherein launch costs are drastically diluted. High quality seeds are manufactured in ICF and sold to manufacturers on earth for use in bulk crystal growth processes. The properties of the final bulk crystals are enhanced through the use of high-quality seeds, and the launch cost per kilogram of product produced is diluted by propagating these seeds into bulk crystals on earth. The result is a competitive space-enabled product. This business strategy will be discussed in detail and supported by specific material examples, including perovskites.

5:00 PM EL20.07.15

Suppressing Leakage Current by Interfacial Engineering for Highly Sensitive, Broadband, Self Powered FACsPbI3 Perovskite Photo Detectors

Bhupesh Bhardwaj[1,2], Urvashi Bothra[1], Shivam Singh[1], Sanjay Krishna[2] and Dinesh Kabra[1]; [1]Indian Institute of Technology Bombay, India; [2]The Ohio State University, United States

Photodetectors has important parameters like; leakage current, specific detectivity(D*), linear dynamic range (LDR) and noise equivalent power (NEP) referred as Figure of merit (FOM). Leakage current is considered as one of the most important among them as it plays an important role in determining other FOMs. This study shows the effect of active layer thickness and different interfacial layers in suppression of leakage current which ultimately effects the overall perovskite photodetector (PPDs) performance. Highly sensitive (D* = 10^13 Jones) PPDs fabricated using device structure of ITO/PEDOT: PSS/FACsPbI3 (Eg =1.51 eV; d nm)/ETL/BCP/Ag with noise current < 1 pAHz^-1/2. These PPDs have broadband response from near-ultraviolet to NIR region (300nm-850nm). The performance of the PPDs enhanced for optimal thickness of active layer of d = 600 nm and ETL PC60BM layer thickness of 50 nm. The leakage current of the PPD is further suppressed by replacing ETL PC60BM (in=0.51pAHz^-½) layer by PC70BM (in=0.27pAHz^½) layer. This further improved values of other figure of merits for PPDs. Comparison with published reports on PPDs suggest FACsPbI3 based these PPDs performs significantly better than most of perovskite-based photodetectors reported so far for given spectral range.

5:00 PM EL20.10.01

Vertical 3-Terminal Photonic Sensors Based on Organic Permeable Base Transistor Su-Hyeon Lee[1,2] and Kyung-Geun Lim[1]; [1]Korea Institute of Standards and Science, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Keyword : vertical organic photo transistor, permeable base electrode, pinholes, anodizing

Vertical organic 3-terminal photonic transistors (VOPTs) operate with low dark current, short response time, and a large amplifying current of photonic carrier. The novel VOPT architecture based on vertical organic permeable transistors (OPBTs) vertically forms conducting channel in the nanometer scale by using permeable base electrode, thus can achieve a large amplifying current and a record-breaking switching speed. VOPTs based on OPBT are also suitable for flexible convergence device using organic semiconductors and optoelectronic materials. In this study, We facilitates permeability of OPBTs and achieved advanced VOPTs. The permeable base electrode pinhole morphologies such as density or size were controlled by the electrodes thickness and deposition rate speed. The surface treatment on organic semiconductor layer reduces the interface energy to control the pinhole formation in permeable base electrode. Vertical transistor with permeable base electrode achieves low dark current, high current density and high switching speed. As a result, the response time and detectivity are significantly improved in VOPTs based on OPBT compared to the organic 2-terminal photodiode or the organic phototransistor with lateral channel.

SESSION EL20.08: Next Generation Organic Photodetectors

Organic Small Molecule Based Emerging Applications in Opto Electronic Kyung-Bae Park[1], Sungyoung Yun[1], Younhee Lim[1], Chul-Joon Heo[1], Jeong-Il Park[1], Hiromasa Shibuya[1], Jeoungin Yi[1], Daiki Minami[2], Taejin Choi[1], Hyeong-Ju Kim[1], Feifei Fang[1], Jisoo Shin[1], Hyerim Hong[1], Juhyung Lim[1], Hwijoung Seo[1] and Byoungki Choi[1]; [1]Samsung Electronics, Korea (the Republic of); [2]Samsung Electronics, Co. Ltd., Korea (the Republic of)

Organic conjugated small molecules are freely band gap tuning, low molecular weight to be available thermally deposited allowing semiconductor process, which have served as an important material for electronic devices today. Wavelength selectivity among absorption properties allowed for expansion with organic light sensors. Image sensor companies have showed sensor demonstrations to replace Si-CIS (CMOS Image Sensor), which accounts for most of the global image sensor market, with organic CIS.[1-3] In particular, unlike inorganic materials, organic material have absorption characteristic of selective wavelength, therefore stacked image sensor can be fabricated with especially green selective organic material. The stacked image sensor with green colour absorbed organic semiconductor material have the advantage of increasing sensing area and increasing sensitivity. In addition, it has the advantage of increasing the number of effective pixels compared to the same pixel size, becoming increased the resolution of the image sensor.[4]

Sensors applied with organic materials are expanding not only to image sensors for cameras but also to bio-recognition sensors in display of mobile. Currently, MUT (Micromechanic Ultrasonic Transducer) and optical Si CIS are used as the authorized finger-print sensors in the form of chips underneath the OLED display. If organic light sensors are applied as bio-recognition sensors, certain sensing areas about the size of existing chips (1cm~2cm) can be expanded to all areas of the display. As a result, multi-fingerprint and palm recognition can be possible, which can enhance security functions.[5,6]

Although it is an early development stage in the field of beyond 6G optical wireless communication, Organic photodetectors, such as organic photodiodes (OPD)and organic photovoltaics (OPV), can be manufactured with a large detection area and a high optical gain. Additionally, these can be operated without an external bias voltage, extending their application range. The optional external bias voltage results in increased efficiency and response time. he present work introduces a high-bandwidth OPD device with a bandwidth of 1.4 MHz, which is nearly a factor of ten faster than the fastest previously reported. Additionally, much faster data rates are demonstrated through the convergence of a preequalization and machine learning (ML)-based digital signal processing technique (DSP). The data transfer rates achieved are 30 Mbps (zero bias) and 150 Mbps (−4 V bias).[7]

In order to contribute the expectations of these diverse electronic devices, organic absorbent molecules would become an important material for information and communication electronic devices in the future due to their high absorption wavelength selectivity and specific characteristic of circular dichroism compared to conventional inorganic materials.

Realizing Photostable Detection in Organic Photodiodes with ZnO Electron Transport Layer Theodorus Jonathan Wijaya, Tomoyuki Yokota, Sunghoon Lee, Ryo Okano, Masaki Kobayashi and Takao Someya; The University of Tokyo, Japan

Organic photodiodes (OPDs) have demonstrated distinctive mechanical properties, such as flexibility and stretchability, which allow their implementation as skin-conforming photodetectors. These photodetectors provide highly reliable measurements of the pulse rate and vein images.[1] This reliability owes to the high specific detectivity (10^{11} – 10^{13} Jones) of the recent OPDs. Achieving this high detectivity has been facilitated by the suppression of dark current via the insertion of an electron transport layer (ETL). ZnO is widely used as an ETL, and the OPDs using ZnO ETL also exhibited mechanical and air storage stability of dark current characteristics, thereby enabling their usage as ultra-flexible photodetectors for continuous measurement of bio-signals.[2] However, dark current in OPDs using ZnO ETL increases by several orders of magnitude after light irradiation, thereby notably reducing its specific detectivity.[3] Sol-gel ZnO ETL is widely fabricated with a post-annealing at a maximum of 180 ^{o}C, whereas ZnO ETL requires a minimum temperature of 280 ^{o}C to fully synthesize from its precursor solution. The defective formation of ZnO ETL is considered to cause the photoinduced increase of dark current in the OPDs. Additionally, the effects of the annealing temperature of the ZnO ETL on the photostability of the OPDs have not been thoroughly studied.
In this work, we examined the effects of the annealing temperature of the ZnO ETL on the photostability of the OPDs. We employed the inverted OPD structure of “glass/ITO (70 nm)/ZnO (30 nm)/P3HT:$PC_{61}BM$ (250 nm)/MoO_x (10 nm)/Ag (100 nm)” where the ZnO ETL was synthesized as a sol-gel from the zinc acetate dehydrate precursor and fabricated using standard spin-coating followed by post-coating annealing. We increased the commonly adopted annealing temperature of the ZnO ETL from 180 to 350 ^{o}C and confirmed that the external quantum efficiency (EQE) of the devices was not affected. By this high-temperature annealing, we reduced the increase of dark current after light irradiation by 51 times, thereby suppressing the increase to approximately 2.0 times the original value. Specifically, the dark current density at –2 V in OPDs with ZnO ETL annealed at 180 ^{o}C increased by 100 times from the initial value of $(6.2 \pm 0.21) \times 10^{-8}$ A cm^{-2} to $(6.2 \pm 0.15) \times 10^{-6}$ A cm^{-2} after irradiation. On the contrary, those with ZnO ETL annealed at 350 ^{o}C increased by only 2.0 times from the initial value of $(1.9 \pm 0.19) \times 10^{-6}$ A cm^{-2} to $(3.9 \pm 0.39) \times 10^{-6}$ A cm^{-2}. By suppressing this increase in dark current, the stability of the specific detectivity of the OPDs based on the shot noise was improved by 7.1 times. Specifically, the OPDs with ZnO ETL annealed at 180 ^{o}C showed an initial specific detectivity of 2.8×10^{12} Jones but deteriorate to 2.8×10^{11} Jones after light irradiation, thereby only exhibiting 10 % retention. On the other hand, the OPDs with ZnO ETL annealed at 350 ^{o}C showed an initial detectivity of 5.9×10^{11} Jones and held the detectivity to a sufficiently high value of 4.1×10^{11} Jones, thus showing a 70 % retention. Additionally, we demonstrated that UV is the cause of this photo-instability by showing that the increase in dark current after irradiation with wavelengths longer than 380 nm was lower than and at most 17.6 % of those observed after sub-370-nm irradiations. Furthermore, A better quality of the ZnO ETL was identified to be crucial to improve the photostability of OPDs using ZnO ETL, as confirmed through XPS and XRD measurements. These results underscore the importance of choosing a defect-free ETL synthesis or material to realize next-generation photostable OPDs.

Organic Photovoltaics for Simultaneous Harvesting of Power and Data in Optical Wireless Communications Iman Tavakkolnia[1], Lethy K. Jagadamma[2], Rui Bian[3], Pavlos P. Manousiadis[2], Stefan Videv[1], Graham A. Turnbull[2], Harald Haas[1] and Ifor Samuel[2]; [1]University of Strathclyde, United Kingdom; [2]University of St. Andrews, United Kingdom; [3]pureLiFi, United Kingdom

The rapid growth of internet-connected devices presents two important challenges. The first is how will they all communicate? The second is how will they be powered? Optical communications can contribute to the solution, particularly in the form of “Li-Fi” in which indoor lighting is modulated to transmit information and supplement Wi-Fi. Organic semiconductors have been shown to be useful as both transmitters and receivers for Li-Fi. In this talk we will show how organic photovoltaics can be used as receivers that simultaneously receive data and generate power. Furthermore by using small arrays useful data rates of up to 363 megabits/second have been achieved.

SESSION EL20.09: Hybrid Photodetectors
Session Chairs: F. Pelayo García de Arquer and Jinsong Huang
Thursday Afternoon, April 13, 2023

1:30 PM *EL20.09.01
Photoconducting Devices with Specific Attributes based on 2D Metal-Halide Perovskites Franziska E. Muckel; University Duisburg-Essen, Germany

Flexible optoelectronic devices offer possibilities for a wide range of novel applications. Especially flexible photodetectors enable functionalities like optical communication or optical sensing for healthcare, lifestyle applications or optical cross-linking systems in the “Internet of Things”. These diverse applications areas result in a variety of required device attributes. One device architecture which is noncomplex, easy-to-fabricate and allows facile tuning of the device functionalities are photoconducting devices. Herein the conductivity of a semiconducting channel is mediated through illumination. By engineering the optical properties as well as the structure of the semiconductor, the functionality of the photodetectors can be altered to meet requirements for specific applications, e.g., defined color ranges, high sensitivities or low noise signals.
Promising materials for flexible photoconducting devices are two dimensional (2D) metal-halide perovskites, which can be fabricated at room temperature out of solution and crystalize as naturally grown multi quantum wells in the form of inorganic semiconducting layers separated by bilayers of electrically insulating organic cations. 2D perovskites exhibit mechanical flexibility combined with the optical and electronic properties of a 2D system.
Here we show, that the excitonic absorption feature of 2D perovskite $(BA)_2PbI_4$ can be utilized to realize filter-free narrow-bandgap photodetectors. We report the fabrication of a lateral, wavelength selective photodetector based on n=1 $(BA)_2PbI_4$, exhibiting a well defined peak in the photocurrent spectrum at 520 nm, which can be related to the excitonic absorption. We achieve colour-selective light detection with a responsivity of 0.750 mA/W and a specific detectivity up to 4.7×10^{10} J. On-Off ratios are larger than 10^4.

Aiming for high-responsive device, we combine a non-continued layer of $(BA)_2PbI_4$ 2D perovskite with a transition metal dichalcogenide as conducting channel to achieve a 2D/2D hetero-photodetector with a gain mechanism. In this architecture, the two-dimensional $(BA)_2PbI_4$ layer traps the minority charge carriers (holes), enabling the electrons to circulate through the transition metal dichalcogenide channel multiple times. Using optimized channel length, we achieve responsivities of up to 20 A/W, which corresponds to a gain of 38.

2:00 PM EL20.09.02

Multidimensional Perovskites for High Detectivity Photodiodes Alessandro Caiazzo[1], Riccardo Ollearo[1], Junyu Li[1], Marco Fattori[1], Albert van Breemen[2], Martijn M. Wienk[1], Gerwin Gelinck[1] and Rene A. Janssen[1]; [1]TU Eindhoven, Netherlands; [2]Holst Centre, Netherlands

Low-dimensional perovskites attract increasing interest due to tunable optoelectronic properties and high stability. In our work, we show that perovskite thin films with a vertical gradient in dimensionality result in graded electronic bandgap structures that are ideal for photodiode applications. Positioning low-dimensional, vertically-oriented perovskite phases at the interface with the electron blocking layer increases the activation energy for thermal charge generation and thereby effectively lowers the dark current density to a record-low value of 5×10^{-9} mA cm^{-2} without compromising responsivity, resulting in a noise-current-based specific detectivity exceeding 7×10^{12} Jones at 600 nm. These multidimensional perovskite photodiodes show promising air stability and a dynamic range over ten orders of magnitude, and thus represent a new generation of high-performance low-cost photodiodes.

2:15 PM EL20.09.03

Near Infrared Photomuliplication-Mode Perovskite Photodetectors with Various Organic Passive Electron transport Layers Seyeong Song; Ulsan National Institute of Science and Technology, Korea (the Republic of)

The pace of advancement and increasing stability and perfomances have provided the possibility for perovskite materials to be commercialized in a variety of applications, including solar cells(PVs), light emitting diodes(LEDs) and photodetectors(PDs). As a next-generation semicondutor, advantages of perovskite-based applications are light-weight, solution-processible, tunable bandgap and easy device fabrication.

Two-terminal perovskite photodetectors (PePDs) with p-i-n structure generally have configuration of transparent conducting oxide /hole transport layer/Perovskite/passive-electron transport layer/electrode, wherein the passive electron transport film is mostly organic semiconductors such as C60 and PCBM. The p-i-n structural PePDs are challenging due to several issues. First, photodetectors work in applied negative bias. However, perovskite optoelectronics are quite unstable at strong reverse bias, since the halide migration can occur into organic layers and work as a p-type dopant in the organic layer, leading to accelerate perovskite separation and the device degradation. Secondly, perovskite and the device are significantly affected by following passive-electron transport layers (P-ETLs) and their technical processing methods. To obtain the high quality of perovskite grains and high performance of the device, efficient energy level alignment and interfacial compact between the perovskite layer and organic P-ETL are required.

We investigate NIR perovskite photodetectors by introducing Tin (Sn) with lead (Pb) halide perovskite, which can detect by 1000 nm. We fabricated p-i-n architecture photomultiplication (PM) mode photodetectors devices and compared device performance of different four type organic P-ETLs including C60, PCBM, non-fullerene acceptor (NFA) and Donor polymer:NFA bulk heterojunction (BHJ) blend films to figure out the photomultiplication phenomenon from breakdown of diode at weak reverse voltage. Since the non-fullerene organic material has interesting molecular stacking changes with and without a chloronaphthalene (CN) processing additive, PePDs based on NFA P-ETL with CN also studied in this work. Furthermore, our NIR PM-mode PePDs were fabricated on flexible substrates and applied to photoplethysmogram (PPG) medical monitoring device application. We believe that these comparison of PePDs performance for passive electron transporting organic layers as well as utilizing the photomultiplication present high potential and possibility in the future sensors industrial market.

2:30 PM *EL20.09.04

Develop Photodetection Toolbox for Ultraviolet Photodetectors Qiuming Yu; Cornell University, United States

Photodetectors have a wide variety of applications in modern technology, and new ones are constantly arising. Therefore, it is highly desirable to be able to design devices quickly and cheaply**.** Traditional design process starts with making decisions and optimizing them to meet application needs. Inverse design offers promising approach for expediting design by starting with application criteria**.** Either way, the toolbox must be thoroughly understood and generalizable to different materials, spectral ranges, and devices**.** In this talk, I will cover our recent work on the development of photodetection toolbox to achieve sensitive, low driving-force, narrowband UV photodetectors. Our UV photodetectors are based on the photodiode structure. To enhance the photodetection sensitivity or to increase the specific detectivity of UV photodetectors, we vary the ratio of p-type conjugated polymer to n-type fullerene electron acceptor and control the photoactive layer morphology to achieve electron-trapping induced band bending and charge injection, and hence inducing the photomultiplication effect to gain the external quantum efficiency much higher than unit. Similar strategy can be applied to the polymer-ZnO nanoparticle nanocomposite system to utilize trapped electrons in ZnO nanoparticles to realize the photomultiplication effect. Additionally, by controlling and utilizing charge generation, separation and transport in the hole-only photodiode devices, we can achieve narrowband, photomultiplication, low-driving force UV photodetectors. Another strategy to achieve the narrowband photodetection is through the charge-collection narrowing by on purpose increase the thickness of the active layer to allow the selective detection of photons at the long-wavelength absorption edge. Considering the function of manipulating light absorption and confining electromagnetic energy into the nanoscale volume, we integrate aluminum plasmonic nanostructures into the photodiode to manipulate the UV photodetection. We can ether place the aluminum nanohole arrays on top of a glass substrate to replace the ITO layer as a transparent electrode or embed aluminum nano-hemisphere arrays into the top aluminum electrode to achieve the bias-dependent photoresponses and enhanced photosensitivity. All these developments are aided by the finite-difference time domain (FDTD) simulations, transfer matrix method (TMM) optical calculations, and experimental studies to understand the charge generation, separation, transport, and recombination in the devices. Our work highlights the importance to correlate the device internal physical processes to the design inputs and the sensing capabilities in order to achieve the desired photodetection.

SESSION EL21.01: Topological and Quantum Materials
Session Chairs: Iuliana Radu and Subhash Shinde
Tuesday Morning, April 11, 2023
Moscone West, Level 3, Room 3011

10:30 AM *EL21.01.01
Topological Thin Films for Electron and Quantum Device Applications Susanne Stemmer, Arman Rashidi, Alexander Lygo, Simon Munyan, Binghao Guo and Robert Kealhofer; University of California, Santa Barbara, United States

Over the past decade, the unique properties of topological quantum matter have generated huge excitement in the materials physics community. At the same time, solid state electronic devices are increasingly limited by current generations of electronic materials. New materials are also needed for enabling quantum information technologies. In this talk, we will discuss progress in heterostructure fabrication and measurements of high-quality thin films of topological semimetals, such as cadmium arsenide. We show that these thin films are highly tunable and describe measurements that can identify different topological states and their unique electronic properties. We also discuss their potential applications in electronic and quantum devices and show results, including from field effect transistors, hot electron transistors, and superconducting hybrid devices.

11:00 AM *EL21.01.02
Opportunities of Topological Semimetals as Novel Material for Computing. Experimental Transport Studies and Device Implementations Heinz Schmid[1], Alan Molinari[1], Federico Balduini[1], Lorenzo Rocchino[1], Igor Kladaric[1], Marilyne Sousa[1], Holt P. Bui[2], Marco Hopstaken[2], Christian Lavoie[2], Rafal Wawrzynczak[3], Marcus Schmidt[3], Claudia Felser[3], Vicky Suess[3], Mathieu Luisier[4], Selma Franca[5], Sergueï Tchoumakov[5], Simone Fratini[5], Johannes Gooth[3], Adolfo Grushin[5], Cezar Zota[1] and Bernd Gotsmann[1]; [1]IBM Research, Europe, Switzerland; [2]IBM Research, US, United States; [3]Max Planck Institute for Chemical Physics of Solids, Germany; [4]ETH Zürich, Switzerland; [5]Institute Neel, France

Topological materials have attracted strong interest in recent years due to their exotic transport properties set by non-trivial band structures. These materials were shown to exhibit exceptional properties such as high electron mobilities and large magnetoresistance, for example. Among the many identified semimetal compounds, we will focus on our recent work involving the two semimetals NbP and CoSi to highlight promising applications. NbP was selected due to the high magnetoresistance and demonstrated to modulate a current in a transistor configuration with very high efficiency. The chiral semimetal cobalt monosilicide (CoSi) has been identified as a prototype for topological materials exhibiting extremely long Fermi arc surface states. However, CoxSi1-x is stable at various stoichiometries and defect densities, the effect of which on topological and normal magnetotransport is little explored. We show a study of CoSi samples ranging from single crystals, via textured polycrystalline films to amorphous thin films grown using molecular beam epitaxy. Exhaustive structural characterization (STEM, AFM, XRD) and chemical analysis (XPS, SIMS, EDS, RBS) enable a detailed correlation to transport as a function of magnetic field, temperature and dimension. This enables us to relate anomalous Hall effects, quantum anomalies in longitudinal and transverse magnetoresistance, quantum oscillations, as well as unconventional size-scaling of conductivity down to the nm-range to structure and composition. As expected from the band structure, transport in CoSi is remarkable in many aspects.

11:30 AM EL21.01.03
Unconventional Resistivity Scaling in Topological Semimetal CoSi Hsin Lin[1], Shang-Wei Lien[2], Ion Garate[3], Utkarsh Bajpai[4], Cheng-Yi Huang[5], Chuang-Han Hsu[1], Yi-Hsin Tu[2], Nicholas Lanzillo[4], Arun Bansil[5], Tay-Rong Chang[2], Gengchiau Liang[6] and Ching-Tzu Chen[7]; [1]Academia Sinica, Taiwan; [2]National Cheng Kung University, Taiwan; [3]Université de Sherbrooke, Canada; [4]IBM Research, United States; [5]Northeastern University, United States; [6]National University of Singapore, Singapore; [7]IBM T.J. Watson Research Center, United States

Nontrivial band topologies in semimetals lead to robust surface states that can contribute dominantly to the total conduction. This may result in reduced resistivity with decreasing feature size contrary to conventional metals, which may highly impact the semiconductor industry. Here we study the resistivity scaling of a representative topological semimetal CoSi using realistic band structures and Green's function methods. We show that there exists a critical thickness d_c dividing different scaling trends. Above d_c, when the defect density is low such that surface conduction dominates, resistivity reduces with decreasing thickness; when the defect density is high such that bulk conduction dominates, resistivity increases as in conventional metals. Below d_c, the persistent remnants of the surface states give rise to decreasing resistivity down to the ultrathin limit, unlike in topological insulators. The observed CoSi scaling can apply to broad classes of topological semimetals, providing guidelines for materials screening and engineering. Our study shows that topological semimetals bear the potential of overcoming the resistivity scaling challenges in back-end-of-line interconnect applications.

11:45 AM EL21.01.04

Exploring Topological Semimetals for Highly Scaled Interconnects Beyond Copper Ching-Tzu Chen[1], Christian Lavoie[1], Nicholas Lanzillo[1], Utkarsh Bajpai[1], Oki Gunawan[1], Asir Intisar Khan[1,2], John Bruley[1], Guy Cohen[1], Vesna Stanic[1], Hsin Lin[3], Ion Garate[4], Gengchiau Liang[5], Shang-Wei Lien[6], Yi-Hsin Tu[5,6], Sushant Kumar[7], Ravishankar Sundararaman[7], Peter Kerns[1], Teodor Todorov[1], Nathan Marchack[1], Jean Jordan-Sweet[1], Cheng-Yi Huang[8], Arun Bansil[6] and Tay-Rong Chang[6]; [1]IBM T.J. Watson Research Ctr, United States; [2]Stanford University, United States; [3]Academia Sinica, Taiwan; [4]Université de Sherbrooke, Canada; [5]National University of Singapore, Singapore; [6]National Cheng Kung University, Taiwan; [7]Rensselaer Polytechnic Institute, United States; [8]Northeastern University, United States

Due to surface and disorder scattering, resistivity of metal wires keeps increasing with shrinking dimensions, which severely impacts the performance of highly scaled integrated circuits. Here we explore a new class of materials – topological semimetals – as an alternative solution. We demonstrate that, via conduction of the protected surface electronic states, resistivity in topological semimetals reduces with decreasing feature size down to ~ nm scale, even in the presence of defects and grain-boundary scattering. This novel scaling behavior sharply contrasts that of conventional metals, such as Cu, and topological insulators. In this talk, we will first present first-principles-based electrical transport calculations of a Si-CMOS compatible topological semimetal CoSi and a prototypical Weyl semimetal NbAs. We will then report experimental evidence for surface-dominated transport in CoSi thin films, showing resistivity below that of the bulk single-crystals. Our proof-of-principle study demonstrates the potential of topological semimetal as beyond Cu interconnect materials.

First Fire-free Selectors Based on Te in an Insulating SiO_x Matrix Isha Datye, Sam Vaziri, Elia Ambrosi, Cheng-Hsien Wu, Jeremy Guy, H.S. Philip Wong and Xinyu Bao; TSMC, United States

Low voltage and off-current selectors are necessary for low power operation of high density one selector-one resistor (1S1R) arrays for 3D-compatible embedded memory. Chalcogenide-based materials are promising for selectors because they have low off-current, high on-current, good endurance, and decent thermal stability [1-2]. However, they typically require a one-time high voltage pulse or "first fire" operation larger than the threshold voltage, which is incompatible with low voltage memory requirements [1-2]. In addition, these selectors often suffer from threshold voltage drift, leading to a narrower memory window [1,3-4].
In this work, we show that selectors based on SiO_xTe_y, a simple and stable material system, are very promising due to their low voltage and off-current, as well as fast switching speed and good endurance [5]. We present selectors with threshold voltage (V_{th}) down to ~1.2 V and off-current of ~3 nA at 0.5 V. By modifying the tellurium to oxygen atomic ratio and film thickness with different deposition conditions, we show tunable first fire voltage (V_{FF}) and V_{th} and also achieve first fire-free selectors ($V_{FF} = V_{th}$). We investigate the switching mechanism of these devices by studying their dependence on bottom electrode size and temperature. We also measure V_{th} drift and find the drift slope to be lower than many values reported in literature for other chalcogenide-based materials.
After one year stored in air, the threshold voltage and leakage current of the uncapped selectors remains fairly stable, indicating good long-term stability. These selectors also have decent thermal stability and exhibit a novel recovery mechanism after annealing. Finally, we demonstrate fast switching speed (~3 ns) and good endurance (>10^{11} cycles), making these selectors very promising for integration with nonvolatile memory.

2:00 PM EL21.02.02
V_3O_5 as a Functional Oxide for Metal-Oxide-Metal Relaxation Oscillators Sujan K. Das[1], Sanjoy Nandi[1], Camilo V. Marquez[2], Armando Rua[2], Mutsunori Uenuma[3], Etienne Puyoo[4], David Albertini[4], Nicolas Baboux[4], Teng Lu[1], Yun Liu[1], Shimul K. Nath[1], Thomas Ratcliff[1], Tobias Haeger[5], Thomas Riedl[5], Ralf Heiderhoff[5] and Robert G. Elliman[1]; [1]Australian National University, Australia; [2]University of Puerto Rico, Puerto Rico; [3]Nara Institute of Science and Technology (NAIST), Japan; [4]Université Lyon, France; [5]University of Wuppertal, Germany

Oscillatory neural networks (ONN) provide a powerful platform for analogue computation and are of increasing interest as accelerators in artificial intelligence hardware, where they provide an energy efficient means of undertaking simple repetitive functions such as calculating dot products, convolutions, applying nonlinearities, and recognising or matching simple patterns. However, it is generally recognised that oscillator-arrays based on conventional CMOS circuits are too large and energy consuming to enable integration into the dense, low-power arrays required for solving complex, real-world problems. This has motivated the development of a broad range of alternative nanoscale oscillators based on phase-change materials, spintronics (i.e. spin-torque and spin-Hall oscillators), Nano-Electro-Mechanical systems (NEMS), superconducting devices (e.g. Josephson junctions), and negative-resistance oscillators. Among these contenders, relaxation oscillators based on negative differential resistance (NDR) in metal-oxide-metal (MOM) devices are of particular interest due to their simple structure, scalability and energy efficiency.

Devices based on VO_2 have been shown to exhibit reliable, energy-efficient operation due to the abrupt conductivity change resulting from its low-temperature (i.e. T_c= 340 K) insulator-metal transition (IMT). However, this temperature is too low for applications requiring large scale integration. A possible alternative is V_3O_5, a Magneli phase of vanadium-oxide, that undergoes an IMT at a temperature of ~420 K.

This study examines the structural, electrical and thermal properties of sputter deposited V_3O_5 films and their application as relaxation oscillators for neuromorphic computing applications. The former includes temperature dependent measurements of the electrical conductivity, thermal conductivity and lattice structure, while the latter are based on lateral (in-plane) metal-oxide-metal device structures. These devices are shown to exhibit electroforming-free volatile threshold switching and negative differential resistance (NDR) with stable (<3% variation) cycle-to-cycle operation. The physical mechanisms underpinning these characteristics are investigated using a combination of electrical measurements, in-situ thermal imaging and device modelling. This shows that the conduction in lateral metal-oxide-metal device structures is confined to a narrow filamentary path due to self-confinement of the current distribution, and that NDR response is initiated at temperatures well below the IMT temperature where it is dominated by the temperature dependence of the insulating phase; and provides new insights into the NDR mechanism. Finally, we investigate the dynamics of individual and coupled V_3O_5-based relaxation oscillators. These results establish V_3O_5 as an interesting new functional material for the development of solid-state neurons for neuromorphic computing.

2:15 PM EL21.02.03
A 2T Neuromorphic Device based on Metal Oxide Transistor with Self-Assembled Monolayer for High-Precision Artificial Intelligence Seongmin Park, Suwon Seong and Yoonyoung Chung; Pohang University of Science and Technology, Korea (the Republic of)

State-of-the-art artificial intelligence computation consumes tremendous power and requires a long time during training as the separated memory and processor of the current computing architecture hinder data transfer. To deal with this problem, researchers have developed a neuromorphic device that can operate weight storage, update, and matrix-vector multiplication near memory. However, conventional neuromorphic devices based on new non-volatile memories suffer from abrupt conductance shifts and poor uniformity, which degrade the accuracy of the neural network.
This work presents a neuromorphic device with excellent synaptic characteristics by utilizing two InGaZnO (IGZO) transistors. The proposed neuromorphic device consists of a read transistor and a write transistor, where the write transistor's source/drain electrode is connected to the gate electrode of the read transistor so that the write transistor precisely adjusts the gate potential of the read transistor. The ideal synaptic properties were achieved by balancing the gate electrode charging/discharging speed and the transconductance change rate to have an identical programming slope within the operation range. The ultra-low leakage current of IGZO prevents the charge leakage from the read transistor gate through the IGZO channel, preventing the programmed weights change during training. Furthermore, with the large-area uniformity of the IGZO transistor, the programming slopes of the proposed neuromorphic device exhibited a very low standard deviation to the average ratio of less than 3%. For large array compatibility, we regulate the output current of the neuromorphic device by introducing an alkyl-phosphonic acid self-assembled monolayer (SAM) between IGZO and source/drain to form an ultra-thin energy barrier. A phosphonic acid SAM with 12 alkyl chains reduced the current of the IGZO transistor by 30%. In addition, the energy barrier formed by the SAM suppressed leakage current during retention, maintaining the stored weights after 300 seconds from programming. With these strategies, the 2T neuromorphic device exhibited outstanding synaptic characteristics within a low conductance range, which is suitable for a high-precision artificial intelligence system.

2:30 PM EL21.02.04
Dual Synaptic Weights Emulation for Artificial Nociceptors and Energy Efficient Neuromorphic Computing Kuan-Ting Chen, Shi-Cheng Mao, Bo-Ru Lai, Ingann Chen and Jen-Sue Chen; National Cheng Kung University, Taiwan

With the increased diverse sets of information in the era of big data, neuromorphic computation is the crucial technology for advancing the data-processing speed. Electronic devices, which mimic the neural activity with good energy efficiency, will be the key for successful hardware implementation of neuromorphic computing. Inspired by the charge transfer mechanism, the capacitance-based synaptic weight is highly advantageous for the energy efficient neuromorphic computing because the capacitor consumes lower power dissipation and is also free of sneak-path issue due to the voltage-expressed transmitted signal. Furthermore, three-terminal artificial synapse is also realized with the same stacking layer to emulate the synaptic functions and features the concurrent signal transmitting-and-learning.
To be compatible with CMOS process technology, here we fabricated a metal oxide-based synaptic capacitor on p^+-Si substrate. The indium tin oxide (ITO) and tantalum oxide (TaO_x) are stacked as the capacitive device. In parallel, the same stacking layers are employed as the channel layer (ITO) and high-k electrolyte dielectric layer (TaO_x), respectively, to form the synaptic transistor. The relocation of oxygen vacancies in TaO_x under the application and removal of the electric field contributes to the analog transistor conductance and capacitance modulation. Consequently, multiple synaptic functions, including pair-pulse facilitation, high-pass filter, long-term plasticity as well as the transition from short-term memory to long-term memory, can be successfully demonstrated in both transistor and capacitive device. On top of that, it is unparalleled to mimic the nociceptive behavior through capacitance as the response. To confirm the feasibility of both electronics, the dataset classification simulation is carried out by incorporating the results of weight updating process to the CrossSim software. A robust stability of cycle-to-cycle variation is found in capacitive device (0.9%) and transistor (1.8%), causing a high recognition accuracy of 95% and 84%, respectively. It indicates that the ITO/TaO_x-based capacitor shows superior performance and has promising potential in the hardware capacitive neural network.

2:45 PM EL21.02.05
Highly Linear Weight Update of IGZO Photonic-Synaptic Transistors by Controlling Oxygen Vacancy for Neuromorphic Computing Taewon Seo, Juyoung Yun and Yoonyoung Chung; Pohang University of Science and Technology, Korea (the Republic of)

Optoelectronic synaptic devices attract considerable attention for neuromorphic computing due to high bandwidth and ultrafast signal transmission. IGZO-based photonic transistors have been studied for synaptic devices because of their CMOS compatibility, ultralow-off current, and transparency. They exhibit excellent synaptic functions, such as paired-pulse facilitation (PPF), photonic potentiation/electrical depression, and transition from short-term plasticity to long-term plasticity. However, IGZO-based synaptic transistors have a problem with the weight update nonlinearity, the most critical factor for the accuracy of artificial neural network (ANN).
Now, we suggest a method to improve the linearity of potentiation/depression plasticity of IGZO TFTs by controlling oxygen vacancies in IGZO thin film. First, a substrate bias was applied during IGZO deposition to remove unstable oxygen bonds. Second, nitrogen plasma was followed to fill the generated oxygen vacancies. X-ray photoelectron spectroscopy (XPS) data showed oxygen vacancies effectively reduced by 35 % using our approach. As oxygen vacancies in IGZO thin film decreased, the recovery behavior of excitatory post-synaptic current (EPSC) was almost improved by two times. PPF measurement, indicating an increase in the post-synaptic response by the second stimulation compared to the first stimulation, exhibited that oxygen vacancy-controlled IGZO-based synaptic transistors perfectly mimic biological synapses. Especially, the nonlinearity factor of weight update was dramatically improved from 1.55 to 0.41, which is a sufficient level for highly accurate ANN. By solving the problem of the weight update nonlinearity in IGZO-based synaptic transistor, which has a benefit in CMOS compatibility and ultralow off current, our approach enables the implementation of ultra-low-power and high-performance artificial optoelectronic circuits for neuromorphic computing.

Phase Change Materials for Energy Efficient Computing Jayakanth Ravichandran; University of Southern California, United States

Neuromorphic computing has gained a lot of interest for the potential to significantly improve the energy efficiency of computing associative tasks. The two key components of this computing methodology focus on mimicking the operation of neurons and synapses. Phase change materials that undergo abrupt volatile and non-volatile changes in conductivity as a function of temperature, and applied electric field are prime candidates to mimic neurons and synapses in an energy and footprint efficient manner. In this talk, I will introduce a novel phase change material, $BaTiS_3$, which belongs to a broader class of phase change materials known as quasi-1D hexagonal chalcogenides. This material demonstrates two properties can be leveraged to mimic simplified forms of neuronal and synaptic processes. At room temperature, the material shows resistive switching behavior, presumably the switching of the ferrielectric dipole moments. Below ~180 K, the material shows voltage tunable and stable changes in conductivity, suggesting the possibility of multistep memory characteristics. The former can be leveraged to mimic low power neurons, and the later as tunable synaptic weights in a neuromorphic computing architecture. This work setups up the potential for novel materials research in creating functionalities necessary to achieve neuromorphic hardware.

4:00 PM EL21.03.02
Electrochemical Random-Access Memory for Low-Energy Computing Yiyang Li; University of Michigan, United States

Data-intensive processes like artificial intelligence consume substantial amounts of energy. In-memory computing using analog resistive memory can be substantially more efficient that conventional digital approaches. In this work, we discuss our work on developing the electrochemical random-access memory (ECRAM) as the "synapse" for in-memory computing. ECRAM is a type of resistive memory that electrochemically shuttles oxygen vacancy point defects between two transition metal oxides through a solid electrolyte. Its electrochemical process yields ~1V switching and very low currents. Importantly, ECRAM can also attain high-temperature operation and the potential for several years of retention time at 85C.

4:15 PM EL21.03.04
Confined Conducting Filaments in HfO_2-Based Resistive Random Access Memory by Al_2O_3 Nanodome Shaped Arrays (NDSAs) via Glancing Angle Deposition Technology Toward Neuromorphic Computing Ying-Chun Shen and Yu-Lun Chueh; National Tsing Hua University, Taiwan

Resistive random access memory (RRAM) is vital to neuromorphic computing applications. However, filamentary RRAM cells are affected by transitions from abrupt switching to analog switching. In this study, we develop Al_2O_3 nanodome shaped arrays (NDSAs) by glancing angle deposition technology (GLAD) to geometrically confine the conducting filaments (CFs), for which conducting atomic force microscopy (C-AFM) was performed to analyze positions and dimensions of filaments. For the Pt/HfO_2/75 % Al_2O_3 NDSAs/TiN device, the dimension of the CFs can be restricted to 10-12 nm, whereas for the Pt/HfO_2/TiN device, the CFs were formed with the dimension of ~50 nm. Moreover, Pt/HfO_2/75 % Al_2O_3 NDSAs/TiN device exhibited synaptic features with more linear potentiation and depression, demonstrating the analog switching. The controllable coverages of Al_2O_3 NDSAs render the geometric design more promising as a memristor for future applications in neuromorphic computing.

4:30 PM EL21.03.05
Artificial Intelligence Tools and One Dimensional Electronic Materials for Future Computer Chips and Energy Harvesting Shuang Tang, Alexandria Burger and Andrew Lemieszewski; State University of New York Polytechnic Institute, United States

The trend of novel electronic materials development is transitting from thin film based chips into smaller scaled materials systems, such as nanowires, nanotubes and nanoribbons. Among many materials candidates, bismuth antimony nanowires are promising ultra-high mobility, low power consumption, and a great richness of electronic phases and band-edge configurations. When the alloy materials system is made into nanowires, the symmetry between the three L-points and the six H-points in the first Brillouin zone can be either kept or broken, providing much larger flexibility than silicon in chip and circuit designs.

Semi-metals, direct-band-gap semiconductors, and indirect-band-gap semiconductors can coexist in one system. One bottle-neck in materials design is accurately predicting the electronic phase and the band structure. For bulk and pure materials, the band structure can be well described using first principle calculations. However, when the materials are alloyed and made into nanostructures, the calculational time that is needed may not be feasible with the current computer power. In the recent decade, pattern recognition techniques and other artificial intelegence have been widely developed and utilized in research of condensed matter physics and materials science.

In this present work, we will use multiple pattern recognition tools, including the support vectors, the trees, the bagging method, as well as the artificial neural networks, to realize the accurate and convenient describing of electronic phases and band structure of bismuth antimony nanowires. Different values of alloy composition, growth orientation, and wire diameter will be discusses. We will also discuss how the size of training pool will affect the predicting accuracy when different tools are used.

SESSION EL21.04: Energy-Efficient Computing I

8:00 AM *EL21.04.01

Hybrid 2D/CMOS Microchips for Memristive Technologies Mario Lanza; King Abdullah University of Science and Technology, Saudi Arabia

Two-dimensional layered materials (2D-LMs) materials have outstanding physical, chemical and thermal properties that make them attractive for the fabrication of solid-state micro/nano-electronic devices and circuits. However, synthesizing high-quality 2D-LMs at the wafer scale is difficult, and integrating them in semiconductor production lines brings associated multiple challenges. Nevertheless, in the past few years substantial progress has been achieved and leading companies like TSMC, Samsung and IMEC have started to work more intensively on the fabrication of devices using 2D-LMs. In this talk, I will discuss the state-of-the-art on micro/nano-electronic devices made (entirely or partially) of 2D-LMs, the most sophisticated circuits ever constructed, and the fabrication of CMOS/2D hybrid microchips. I will put special emphasis on devices that employ hexagonal boron nitride, the only 2D-LM with an enough high band gap to be employed as dielectric. I will also discuss the main technological challenges to face in the next years and provide some recommendations on how to solve them.

8:30 AM *EL21.04.02
Two-dimensional Materials for Energy-Efficient Computing Saptarshi Das; The Pennsylvania State University, United States

In this talk, I will focus on describing a new paradigm of devices based on two-dimensional (2D) materials for sensing, computing, storage, and hardware security inspired by various insect, avian, and mammalian brains. We exploit unique electronic and optoelectronic properties of layered 2D materials to design high-performance, ultra-low-power, artificially intelligent, and inherently secure solid-state devices inspired by natural intelligence. For example, we have mimicked auditory information processing in barn owls (*Nature Communications*, *10, 3450, 2019*), collision avoidance by locusts (*Nature Electronics, 3, 646–655, 2020*), and subthreshold signal detection by paddlefish and cricket using stochastic resonance (*Nature Communications, 2020*). We have also mimicked probabilistic computing in animal brains using low-power Gaussian synapses (*Nature Communications*, *10, 4199, 2019*), and memristive graphene synapses (*Nature Communications, 11, 5474, 2020*) and realized biomimetic devices that can emulate neurotransmitter release in chemical synapses (*ACS Nano*, *11, 3, 2017)* and neural encoding in afferent neurons *(Nature Communications, 12, 2143, 2021)*. We have also made thes devices secure through SAT-attack-resistant hardware obfuscation using camouflaged 2D heterostructures (*ACS Nano, 15, 2, 2021*) and by realizing machine learning resilient and reconfigurable physically unclonable functions (*Nature Electronics 4, 364-374, 2021*).

9:00 AM *EL21.04.03
Opportunities and Limitations of Low-Dimensional Channel Materials for Energy Efficient Logic Computing Sheng-Kai Su[1], Edward Chen[1], Gregory Pitner[2], Terry Y.T. Hung[1], Meng-Zhan Li[1], Chao-Ching Cheng[1], H.S. Philip Wong[2,3] and Iuliana P. Radu[1]; [1]Taiwan Semiconductor Manufacturing Company (TSMC), Taiwan; [2]Taiwan Semiconductor Manufacturing Company, United States; [3]Stanford University, United States

Applications of abundant-data computing demand low energy consumption and concomitant high speed of the electronic systems. Increasing transistor density by continuous lateral dimension scaling is still the backbone to meeting such demand [1]. However, short-channel effect increases power consumption. Challenges to scaling Si technology and capabilities of heterogenous integration has stimulated interest in low dimensional materials (LDMs) such as two-dimensional (2D) transition metal dichalcogenides (TMDs) and 1D carbon nanotubes (CNTs) [2].

In this presentation, we explore the potential and challenges of using low dimensional materials as channel for extremely scaled transistors in advanced logic technology nodes. Based on the current hardware data, a multi-physics model to describe the ON current, sources of leakage which limit OFF current of MOSFETs with LDMs is used to project the scaling viability below 45 nm contacted-gate pitch (CGP). The scaling viability are analyzed by separately considering effects from shrinking the gate length, contact length, and extension length for different device architectures.

2D TMDs are high carrier density but low velocity channel materials [3], thus multiple Nanosheets are desired to increase effective device width. CNTs with high mobility and injection velocity in a ~1 nm semiconducting cylinder are especially promising for ON-performance with low power applied voltage V_{DD}. To preserve the advantage of high intrinsic current, low contact resistance and low leakage current are required for energy efficient computing.

Unlike contact to bulk Si, the LDM underneath the contact is atomically thin, therefore maintaining pristine LDM surface during metal deposition becomes even more important than for bulk material. Similarly, doping techniques used in Si technology, which could cause surface damage, might not be suitable for LDM. Uniquely for CNT with long mean free path, the effect of metal coupling could dominate over diffusion limited “current crowding” effect from low mobility materials such as Si or TMDs. The effect of metal coupling to reproduce the experimental observations is important, and we investigate its impact on contact resistance and leakage current [4]. To achieve a good balance between reducing access resistance and leakage, we compare different doping techniques and analyze the challenges of dielectric doping.

It is revealed that contact with strong enough metal coupling and high extension doping generated from dielectrics is desired for short contact length. For CNTs, a trade-off between extension length and contact length reductions to compromise among ON and OFF currents is analyzed from the perspective of CGP scaling. For 2D TMDs with large bandgap, leakage is not a limitation for CGP scaling with a Nanosheet architecture. However, low contact resistance for energy efficient CMOS with large bandgap channel material is challenged. Efforts in advancing contact, doping, and material uniformity (e.g., CNT’s diameter and pitch) for LDMs are necessary before an energy efficient logic technology can be developed.

Heterogeneous Integration of HfO_2 Resistive Random Access Memories on 2D van der Waals Materials Regina Dittmann[1], Urska Trstenjak[1], Niclas Schmidt[1], Kalle Goss[1], Alexander Gutsche[1], Konstantin Rushchanskii[2] and Silvia Karthäuser[1]; [1]PGI-7, Germany; [2]PGI 1, Germany

In order to make use of the functionality of different material classes for future energy-efficient computing, we investigated to co-integrate HfO_2-based redox-based random access memory (ReRAM) on 2D van-der Waals materials. For that purpose, we investigated the van der Waals epitaxy of HfO_2 thin films and nanoislands on graphene and on highly oriented pyrolytic graphite (HOPG), respectively. We identified a growth window for the pulsed laser deposition of HfO_2 that preserves the graphene transferred to thermally oxidized Si wafers. This enabled us to successfully fabricate HfO_2/Ti ReRAM cells with graphene bottom electrode. Based on the growth process developed for HfO_2 thin films, we deposited HfO_2 nanoislands on HOPG. The electronic and structural properties of these well separated, crystalline HfO_2 nanoislands are investigated by scanning probe methods. The topography reveals homogeneously formed HfO_2 nanoislands with areas down to 7 nm^2 and a thickness of one unit cell. They exhibit several in-gap states in addition to the bulk band gap, implying bulk properties of these ultra-scaled memristive objects. Nanocrystals with a diameter of 2.7−4.5 Å are identified next to carbon vacancies in the topmost HOPG layer, indicating that carbon is incorporated into the islands at early nucleation stages. The comparison of the theoretically determined lowest-energy clusters and electronic states with the experimental results allows us to identify the structure of the most relevant HfO_2 sub-nanometer crystals formed during the first nucleation steps and to assign the in-gap states to the observed carbon incorporation during heterogeneous

integration [1].

10:30 AM *EL21.05.01
Magnetoelectrics at the Nanoscale for Spintronic Computing Applications Florin Ciubotaru[1], Anaïs Guerenneur[1,2], Daniele Narducci[1,2], Moritz Geilen[3], Frederic Vanderveken[1,2], Federica Luciano[1,2], Xiangyu Wu[1], Fanfan Meng[1,2], Sebastien Couet[1], Burkard Hillebrands[3], Inge Asselberghs[1], Sorin Cotofana[4], Iuliana Radu[1], Gouri Sankar Kar[1], Philipp Pirro[3] and Christoph Adelmann[1]; [1]imec, Belgium; [2]KU Leuven, Belgium; [3]TU Kaiserslautern, Germany; [4]TU Delft, Netherlands

Among the technologies that could potentially represent a paradigm shift with respect to CMOS technology, spintronic computation presents several advantages to achieve area and power reduction. The possibility to perform complex logic functions as majority gates, and the non-volatility of the magnetic materials could provide new functionalities to circuit designers for various applications. However, no concept for a complete magnetic/spintronic computing system exists. Therefore, the spintronic devices need to be complemented by CMOS in a hybrid spintronic–CMOS system. A major limitation for the realization of a such hybrid technology is the lack of scalable and energy efficient transducers capable to couple efficiently the electric and magnetic domains.
Current spintronic device concepts are often based on the control of the magnetization by currents, for example via magnetic Oersted fields, or using spin-transfer/spin-orbit torque. However, such approaches are typically not energy-efficient, therefore it would be desirable to control the magnetization by electric fields instead. In the last years, magnetoelectricity has seen a renaissance due to material development, as well as technological and theoretical progress. The promise of magnetoelectricity is a large improvement in energy efficiency compared to electric currents. Furthermore, downscaling the device dimensions would allow for an increase of the magnetoelectric coupling coefficients since they are electric field dependent. Therefore, magnetoelectricity may become an enabling factor for novel low-energy computing devices.
Magnetoelectric composite materials consisting of piezoelectric and magnetostrictive films are one of the most promising approaches for the magnetization control by electric fields. In this case, the magnetoelectric coupling occurs via strain: applying an electric field (voltage) across the structure generates strain in piezoelectric layer, which is then transferred to the adjacent magnetostrictive layer. This leads to an effective magnetic field that can rotate the magnetization of the system, or to generate spin waves if radio-frequency voltages are applied. An analogous inverse effect also exists which links changes in the magnetization direction to strain, and consequently, to electric fields.
For microelectronic applications, magnetoelectric heterostructures must be integrated into devices and miniaturized to the nanoscale. Here we will present an overview of our recent work on magnetoelectric systems and discuss materials, device design and fabrication, as well as the impact of different effects (device geometry, scaling, etc.) on the voltage coupling coefficients. We show that the device downscaling can lead to an enormous increase in the voltage response of magnetoelectric structures. Moreover, many applications require fast responses of the devices with targeted operational frequencies in the GHz range. We will present sub-micron scaled magnetoelectric spin-wave transducers and demonstrate their operation. COMSOL Multiphysics and micromagnetic MuMax software packages were further used to study the mechanical response and the magnetic behaviour, respectively, of different magnetoelectric devices, both in the DC and RF regimes. The magnetoelastic fields were estimated as well. Finally, we discuss the potential of magnetoelectric transducers for spin-wave computing applications.

Galfenol (FeGa) Electrode Material for Magnetic Tunnel Junctions for Low Power Nano-Computing Suyogya Karki[1], Jaesuk Kwon[1], Joe Davies[2], Supriyo Bandyopadhyay[3] and Jean A. Incorvia[1]; [1]The University of Texas at Austin, United States; [2]NVE Corporation, United States; [3]Virginia Commonwealth University, United States

Magnetic materials are an exciting material class for computing due to competitive write speeds, back-end-of-the-line compatibility, radiation hardness, non-volatility, and energy efficiency. Magnetic tunnel junctions (MTJs) are basic building blocks for magnetic devices used in spin transfer torque-magnetic random-access memory (STT-MRAM), magnetic logic-in-memory and neuromorphic computing applications. MTJs are trilayer structures in which a thin insulating layer is sandwiched between two ferromagnetic (FM) layers, where the relative magnetization of the ferromagnetic electrodes (fixed and free layers) can encode either a higher (bit 1) or a lower (bit 0) resistance state. In this work we introduce a 4-layer MTJ where the free layer is a magnetic bilayer comprising exchange-coupled Galfenol (FeGa) and CoFeB layers. The MTJ is fabricated on a PMN-PT piezoelectric substrate that is strained with a voltage to reorient the magnetization of the strongly magnetostrictive FeGa layer, which also rotates the magnetization of the CoFeB layer owing to exchange coupling. This modulates the MTJ resistance. Like highly energy-efficient VCMA switching, straintronic switching is also extremely energy-efficient. Thin films of FeGa are sputter deposited using an AJA sputter system, and X-ray diffraction measurements are used to confirm the preferred (110) crystal orientation of the films. The MTJ stack was grown with layers Si (Substrate)| SiO_2 (100)| Ta (5) | FeGa (5) |CoFeB (4) | MgO (2) | CoFeB (6) |Ta (5) | Ru (5); numbers are in nm and the stack was post annealed at 270 °C for 1 hr. The in-plane hysteresis loop of the stack shows two distinct switches of the top CoFeB and the bottom CoFeB|FeGa layers. In collaboration with NVE corporation, CIPT measurements show promising on/off ratio of the stack. The successful demonstration of piezoelectric/FeGa MTJs is a promising result for high-efficiency magnetic write performance in nanomagnetic computing.

Chiral Non-Collinear Spin Textures in Nominally Centrosymmetric Magnets Rana Saha, Holger L. Meyerheim and Stuart S. Parkin; Max Planck Institute of Microstructure Physics, Germany

One of the major topics in spintronics today is to study magnetic materials in which neighboring magnetic moments are neither parallel nor anti-parallel but are rather non-collinear and can thereby form complex, topological, spin textures. Perhaps the most extensively studied of these is the skyrmion; this is a tiny magnetic nano-object with a chiral magnetic boundary and which is typically circular in shape. A prerequisite for the formation of such chiral nano-objects is that the parent material has a structure that is non-centrosymmetric. What has surprised the spintronics community recently is the observation of skyrmions in several materials that are centrosymmetric. Here we show evidence for skyrmions in a member of the family of van der Waals materials, $CrTe_2$, that is nominally centrosymmetric. The symmetry of the structure of this 2D compound is lowered in a very special manner by self-intercalation of Cr atoms within the so-called van der Waals gaps between tri-layers of Te-Cr-Te from which the structure is formed. Furthermore, we show from detailed, high-resolution, x-ray structure analysis that the self-intercalated Cr atoms form an ordered 3D superstructure that hasn't previously been observed in any known van der Waals compound. The superstructure gives rise to two inequivalent van der Waals gaps, both partially filled by Cr atoms but in different ways. As a consequence, neighboring Te-Cr-Te tri-layers experience an asymmetric environment involving relaxations of the atomic positions along the vertical *c*-axis, thereby reducing the crystal symmetry from Pm to P3m1, the latter being non-centrosymmetric. The latter has a C_{3v} point group that is compatible with the appearance of Néel-type skyrmions, which were directly imaged using state-of-the-art Lorentz transmission electron microscopy over a wide temperature range.

In the context of a growing demand for data-intensive applications, the ubiquitous von Neumann computer architecture suffers from throughput limitations due to the memory transfer rates lagging behind CPU speed, as well as from the energy cost of information shuttling. This can be mitigated by innovative architectures and nanodevices enabling a higher degree of locality in information processing, blurring the lines between memory and compute functions, extending beyond the boundaries of purely charge-based and/or conventional Boolean logic paradigms. We hereby review some recent advances in the field of spintronics-based component research and illustrate how they may, at different levels, contribute to the advent of more energy-efficient computing systems.
Trade-offs between programming energy, speed and endurance prevent most emerging NVM technologies from moving up the memory hierarchy. Among the more promising candidates, Spin Transfer Torque (STT) MRAM is considered as a denser and low power alternative to SRAM for last-level cache. Yet, sub-10ns programming conditions would be hardly compatible with standard lifetime requirements, due to the need for large currents across the MgO-based magnetic tunnel junction (MTJ). Leveraging the strong spin-orbit coupling in some heavy metals or topological insulators, Spin Orbit Torque (SOT) MRAM enables switching the state stored in the MTJ by flowing a charge current near it rather than through it, effectively decoupling the read and write paths. While nanosecond switching and high (>1^{e}12 cycles) endurance are reachable, future work on material and interface engineering directed at charge-spin conversion efficiency and selective addressing should help further density improvements.
From the standpoint of digital logic, a number of spin-based components using spin-polarized transport have emerged over the years as possible beyond CMOS substitutes combining low switching energy, built-in non-volatility and possibly higher logic density. In many cases however, these benefits could be overshadowed by circuit overhead for either signal amplification (maintaining logic levels for long range transfer, cascading, fanout) or error correction. In an effort to alleviate this issue, some recent proposals combine transduction mechanisms to couple hybrid spintronic devices through charge-driven interconnects. Two such examples are the MESO (MagnetoElectric Spin Orbit) and FESO (FerroElectric Spin Orbit) devices. The latter relies on the property that the direction of a charge current generated by spin-orbit coupling may be controlled by the polarization of a ferroelectric. This effect was demonstrated in two classes of materials: two-Dimensional Electron Gases (2DEG) appearing at oxides surfaces or interfaces, and ferroelectric Rashba semiconductors, opening intriguing perspectives towards the integration of non-volatile logic with aJ switching energy and manageable error rates.
Finally, other more disruptive computational paradigms can not only cope with, but benefit from noise or stochasticity. Some learning or inference algorithms were initially inspired by the physics of interconnected non-linear elements probabilistically evolving towards collective states minimizing their energy. Conversely, hardware networks of directly interacting components could be designed to naturally execute those energy-based computing algorithms with a much reduced need for data movement or auxiliary functions. For instance the so-called Ising machines, particularly suitable as combinatorial optimization solvers, can take many shapes and forms such as dynamical systems of coupled oscillators or networks of binary stochastic neurons. The latter are functionally equivalent to random telegraph signal generators with tunable dwell times, thus distinguishing superparamagnetic MTJs and their unique property of thermally-induced switching as elegantly simple and efficient building blocks.

Ultrathin Ferroelectric Films for Next Generation Logic and Memory Applications Sayeef Salahuddin; University of California, Berkeley, United States

Compared to archetypical perovskites, fluorite HfO_2 based ferroelectric materials are process-compatible with advanced CMOS transistors. As a result, they promise to bring ferroelectric technologies into wide-spread applications. At the same time, ferroelectricity in these materials is also different. In conventional perovskites, the polarization becomes weaker as the thickness is decreased due to 'size effects'. Balking this conventional trend, our recent work has shown that ferroelectricity in HfO_2-like fluorite films in fact enhances as the thickness goes down. The ferroelectricity can be demonstrated even in a 0.5 nm thick film, which is just one cell! In this presentation I shall discuss these results. In addition, I shall also discuss Negative Capacitance transistors with just 18A thick ferroelectric material- the same thickness of high- dielectric used in today's advanced transistors. I shall further present ferroelectric field effect transistors with thin ferroelectric gate oxide. These results demonstrate substantial potentia for ultrathin, integrated ferroelectric materials for next generation logic and memory devices.

Manipulation of Antiferromagnetism in Freestanding BiFeO$_3$ Membranes Siang Hong Tan[1], Xuheng Diao[1], Chang-Yang Kuo[1], Qi-Wu Shi[2], Shang-Jui Chiu[3] and Yen-Lin Huang[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Sichuan University, China; [3]National Synchrotron Radiation Research Center, Taiwan

BiFeO$_3$ (BFO) is arguably the only material that exhibits two order of parameters above room temperature with a Curie temperature of 1100 K and Nèel temperature of 653 K. Moreover, these two order parameters, ferroelectricity, and antiferromagnetism, are strongly coupled, known as magnetoelectric coupling. Owing to this magnetoelectric coupling, extremely low switching energy to alter the states of orderings can be realized by reducing the ferroelectric switching voltage as well as the ferroelectric polarization of BFO. Recent studies show that by optimizing the chemical composition of BFO, size scaling, and the removal of substrate clamping effect, the BFO ferroelectric switching voltage can be well improved[1]. Freestanding BFO membranes exhibit ~30% coercive voltage reduction and ~50% switching speed enhancement[2]. However, the methods to obtain large area of freestanding BFO films are still challenging as well as the understanding of its antiferromagnetic ordering. Here, we synthesized high-quality BFO epitaxial thin films on SrTiO$_3$ single crystal substrates by pulsed laser deposition, and optimized the freestanding process of BFO membranes by introducing various oxide buffer layers, such as SrRuO$_3$, and SrTiO$_3$, in between the sacrificing layer, La$_{0.7}$Sr$_{0.3}$MnO$_3$, and the BFO layer. Moreover, we used XMLD (X-ray Magnetic Linear Dichroism) to characterize the antiferromagnetic orientations of BFO membranes, we found that the antiferromagnetic axis of BFO is lifted from in-plane toward out-of-plane direction ~<112>$_C$, where C is noted as a cubic system, after the substrate was removed. We also notice that the tilting angle of the antiferromagnetic axis of BFO is strongly influenced by the thickness of the BFO layer and the buffer layer and that implies the antiferromagnetic axis degree of freedom is tunable by altering the elastic boundary conditions. Finally, we further conduct magnetotransport measurements to confirm whether the efficiency of magnetoelectric coupling can be improved after the freestanding process.

Hafnium-based oxide thin films, such as Hf0.5Zr0.5O2 (HZO) have great potential for nanoscale device applications with their low power, high-speed, non-volatility, and compatibility with modern CMOS technology. However, fabricating a stable phase of HZO thin films exhibiting robust ferroelectricity is not an easy task. The major mechanism to stabilize the ferroelectric phase of HZO is to utilize an epitaxial strain imposed from a lattice-mismatched substrate. This limits the process window for ferroelectric HZO thin films. In addition to strain effect, the chemical composition of the bottom electrodes and the oxygen vacancies level will also affect the polar stability of the HZO thin-film. How to stabilize the polar phase of HZO and explore the boundary of ferroelectricity of HZO thin films are the central challenges for HZO-related devices and applications.
In this study, we demonstrate the robust ferroelectricity of HZO epitaxial thin films in three different types of phases, which are pure polar-O-phase(orthorhombic), pure nonpolar-M-phase (monoclinic) and mixed O and M-phases. We then obtain HZO films without substrates (freestanding) at a millimeter scale. Through XRR (X-ray Reflectivity) and XRD fringes, we found that the nonpolar-M-phase started to appear from the polar-O-phase after the thickness is thicker than 7 nm resulting in the suppression of ferroelectric polarization. Finally, we discuss the phase competition between the polar O-phase and non-polar M-phase with and without the substrate clamping effect. Our approach can provide fundamental insights into the limit of ferroelectric switching of HZO-based films and the role substrate plays in polar phase stabilization.

Ferroelectric Field-Effect Transistors—Logic Compatibility and Microstructure Asif I. Khan; Georgia Institute of Technology, United States

Over the last decade, the discovery of ferroelectricity in fluorite-structured binary oxides, namely HfO$_2$ and its alloyed variant, led to resurgent interests into ferroelectric devices for embedded memory applications [1,2]. In this talk, we will highlight recent advancements in ferroelectric field-effect transistors (FEFETs). First, we will present our work on reducing write voltage in FEFETs down to logic compatible levels for embedded memory applications by engineering the interfacial oxide layer and gate metal electrodes. Next, we will highlight our efforts on understanding and controlling the microstructure of ferroelectric layer in FEFET gate stacks to address the variability challenge, using multi-scale transmission electron microscopy including in-situ, electrical biasing approaches [3]. The talk will end with an outlook for FEFETs for different domains, such as embedded, storage class and storage applications.

The research is supported by the National Science Foundation, the Defense Advanced Research Program Agency (DARPA), the Applications and Systems-Driven Center for Energy-Efficient Integrated Nano Technologies (ASCENT), one of six centers in the Joint University Microelectronics Program (JUMP), a SRC program sponsored by the DARPA, and an Intel Rising Star award.

BEOL-Compatible Diamond Growth for Thermal Management for Efficient Computing Srabanti Chowdhury; Stanford University, United States

Efficient computation demands of 21st -century applications far exceed the capabilities of today's systems. Traditional approaches are stalling to serve the roadmap for next generation computation where large efficiency and speed improvements are needed. These challenges get worse as 2D scaling of transistors hits fundamental limits: the 'miniaturization wall'. The next leap in performance and energy efficiency requires the next surge in integration. Ultra-dense on-chip 3D integration with inter-layer via pitch of 100 nm are the chips especially for abundant-data applications (e.g., AI, analytics, graphs) [1]. 3D chip integration can be realized in more than one way: monolithically, or heterogeneously. Regardless of the device technology proposed, fast compute units must operate in 3D layers to overcome the memory wall and the miniaturization wall. This criterion, alone, imposes an enormous thermal challenge and demands solutions beyond the traditional ones such as improved heat sinks outside the chip or thermal vias within the chip. It should be noted that thermal vias including dummy thermal vias are not enough and comes with significant electrical performance penalty. Novel approaches like spreading the heat inside chips using thermally conductive material are necessary. Our current demonstration of thin-film diamond grown at BEOL compatible temperatures (400oC) positions itself as a potential solution for heat spreading [2]. Diamond is perhaps the most attractive candidate for high thermal conductivity (>2000W/m/K in its single crystalline form). Due to its large bandgap (5.47 eV) and highly insulating nature, diamond is excellent for integration with device where electrical behavior should be preserved, and phonon bottleneck is removed. At the device level, Joule heating and resulting high temperature in the channel due to the increased power density results in performance degradation and premature failure. Diamond integration near the hot spot can spread the heat by increasing the heat transfer coefficient. Diamond is mostly grown at high temperatures (700-1000°C), which limits its integration with many semiconductor technologies. We have recently demonstrated a high-quality 400°C-diamond by modifying the gas chemistry at different nucleation stages, with a sharp sp3 Raman peak (FWHM≈6.5 cm-1) and high phase purity (97.1%), like 700°C-diamond (>98%) is demonstrated. An average grain size of 650 nm with a thickness of 790 nm corresponding to an anisotropy ratio of 1.21 at 400°C close to the best-reported of 1.12 at 700°C is achieved. This near-isotropic diamond exhibits a relatively high thermal conductivity of ~300 W/m/K and a thermal boundary resistance as small as only 5 m2K/GW on BEOL compatible dielectric layers.

3:45 PM *EL21.07.02
Ferroelectric Tunnel Junctions for Compute-in-Memory Saima Siddiqui, Chia-Ching Lin, Sou-Chi Chang, Nazila Haratipour, Bernal G. Alpizar, Sarah Atanasov, Jason Peck, Tristan Tronic, Anandi Roy, Dominique Adams, I-Cheng Tung, Adedapo Oni, John Richards, Matthew Metz and Uygar Avci; Intel Corporation, United States

Energy efficient computing is one of the major challenges of today's semiconductor industries. To support the artificial intelligence (AI), the computation is more memory centric and requires frequent access beyond the cache. Data shuttling (known as "memory wall") is identified as the main bottleneck for such implementation of AI with the current von Neumann architecture. Modifying the computing system is a potential option for circumventing this bottleneck, and among different computing architectures, computing inside memory (CIM) is the most energy-efficient for eliminating the memory wall of state-of-the-art processors. It has been shown that the non-volatile memories in the cross-point architecture can potentially improve the system efficiency significantly from below one to a few hundred TOPS/W. Different non-volatile memories including resistive random-access memory (RRAM), phase change memory (PCM), magnetic RAM and ferroelectric (FE) based devices i.e., FeRAM, FeFET and tunnel junctions (FTJs) are actively studied for efficient non-volatile memory and CIM applications. Recently, HfxZr1-xO2 (HZO) FE materials have attracted significant attention as embedded non-volatile memory (eNVM) due to thickness scalability and CMOS back-end-of-line (BEOL) compatibility [1]. In particular, it has been shown experimentally that cache-level memory with much lower refresh power can be enabled by HZO-based low-voltage FeRAM with endurance of >1012 cycles for high-speed read/write operations at elevated temperatures [2-4]. These devices are designed based on the fundamental understanding from multi-domain phase-field device-level framework for polycrystalline HZO FE and anti-ferroelectric (AFE) thin films [5]. However, compared to memory options in conventional memory hierarchy, the performance requirements such as write and read energies, endurance as well as retention are different in CIM applications, and thus device technology co-optimization is critical. Among different resistive memory devices, FTJs are of particular interest as they offer the lowest switching energy, high endurance and retention.
FTJ is a two-terminal device with a ferroelectric layer sandwiched between two electrodes. The resistance of this device changes based on the polarization of the FE layer. Depending on either complete or partial switching of the FE layer, FTJ can be used for digital or analog CIM. In this work, we will demonstrate HZO- based planar FTJs with very low write current (3.8×101 A/cm2) and voltage (1 V) by material and structural engineering. Here, we optimize FTJs' performance for read ON current (10-3 A/cm2 at 0.3V), ON/OFF ratio (7), endurance (>1010), retention (100 s), and nonlinearity (0.01/-2.4) with 16 individual states for analog CIM. The write pulse of our planar FTJs can be scaled down to 250 ns without degradation in performance, and it is expected that polarization switching can be as fast as 2 ns in scaled dimensions [2]. There are still challenges (i.e., low read current, ON/OFF ratio, retention etc.), which need to be solved for the technological implementations of FTJs for CIM. However, we show that a high accuracy of ~90% is achieved in recognizing digits from Modified National Institute of Standards and Technology (MNIST) dataset by our FTJs with both binary and multiple states [6]. These results highlight that HZO-based FTJs are promising for high performance non-volatile memories and electrical synapses. [1] T. Room Temperature Low-Energy Resistive Switching in Flux-Grown Quasi-1D Chalcogenide $BaTiS_3$ Huandong Chen and Jayakanth Ravichandran; University of Southern California, United States

Low energy switching in the form of either volatile or non-volatile is critical in achieving energy efficient computing. Asymmetric resistive switching between two different phases or states are typically achieved by phase transitions such as metal-to-insulator transitions, but the energy consumption to overcome the barrier is usually substantial. On the other hand, resistive switching between bistable states such as ferroelectric switching is much more energy efficient. $BaTiS_3$ is a 'ferroelectric-like' semiconductor that features large Ti out-of-plane displacements at room temperature like $BaTiO_3$ and is promising in demonstrating such bistable switching. Here, we show the non-volatile resistive switching over one order of magnitude achieved below 0.5 V from a bulk $BaTiS_3$ device with the channel size ~ 100 µm in plane, and the status can be reset via a reverse scan. The scaling of the switching voltage with respect to channel sizes is also discussed. Our study identifies $BaTiS_3$ as a unique ferroelectric semiconducting system that achieves low energy resistive switching at room temperature.

Low-Voltage Control of Synaptic Behavior in WO_3 based Two Terminal Protonic Devices Satya Prakash Pati, Satoshi Hamasuna and Takeaki Yajima; Kyushu University, Japan

Artificial neuromorphic devices are capable of processing information by consuming much lower power in comparison with traditional computing technology [1]. Among diverse synaptic structure, conductance switching in metal/insulator/metal type memristive devices are promising candidate owing to their analogous working mode. Most of the conventional memristive devices are filamentary type, where electrical control of migration of ions (Li^+, Na^+, K^+, Ca^{2+} etc.) or oxygen defects result in the change of conductance state. Due to the formation of random filament and relatively low diffusion capability of such ions, these devices suffer from poor reproducibility and relatively high voltage. To circumvent the issue, proton (H^+) could be a promising candidate owing to its lowest ionic size and high diffusability [2]. Moreover, most of the conventional protonic devices reported are 3-terminal type having an insulating barrier layer, and therefore, their operating voltage is still over 1-Volt range [3-6]. To avoid the issues of power consumption, further reduction of operating voltage should be verified. In this concern, we propose a 2-terminal protonic device in the stacked geometry without any barrier layer. Herein, we have demonstrated the ultra-low voltage switching of conductance state in a 2-terminal protonic device comprising an amorphous WO_3 layer as proton conductor.
Heterostructure of Si (Sub.)/SiO_2 (500nm)/Ti (3nm)/Pt (30nm)/WO_3 (120nm)/Pd (30nm) was fabricated by using e-beam evaporation and pulsed laser deposition. Microstructural measurements confirm the fabricated WO_3 layer is amorphous and atomically flat having roughness ≈1.5nm. Additionally, WO_3 film is highly porous having density 5.76 gm/cm^3 which is less than its bulk value 7.16 gm/cm^3. In order to define the chemical potential of hydrogen, proton transport measurements were performed under Ar+H_2(5%) mixture gas with a fixed pressure 6.86 kPa. To understand the hydrogen incorporation process in WO_3, conductance was measured as a function of H_2 exposer time with different applied voltages. The result exhibits a gradual increase in conductance up to 3-order of magnitude over time, and the increasing rate is dramatically changed as a function of the applied voltage. At negative voltages, WO_3 still maintains its semiconducting properties while application of positive voltages induces a large change from semiconducting to conducting state. The results clearly indicate the hydrogen incorporation is strongly affected by the applied voltage, where the H-ions from Pd reservoir progressively drifts into WO_3 channel through the electrochemical reactions in the two-terminal device. We also investigated the conductance change from the viewpoint of hydrogen chemical potential rather than the applied voltage, where H_2 pressure was varied while the applied voltage was kept constant at 0.5 volt. The result shows that the device response time is largely delayed by decreasing the H_2 pressure, corroborating the underlying electrochemical reaction. Based on these thorough understandings, the reversible conductance change as like potentiation and depression in biological synapses was achieved by switching the polarity of input voltage from -0.2V to +0.2V. Despite this low operation voltage, we have obtained the conductance modulation of 22% at room temperature. These findings will pave a way to the design of low power consumption protonic neuromorphic devices.

Low-Operation Voltage Non-Volatile Memory Characteristics with Oxide-Semiconductor Thin-Film Transistors Through Interaction Between Oxide Semiconductor Channel and Gate Oxide Jimin Han, Boyoung Jeong and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

The demand on high-density and high-performance non-volatile memories is increasing for emerging data-centric applications. Among various non-volatile memories, a memory adopting a single metal-oxide-semiconductor field-effect transistor (1-MOSFET) operates with the modulation of the channel conductance to store the information. Mechanism of the channel conductance modulation is largely dependent on the properties of gate stack composed of semiconductor channel and gate oxide layers. One of the most representative 1-MOSFET memory to modulate the channel conductance is a floating-gate (charge-storage node or charge-trap layer) memory cell comprising a flash memory. This cell performs memory functions in the charge-storage-based way that the threshold voltage is shifted as a result of electrical charging of the floating gate (or charge-storage node) by tunneling of electrons through tunneling oxide upon voltage application to the control gate. Alternative way includes the use of a non-charge-storage-based (or ion-based) memory operation by tuning gate stack properties such as the changes in carrier mobility and dopant concentration in the channel layer, and gate oxide capacitance. There have been extensive efforts to make advance in 1-MOSFET memory to fully exploit its high density integration capability with a low cost per bit. Nevertheless, it is still challenging to achieve low operation voltage as well as high operation speed, which are particularly crucial for the application to energy-efficient computing systems that perform data-processing cooperated with memory units. In this study, charge-storage-based and non-charge-storage-based 1-MOSFET non-volatile memory were investigated to achieve low voltage operation in oxide-semiconductor thin-film transistor (TFT) with various gate stacks. For example, the memory with an indium-zinc oxide (IZO) channel layer and an oxygen-deficient HfO_{2-x} gate oxide deposited by sputtering exhibited non-charge-storage-based non-volatile memory characteristics, where the channel conductance was modulated as driven by oxygen ion exchange between gate oxide and channel layers. The device with an indium-gallium-zinc oxide (IGZO) channel layer and HfO_{2-x} gate oxide deposited by atomic layer deposition showed the charge-trap memory properties with threshold voltage shift by electrical charging in the oxygen-deficient low-temperature ALD HfO_{2-x} charge-trap layer. In particular, the UV/ozone treatment of interface between gate oxide and oxide semiconductor channel layer adjusted the electrical charging and oxygen ion exchange behaviors. The memory with ZnO channel layer and NbO_x gate oxide showed also the charge-trap memory characteristics thanks to the high trap density in NbO_x as a charge-trap layer. These presented devices exhibited various non-volatile memory characteristics such as gate voltage polarity-dependent programming and erasing operations, the good retention of memory states and endurance properties upon repeated operations. In addition, since these devices did not adopt the tunneling oxide, thus enabled lower voltage operation compared to conventional floating-gate memory cell. These results demonstrated that the properties of gate stack layers including oxide semiconductor, ion-exchange layer, charge-trap layer, and interfacial tunneling oxide formation by post-deposition treatments could be adjusted, and consequently determine charge-storage-based or non-charge-storage-based non-volatile memory functions with the low voltage operation for energy-efficient computing systems.

Non-Charge Storage Based Nonvolatile Memory with IGZO Oxide Semiconductor and $LiCoO_x$ Charge Trap & Ion Supplying Layer with Large Memory Window Boyoung Jeong, Jimin Han, Taeyun Noh and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Demand for developing advanced nonvolatile memories significantly increases as emerging data centric applications such as artificial intelligence, the Internet of Things, and automated systems have evolved [1]. Among various nonvolatile memories, charge storage-based flash-type memory has been the most representative. However, adopting charge storage-based nonvolatile memory has some reliability issues such as unintended shift of threshold voltage (V_T) or electrostatic coupling effects [2]. In this study, we investigated non-charge storage-based nonvolatile memory with IGZO channel layer and $LiCoO_x$ as ion supplying layer and charge-trap layer. To demonstrate non-charge storage-based memory behavior, two thin-film transistors (TFTs) having different HfO_2 tunneling oxide thickness, i.e., IGZO/HfO_2(5 nm)/$LiCoO_x$ and IGZO/HfO_2(2 nm)/$LiCoO_x$ stacks, were prepared, and their memory performances were examined. The IGZO/HfO_2(5 nm)/$LiCoO_x$ device showed the clockwise hysteresis in transfer curves with $\Delta V_T \sim 5$ V due to electrical charging in the $LiCoO_x$ layer upon applying the gate voltage sweep of -5 ~ +25 V in forward and backward direction. On the other hand, IGZO/HfO_2(2 nm)/$LiCoO_x$ device with a thinner HfO_2 layer showed much enhanced memory window with ΔV_T up to approximately 20 V in clockwise hysteresis in the same measuring condition. The V_T shift could be induced by the electron charging in the $LiCoO_x$ layer as well as the Li ion migration between IGZO and $LiCoO_x$ layer that depends on the thickness of HfO_2 tunneling oxide. In particular, Li ions could pass through the 2 nm-thick HfO_2 tunneling oxide and modulate the channel conductance as dopants in the case of 2 nm-thick HfO_2 device, while only electron charging would induce the V_T shift in the case of 5 nm-thick HfO_2 device because Li ion cannot penetrate through 5 nm-thick HfO_2. Since Li ions act as p-type dopants in IGZO channel layer, the IGZO channel conductance decreases and V_T shifts positively during application of positive gate voltage as a result of Li ion migration from $LiCoO_x$ layer to IGZO channel layer, in addition to the electrical charging of $LiCoO_x$ layer. Thanks to the use of thinner HfO_2 tunneling oxide, both electron charging and Li ion migration in response to the applied gate voltage lead to the wide memory window more efficiently. This study demonstrates non-charge storage based nonvolatile memory characteristics through viable approach of introducing Li ion as dopants in order to improve the nonvolatile memory performance for advanced nonvolatile memory application.

Analog Synaptic Characteristic in Bilayered Gd-Doped Ceria and CeO_2 Memristors for Neuromorphic Computing Sola Moon, Kitae Park, Peter H. Chung, Dwipak P. Sahu and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Neuromorphic computing, inspired by the human brain that consumes less than 20 W of power, is emerging as an alternative to the existing von Neumann computing system suffering from its limits in device scalability and delayed data transfer between memory and processing unit [1]. In order to develop neuromorphic computing systems, significant efforts have been made to develop artificial electronic synaptic devices that mimic biological synaptic functions. Among various synaptic devices, analog resistance switching-based oxide memristive devices have promising opportunities due to their unique properties such as high density, good scalability, and high energy efficiency. In this study, we have demonstrated linear, symmetric, and analog synaptic characteristics in the bilayer structures of Pt/Gd-doped ceria (GDC)/CeO_2/Pt and Pt/CeO_2/Gd-doped ceria (GDC)/Pt memristors with different oxide stacking order. In particular, Gd-doped ceria, being one of the oxides having high ionic conductivity among mixed oxygen ionic-electronic conductors. Also, Gd-doped ceria has been reported to form a high concentration of oxygen vacancies [2]. As the concentration and mobility of oxygen-based defects play a significant role in oxide-based memristors, the bilayered CeO_2 and GDC memristors were fabricated and their synaptic properties were investigated. The use of bilayer memristors by stacking CeO_2 with more oxygen-deficient GDC turned out to have improved linearity and symmetry in potentiation and depression behaviors thanks to redistribution of oxygen vacancies between CeO_2 and GDC. The Pt/GDC/CeO_2/Pt memristors showed the potentiation behavior with decreasing resistance upon applying positive voltage at top Pt electrode while the application of negative voltage caused the depression with increasing resistance. The Pt/CeO_2/GDC/Pt memristors with reverse stacking order of GDC and CeO_2 exhibited opposite dependence of resistance change on the applied voltage polarity, which is associated with the resistance switching mechanism of energy barrier modulation at GDC/CeO_2 interface and Schottky barrier modulation at the interface with electrodes. Pattern recognition simulations using the modified MNIST dataset showed accuracy levels of up to 88% in bilayer memristors, confirming the potential of these bilayer memristors as artificial synapses for neuromorphic computing.

Effects of *In Situ* SiN Layer on the Leakage Current of AlGaN/GaN HEMTs Juyeong Park[1], Jong Bae Kang[2] and Jaehyung Jang[2,3]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]KENTECH Institute of Energy Materials and Devices, Korea Institute of Energy Technology, Korea (the Republic of); [3]Korea Institute of Energy Technology, Korea (the Republic of)

For conventional GaN based high electron mobility transistors (HEMTs) fabrication process, Au based ohmic contacts are usually adopted to form low resistance ohmic contact. However, Au based ohmic contact usually needs high temperature annealing process and it induces high density of surface states which causes high leakage current of devices [1]. In this work, in-situ SiN layer is employed to prevent degradation of the GaN surface from high temperature annealing during fabrication of GaN HEMT. Since in-situ SiN was grown at high temperature environment, it is heat resistant enough to protect GaN surface from high temperature stress. Three samples were fabricated and compared to analyze the effect of in-situ SiN layer.

The heterostructures was grown on a Si substrate consisting of 50-nm-thick SiN cap layer, 20-nm-thick $Al_{0.25}Ga_{0.75}N$ barrier, GaN channel and buffer layer. The fabrication process starts with mesa-isolation with inductively-coupled-plasma reactive-ion-etching (ICP-RIE) using BCl_3/Cl_2 gas. The in-situ grown SiN on the region of ohmic contact was etched with ICP-RIE using SF_6 gas. The multilayer Ti/Al/Ni/Au (30/180/40/150 nm) metallization was deposited using e-beam evaporator. Rapid thermal annealing (RTA) process was followed to form the ohmic contacts. The samples were annealed at the temperatures of 900°C for 70s in nitrogen ambient. For a sample A, any surface treatments or etching processes were not applied. For the sample B, TMAH treatment was applied on the surface of sample for 1min at the temperature of 100°C to remove high temperature stress related surface states [2]. For the sample C, the in-Situ SiN layer was etched with low power ICP-RIE using SF_6 gas. The Ti/Au (20/300 nm) pad metallization was deposited using e-beam evaporator. Finally, Ni/Au (20/300 nm) was deposited to form the gate electrodes using e-beam evaporator. The fabricated GaN HEMTs have an 8.5-µm source-drain spacing, 3-µm gate length and 2×50µm gate width. The electrical characteristics of the GaN HEMTs were measured using HP4155A semiconductor parameter analyzer.

The leakage currents of fabricated samples were compared to analyze the effects of in-situ SiN. The gate leakage current densities of sample A, B and C were 73 µA/mm, 142 nA/mm, 5 nA/mm respectively at the gate bias of -10 V. The sample C exhibited the lowest gate leakage current, followed by the sample B and sample A. It was found that the TMAH treatment reduces the leakage current by removing surface states on SiN. The removal of SiN damaged due to the thermal stress further reduced the leakage current. The low leakage current of sample C implies that the in-situ SiN successfully protected the GaN surface from high temperature stress suppressing the formation of surface states on the GaN surface.

Analog Synaptic Characteristics of CeO$_2$-based Memristor Crossbar Array for Neuromorphic Computing Kitae Park, Jiyeon Ryu, Dwipak P. Sahu and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Artificial synapses with analog resistive switching devices have been actively researched since they are essential elements for brain-inspired neuromorphic systems as promising computing systems particularly for data-centric applications such as artificial intelligence.[1] In this study, the CeO$_2$-based memristor was fabricated as 32x32 crossbar array structure. Two-terminal of access lines with Pt electrodes were deposited by e-beam evaporation and patterned with 10 µm width by photolithography and lift-off process and the switching layer (CeO$_2$) was deposited by RF magnetron sputtering. The synapse array exhibited analog, gradual, and voltage-polarity dependent resistive switching, which emulates biological synaptic behaviors of synaptic weight updates. The conductance of the device in array, corresponding to synaptic weight, increased upon consecutive positive voltage pulses and reversibly decreased upon negative pulses. In addition, its non-linear current-voltage characteristics matched well with Schottky conduction, which efficiently reduced sneak current in array architecture working as Schottky diode selector at the same time. Moreover, several electrical properties analogous to those of biological synapse were observed such as paired-pulse facilitation, spike rate-dependent plasticity. Time-dependent conductance decay could also be fitted well with multiple exponential decay functions that could separately assess short-term memory and long-term memory, and the retention at long-term memory turned out to be ~55 % after 1 hour. The resistive changing is thought to be induced by redistribution of oxygen vacancies in CeO$_2$ switching layer, particularly at the interface with electrodes. X-ray photoelectron spectroscopy analysis unveiled that CeO$_2$ layer has considerable amounts of oxygen vacancies to induce resistive switching. Furthermore, memristor with NbO$_x$/CeO$_2$ bilayer exhibited enhanced resistive switching dynamic range and non-linearity. This is because NbO$_x$ layer worked as not only an oxygen vacancies reservoir, but also threshold switching selector.[2] This study demonstrated that analog synaptic CeO$_2$-based memristor crossbar array could be promising synaptic elements for neuromorphic computing.

Sub-1.0 V Low Voltage Resistive Random Access Memory Operations with Ag/VO$_x$/Pt Structure Jiyeon Ryu, Kitae Park and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Recently, as the importance of date-centric applications increases such as artificial intelligence which requires huge amount of real-time data processing, high performance non-volatile memories are highly required, particularly enabling high density integration and low voltage operations for stand-alone memory and computing elements in processing-in memory applications. Among various non-volatile memories, resistive random access memory (RRAM), which has a simple metal-insulator-metal (MIM) structure, has excellent scalability, easy fabrication also for 3D architecture, and has been reported to have potential for low voltage and high speed operations. In this study, the Ag/VO$_x$/Pt RRAM devices were demonstrated to show sub-1.0 V low voltage and high speed operation with low switching current, high endurance, and high memory window. Resistive switching was induced by the formation and rupture of silver filament through VO$_2$ layer by applied bias. The DC current-voltage curves showed average value of V_{SET} of +0.23 V, V_{RESET} of -0.07 V without electroforming step. In addition, highly stable cycle-to-cycle endurances up to 3000 cycles with on/off resistance ratio > 10^2 without any degradation. Voltage pulse measurements also revealed the low voltage and fast switching with V_{SET} < 1.0 V with the switching time < 1 µs in our measurement setup. Auger electron spectroscopy, Rutherford backscattering spectroscopy, and X-ray photoelectron spectroscopy analysis confirmed that the VO$_x$ layer is composed of mixture of VO$_2$ and V$_2$O$_5$ phases. Transmission electron microscopy analysis revealed that VO$_x$ layer is mostly in amorphous state with small fraction of crystallites. This amorphous structure of VO$_x$ layer in addition to its inherent structural nature enabling to hold metallic elements within the lattice was advantageous in conductive-bridge random access memory of RRAM to achieve facilitated filament formation at low voltage thanks to the abundant oxygen vacancies in the amorphous phase. In addition, the homogeneous amorphous structure is desirable to achieve uniform device-to-device distribution. The presented results of highly stable, forming-free, low voltage and high speed switching operation of Ag/VO$_x$/Pt RRAM devices demonstrated their potential for stand-alone non-volatile memory and computing elements in the processing-in-memory applications.

Synaptic Characteristic of Li Doped HfO$_2$ with TiN Electrode Gyumin Park and Byung Joon Choi; Seoultech, Korea (the Republic of)

The human brain is capable of simultaneously processing and memory with low power consumption. A computing method that imitates these characteristics is called neuromorphic computing. Neuromorphic computing has high energy efficiency by mimicking brain works in hardware. To mimic the brain, we need to imitate synaptic behavior: electrical stimulus causes a continuous resistance change in the synaptic device. Resistive random access memory(RRAM) is one of the strong candidates attended for the synaptic device. The two-terminal structure of RRAM enables high-density integration. The simple structure makes crossbar array: Structure used in neuromorphic semiconductors. But RRAM needs the forming process, higher than the operating voltage. The forming process degrades the endurance of RRAM.

In this study, we confirmed the synaptic behavior, forming voltage controllability of lithium-doped hafnium oxide with a titanium nitride electrode. The structure is Pt/Li: HfO$_2$/TiN. The bottom electrode, 85nm-thick TiN as Li reservoir was deposited by magnetron sputter. The switching layer, Li:HfO$_2$ was co-sputtered in a lithium-rich to have a forming-free characteristic by Magnetron sputter. The top electrode, 200nm-thick Pt was deposited by Magnetron sputter. The richer lithium concentration (Li:Hf = 1:1) modulates the forming voltage from 2.5V to 2V. The device shows synaptic characteristics. The synaptic characteristics are Habituation, Sensitization, and Paired Pulse Facilitation (PPF). Habituation is that the conductivity increases as the pulses are applied, and the element becomes insensitive to the electrical pulse. Sensitization is when the conductivity decreases as the pulse is applied, making the device sensitive to the electrical pulse. PPF is a phenomenon in which short intervals of electrical pulses are input like a signal with strong conductivity, and wide intervals are input as a weak signal. We also checked the 8x8 crossbar array learning speed simulation of the learning speed based on the nonlinearity : (G : synaptic weight, G_0 : initial weight A : Constant to fit the graph, B : nonlinearity, P : number of pulses, P_0 : initial number of pulses) Our device’s nonlinearity was 0.1/3.6 (Potentiation/Depression). When simulated with this nonlinearity, the accuracy was confirmed to be 96.3% at 500epoch. —through simulation, the accuracy increased to 97.9% at 500epoch when the nonlinearity of depression was only 1— our research showed the possibility of a forming-free device with modulation of lithium concentration. We confirmed even if the synaptic device has insufficient linearity and symmetry, it can be used as a neuromorphic device.

Modulation of Ion Dynamics by Interfacial Ferroelectricity for Electrolyte-Gated Synaptic Transistors Minho Jin, Jae Hak Lee, Haeyeon Lee, Jiyeon Kim and Youn Sang Kim; Seoul National Univeristy, Korea (the Republic of)

With becoming the era of artificial intelligence (AI) and processing of big data, conventional von-Neumann architecture in computing technology has reached its limits in processing large amounts of data, such as low processing speed referred to as von-Neumann bottleneck, high energy consumption, and low integration density. To overcome these limits, neuromorphic computing architecture that mimics the relationships between neurons and synapses in the human brain has been newly proposed for energy-efficient analog computing.

As resistors constituting a neuromorphic architecture, Li^+ electrolyte-gated transistors (EGTs) with the channel of oxide semiconductors have attracted significant attention as a promising candidate for artificial synapses because of mitigating the limitations of 2-terminal devices, the fast response of Li^+ ions, low energy consumption with low operating voltage, and high applicability to flexible electronics. Due to the inherent nature of Li^+ EGTs show, however, limitations such as poor long-term synaptic plasticity and nonlinear/nonsymmetric conductance update for analogy computing. Because Li^+ ions under the external electric field are abruptly transported at the channel/electrolyte interface, electrical conductance modulated by an electrochemical reaction between Li^+ ions and the channel also changes abruptly, hindering the practical applications of artificial synapses. Considering the ion dynamics at the interface, therefore, is necessary to develop Li^+ EGTs.

One of the solutions for the preventing abrupt transport of Li+ ions is the introduction of the ion dynamics-modulating interlayer. Herein, we present Li^+ EGTs integrated with ferroelectric poly(vinylidene fluoride-*co*-trifluoroethylene) (PVDF-TrFE) polymer as a channel/electrolyte interlayer. Due to the polarized domains of PVDF-TrFE, the transport of Li^+ ions at the channel-electrolyte interface is accelerated and Li^+ ions effectively penetrate the channel along the fluorine sites in PVDF-TrFE. Partial polarization switching in ferroelectric domains also enables the sequential transport of Li^+ ions at the interface. Moreover, the self-diffusion of Li^+ ions from the channel to the electrolyte is suppressed by the downward polarized domains. We verify the changes in ion dynamics by electrochemical impedance spectroscopy (EIS) measurement, where the data shows that PVDF-TrFE reduces the charge transfer resistance at the interface. Also, the electrochemical reaction by Li^+ ions majorly occurs in the oxide channel, rather than the PVDF-TrFE interlayer. This indicates that the changes in electrical conductance of Li+ EGT is due to the electrochemical doping of Li^+ ions into the oxide channel. We confirm, therefore, that Li^+ EGTs successfully demonstrate various synaptic characteristics, such as excitatory postsynaptic current, long-term synaptic plasticity over 500 s, and paired-pulse facilitation. Also, confirming availability as an artificial synapse, conductance modulation in Li^+ EGTs shows a high dynamic range (G_{max}/G_{min}) of 92.42, high linearity, and superior stability over 100 cycles. Based on their synaptic characteristics, simulations of image classification and recognition using a convolution neural network for the CIFAR-10 dataset indicates that Li^+ EGTs are suitable as artificial synapses with high inference accuracy of 89.13%. We present materials discovery and novel methodological approaches for the modulation of ion dynamics at the interface to develop practical artificial synapse.

5:00 PM EL21.08.10

Facile Solvent-Dipping Method to Control Sulfur Vacancy for MoS_2 Synaptic Memristor Jiyeon Kim[1], Jae Hak Lee[1], Minho Jin[1], Haeyeon Lee[1], Ji Soo Kim[1], Eunho Lee[2] and Youn Sang Kim[1]; [1]Seoul National University, Korea (the Republic of); [2]Kumoh National Institute of Technology, Korea (the Republic of)

Neuromorphic computing is emerging compared to conventional computing systems based on Von Neumann structure which have limitation of processing delay when massive data is delivered between CPU and memory. To overcome this Von Neumann bottleneck, human-brain imitating synaptic devices have been attracted in neuromorphic system. Especially, memristors have attracted great attention due to the low switching voltage, enabling low-power consuming devices. Also, non-volatile memory characteristics of memristor can emulate potentiation process in synapse. In order to determine whether the memristor exhibits neuromorphic properties, synaptic behaviors such as synaptic plasticity and linearity need to be accompanied. To implement synaptic memristor, molybdenum disulfide (MoS_2), which is a representative example of transition-metal dichalcogenides (TMDs), has been used for channel layer of synaptic memristor because its eletrical properties such as high mobility and large bandgap can be easily controlled by number of layers, which is available due to its two-dimensional structure. Among its distinctive characteristics, many researchers are focusing on precisely controlling sulfur vacancies of MoS_2, which is directly related to synaptic memristor operation according to conductance change. However, traditional fabrication methods to make sulfur vacancies showed some limitations such as plasma damage, complicated process by chemical vapor deposition (CVD) and contamination of CVD reactor, suggesting necessity of concise and non-destructive method. Herein, we introduced facile solvent-dipping method immersing the samples in the solvent to control sulfur vacancies, considering polarity index and Hansen solubility parameter (HSP). We selected three solvents with similar HSP but different polarity: tetrahydrofuran, chlorobenzene, and toluene. Toluene has been reported as a common solvent to make sulfur vacancies in MoS_2. Moreover, in this study, polarity index was newly proposed to confirm if the polarity of solvent affects sulfur vacancy generation in MoS_2 when selected solvents have similar HSP values. We confirmed tetrahydrofuran-treated synaptic memristor generated the highest sulfur vacancies because bipolar solvent can remove both polar and nonpolar sulfur. This unique solvent-dipping process resulted in great performance of tetrahydrofuran-treated synaptic memristor; non-volatile memory characteristics such as high programming/erasing current ratio ($>10^3$) and long retention ($>10^4$ s) and synaptic behaviors of paired-pulse facilitation (PPF) about 170% and 8-times increased linearity. Neuromorphic computing was conducted by Modified National Institute of Standards and Technology (MNIST) to show synaptic behavior clearly, demonstrating increased recognition accuracy after solvent treatment. Visual simulation was illustrated to verify long term potentiation/depression (LTP/LTD) of synaptic devices. Flexible synaptic memristor was also fabricated and maintained its performance without noticeable degradation while bending test was operated, suggesting possible application in next-generation flexible devices. We suggested concise, non-destructive, and reliable solvent-dipping method to control sulfur vacancies in TMDs, and this is a novel study to our knowledge. Our research provides the framework for TMD-based neuromorphic devices, requiring further research for real application in brain-imitating neuromorphic system.
