SESSION CH01.01: Synchrotron/X-Ray/Spectroscopy Techniques for Batteries

Session Chairs: Rosa Arrigo and Akihiro Kushima
Monday Morning, April 10, 2023
Moscone West, Level 3, Room 3022

8:15 AM *CH01.01.01
Synchrotron-Based X-Ray Characterization of Li-Ion Battery Degradation Mechanisms Johanna N. Weker; SLAC National Accelerator Lab, United States

Synchrotron-based X-rays are a powerful characterization tool that can probe across many relevant length scales (from atomistic to millimeter) with different techniques that are sensitive to distinct features such as microstructure, chemistry, and morphology. Because of the high flux available and penetrating power of X-rays, batteries can be probed under realistic conditions, which enables us to understand and overcome failure mechanisms of the generation battery materials. I will discuss our multimodal approach combining information from high resolution transmission X-ray microscopy, X-ray diffraction, and X-ray absorption spectroscopy to study a range of different battery chemistries. Specifically, I will present recent work on using X-ray microscopy to study nanoporous architectures for alloying anode to accommodate their large volume changes. I will also demonstrate the value in X-ray tomography at multiple length scales (from nm to micron) to characterize the degradation of $LiNi_{0.5}Mn_{0.3}Co_{0.2}O_2$ cathodes from fast charging.

8:45 AM CH01.01.02
Structure-Dynamics Investigation of Electro-Responsive Redox-Polymer by *In Situ* Neutron Reflectometry Hanyu Wang[1], Riccardo Candeago[2], Mathieu Doucet[1], Jim Browning[1] and Xiao Su[2]; [1]Oak Ridge National Lab, United States; [2]University of Illinois at Urbana-Champaign, United States

Heavy metal contamination has been a major health and environmental hazard on the global scale. The development of smart materials for water purification and environmental remediation has received intense attention. In recent years, redox-active materials have been demonstrated to be an attractive platform for separations due to their molecular selectivity and electronic tunability. The main features of these systems are the fast electron transfer and redox processes at moderate potentials, which allow reversible adsorption and desorption of ionic components. Furthermore, due to the selective performance differences among these redox-polymers, a promising platform for electrochemical separations can be built by tailoring polymer structures for targeted metal recovery processes, depending on the stream compositions. Our planned study aimed to combine the electrochemical characterization with a simultaneous, non-destructive *in situ* or *operando* characterization technique, so to correlate oxidation states of the redox-active centers with migration of ions and solvent in the polymer film. Neutron reflectometry (NR) is the ideal candidate for investigating thin-film systems in a non-destructive and non-invasive fashion. Liquids Reflectometer (LR) at the Spallation Neutron Source (SNS) at Oak Ridge National Laboratory (ORNL) measures the surface and interfacial structures of the thin films in a horizontal sample geometry on length scale of 0.5 nm to 350 nm, and tracks changes of layer thickness, scattering length density (SLD), and roughness as a function of depth. The unique sample environment at LR offers the capability to conduct *in situ* electrochemistry to probe the morphological and structural changes of redox-polymer interfaces during operation as a function of chemical and electrochemical gradients over time. Electrochemical *in situ* NR experiments studied the equilibrium of swelling/deswelling of the poly(vinyl ferrocene) (PVFc) in presence of ReO_4^- with H_2O and D_2O (Figure 1 a and b, reflectivity curve; Figure 1 c, corresponding scattering length density profile). The NR data revealed high uptake capacities when applying voltages beyond the oxidation potential for ferrocene, showing promising results for implementation in real conditions. Dynamic data was collected too (Figure 1 d). After data analysis, we were able to track the capture or the release of the target ions (e.g., ReO_4^-) as the electrochemical process happens (Figure 1 e). This study will allow us to answer questions such as: what is the role of solvation in determining selectivity? What roles do uptake kinetics, diffusion limitations in the film play for selectivity? Answering these questions will be critical for creating new, more selective separation systems through the rationally design of the polymer structure and operating conditions.

9:00 AM CH01.01.03
Advanced *In Situ* X-Ray Analysis for Understandings on Chemo-Mechanistic Dynamics in Lead-Acid Batteries Seongjun Kim, Mark Wolfman,

Tiffany Kinnibrugh, Jaejin Kim, Alan Kastengren, Paul Fenter and Tim Fister; Argonne National Laboratory, United States

Since developed in 1859, the lead-acid batteries have been loved as secondary power source for various vehicles because of its cheap price and easy production process. Although the lead-acid battery is inferior in terms of specific energy and power density from the high atomic weight Pb compared to state-of-art lithium-ion batteries (LIB), this classical system has still loved worldwide all times because of its bold economic advantages. High powder density and simplicity of manufacture solidifies their status in the battery market. In addition, it is noteworthy that the almost every component after use can be recycled and long storage time in the perspective of energy sustainability.
Climate change is becoming a global issue that all humans must be concerned about. The internal combustion (IC) vehicle is one of the largest sectors that occupies the cause of air pollution and global warming. Accordingly, the hybrid electric vehicle (HEV) was designed to reduce fuel consumption along with development of full elective vehicles (FEV). The HEV consists of electric motor and IC engine, which needs high power whenever the start-stop system turns on and off. Therefore, the high-power lead-acid battery being used in conventional IC vehicles is still a good option for HEV system. However, the lead-acid battery should overcome some major problems in order to compete other types of batteries. Deep discharge cause facilitation of rapid sulfation, also the irreversible crystallization of lead sulfate ($PbSO_4$) can decrease the battery lifespan and performance. In other words, examining the structure transformation of two active materials, positive active material (PAM) and negative active material (NAM), is important to enhance the battery capacity and cycle life. The internal morphological variation can lead to change porosity and surface area in the electrode, which is crucial parameter to determine the performance. However, the existing post-mortem analysis such as scanning, and transmission electron microscopy (SEM and TEM) do not show the real-time changes during cycling.
Synchrotron x-ray computed tomography (XCT) is a promising technique to investigate two- or three-dimensional (2D or 3D) morphological transformation. Through in situ or in operando measurement, the morphology changes by phase transition during cycling can be identified in real-time. Images obtained from the XCT can be reconstructed to the 2D slice image, which is able to reassemble to the 3D images. The porosity and particle evolution by the different state of charge (SOC) is interpreted by the techniques. Additionally, the other synchrotron x-ray techniques such as diffraction (XRD) and transmission x-ray microscopy (TXM) support the intrinsic chemo-mechanical dynamics in the lead-acid batteries.
This presentation will provide much interest in the lead-acid batteries and information on the mechanism analysis using various synchrotron x-ray techniques. The application of in situ and operando x-ray measurements enable to enhance general comprehensions on the battery chemistry beyond not only lead-acid but other types of batteries.

9:15 AM CH01.01.04
Ultrafast Dark-Field X-Ray Microscopy – A New Tool for Analysis of Multiscale Dynamics Leora E. Dresselhaus-Marais; Stanford University, United States

Defects and structural distortions dominate the dynamics of metals and functional materials. But many processes – from fracture to phase transitions – have dynamics that rely on multiscale dynamics that are difficult to reconcile between mm-A lengthscales and ms-ps timescales. Dark-field X-ray microscopy (DFXM) can now directly image defects in single- and poly-crystals, resolving distortions deep beneath the surface over a wide field of view, with high sensitivity to strain and inclination in the lattice. We have developed time-resolved DFXM over the past 5 years for multiscale analysis of dynamics, and recently extended this to ultrafast timescales at X-ray free electron lasers. I will present the new DFXM toolbox we have developed and demonstrate how they inform important multiscale structural dynamics relevant to mechanics and thermal engineering. Our DFXM experiments can now collect movies of mesoscale phonon-defect interactions and deformations *in-situ* over ms-fs timescales, offering key opportunities to inform models yet untested.

9:30 AM CH01.01.05
High-Resolution Kinetic Studies of Battery Degradation Using Laboratory X-Ray Microscopy Kristina Kutukova[1], Victor Shapovalov[2] and Ehrenfried Zschech[1]; [1]deepXscan GmbH, Germany; [2]The Smart Materials Research Institute, Southern Federal University, Russian Federation

Advances in the design of new materials for efficient and durable energy storage and conversion systems are critical to current and future energy technologies. Performance and lifetime of batteries strongly depend on the 3D morphology of hierarchically structured materials and on morphology changes during operation. Morphological changes, i.e., particle fracture and surface deterioration, are among the most prominent sources of electrode degradation and eventual irreversible capacity loss. Advanced characterization techniques are needed to gain a deep understanding of the degradation mechanisms that affect performance and limit the lifetime of energy storage and conversion systems.

The potential of X-ray microscopy (TXM) and nano-XCT studies as a non-destructive method for characterizing kinetic processes in 3D-structured systems has been demonstrated mainly at synchrotron radiation beamlines. In this talk, we are presenting a customized solution for a laboratory nano-XCT tool with an integrated operando cell, and we are demonstrating its applicability for the study of kinetic processes in electrode materials, that cause degradation of batteries at the nanoscale, using a photon energy of 8 keV (Cu-Ka radiation). For laboratory nano-XCT tools, the selection of the material for the windows is particularly important because of the lower brilliance of the X-ray sources compared to synchrotron radiation sources. Ideally, the windows for an electrochemical *operando* cell must be transparent for photons in the selected energy range, it has to be rigid, nonpermeable to gases and moisture and electrically conductive. Glassy carbon, widely used in a variety of electrochemical and electrocatalytic applications, fulfils these requirements. It acts simultaneously as a current collector and a window. Glassy carbon is suitable for applications with most electrode compositions for Li- and Na-ion batteries. However, the thin glassy carbon windows are extremely fragile and require proper structural support from the cell enclosure.

A special custom-built electrochemical cell with glassy carbon windows/current collectors was designed and integrated into a TXM tool. The design of the electrochemical cell allows X-rays to pass through the sample at a wide range of angles, which allows limited-angle X-ray tomography to image the 3D morphology of the porous material and the evolution of defects like microcracks during battery cycling.

We demonstrate the capability of laboratory nano-XCT for the non-destructive imaging of microcracks in particles of $Na_{0.9}Fe_{0.45}Ti_{1.55}O_4$ (NFTO) cathode material in Li-ion batteries [1]. Many particles of the as-prepared cathode material show already initial microcracks. These microcracks start to grow at the first charge/discharge cycle. Further charging/discharging results in division of large particles into smaller ones. Chemo-mechanical stress caused by the supposed electrochemical substitution of Na by Li ions might accelerate the processes of microcrack formation and propagation. A notable observation is that the probability for formation and growth of microcracks is higher for large particles with low density than for the more dense and finer particles. A possible reason for the higher fracture susceptibility of large particles (especially at higher current densities) might be the state-of-charge (SOC) heterogeneity. The impact of the morphology on the degradation of battery materials, particularly the size- and density-dependence of the fracture behavior of the particles, is revealed based on a semi-quantitative analysis of the formation and propagation of microcracks in particles.

This study opens new perspectives for the nondestructive characterization of novel electrode materials for batteries. In-situ and operando X-ray microscopy allows kinetic studies of morphology changes and defect evolution during battery cycling with about 100nm resolution.

Revealing and Controlling Dynamic Lithium Insertion Pathway at High Rate via *In Situ* XRD and X-Ray Microscopy Bonho Koo[1], Jinkyu Chung[1], Juwon Kim[1], Hyejeong Hyun[1], Dimitrios Fraggedakis[2], Jian Wang[3], Namdong Kim[4], Markus Weigand[5], Tae Joo Shin[6], Daan Hein Alsem[7], Norman J. Salmon[7], Martin Z. Bazant[2,2] and Jongwoo Lim[1]; [1]Seoul National University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States; [3]Canadian Light Source, Canada; [4]Pohang Accelerator Laboratory, Korea (the Republic of); [5]Helmholtz-Zentrum Berlin, Germany; [6]Ulsan National Institute of Science and Technology, Korea (the Republic of); [7]Hummingbird Scientific, United States

Lithium-ion insertion kinetics fundamentally hinges upon phase transformation behavior during (dis)charging. At high c-rates, kinetic hysteresis is amplified and phase evolution becomes heterogeneous and unpredictable. For instance, discharging becomes more sluggish than charging for most of the battery electrodes. In addition, single-phase $LiNi_xMn_yCo_zO_2$ (NCM) undergoes phase separation behavior. Here, we developed an operando soft x-ray microscopy to track the lithium transport and phase evolution on the surface and bulk of individual battery particles over a wide range of cycling rates (0.01 – 10C). Our result unambiguously reveals that dynamic asymmetry between fast charging and discharging originates from auto-inhibitory Li-rich and autocatalytic Li-poor surface domains, respectively. In addition, we developed synchrotron-based operando fast XRD to track phase evolution during fast cycling. We electrochemically manipulate the lithium-ion concentration distribution within NCM particles to effectively promote solid-state lithium diffusion. Our method succeeded in redirecting the unwanted phase separation at a fast rate to solid-solution behavior. Our work lays the groundwork for developing high-power applications and ultrafast charging protocols.

10:30 AM CH01.01.08
Solid-State Synthesis and Electrochemical Electrode Reactions Investigated by *In Situ* X-Ray Diffraction Matteo Bianchini[1,2,3], Damian Goonetilleke[2], Marie Duffiet[2], Torsten Brezesinski[2] and Jürgen Janek[2,4]; [1]University of Bayreuth, Germany; [2]Karlsruhe Institute of Technology, Germany; [3]BASF SE, Germany; [4]Justus-Liebig-Universität Giessen, Germany

In situ diffraction studies can capture transient crystalline phases forming during chemical reactions. Whether the reaction is a chemical solid-state synthesis, or an electrochemical intercalation process within typical layered compounds used as battery electrodes, proper sample environments can nowadays be developed to perform *in situ* diffraction experiments. Furthermore, *operando* studies, in the case of batteries, can be used to capture the materials' evolution during the realistic functioning of the device.
In both cases, the time-resolved nature of the experiments allows to obtain a greatly increased amount of information. For example, in the synthesis of inorganic materials, reactions often yield non-equilibrium kinetic byproducts instead of the thermodynamic equilibrium phase [1]. To rationalize that, the competition between thermodynamics and kinetics occurring during the process need to be investigated in real time. Fully determining the reaction pathway potentially is a key requirement to achieve the rational synthesis of target materials [2, 3]. In this presentation, recent examples from our work applying *in situ* synchrotron XRD to understand the synthesis of relevant industrial compounds such as $LiNiO_2$ [4] and $LiCoO_2$ (2022, unpublished) will be reported and compared. The use of neutrons as possible probes with Li sensitivity for such reactions will also be demonstrated.
In addition, a recent example of the use of *in situ* (and *operando*) XRD to the $LiNi_{1-y}Mn_yO_2$ ($y = 0, 0.05, 0.1, 0.17, 0.25$) series of positive electrode materials will be reported [5], where we have ensured a fair comparison of the samples by obtaining an equal amount of delithiation of all samples during charge. We found in particular a significantly decreasing anisotropy (difference in the variations of the *a* and *c* unit cell parameters) in the crystallographic lattice change of the materials with increasing y, signifying that Mn-containing compounds yield lower mechanical strain to the cathode composites.

Excitonic and Surface Effects in X-Ray Absorption Spectra of Fluoride Salts Ana Sanz-Matias[1], Subhayan Roychoudhury[1], Xuefei Feng[1], Feipeng Yang[1], Li Cheng Kao[1], Kevin R. Zavadil[2], Jinghua Guo[1] and David Prendergast[1]; [1]LBNL, United States; [2]Sandia National Laboratories, United States

Due to the practice of employing electrolytes with fluorine-containing species (salt, solvent, or additives) that electrochemically decompose and deposit on the electrodes, fluoride salts may appear as evolving components of electrochemical interfaces in Li-ion batteries and emergent multivalent ion cells. We explore fluorine K-edge XAS of mono- (Li, Na, and K) and di-valent (Mg, Ca, and Zn) fluoride salts from a theoretical standpoint and discover a surprising level of detailed electronic structure information about these materials despite the relatively predictable oxidation state and ionicity of the fluoride anion and the metal cation. Given ultimate applications to evolving interfaces, some understanding of the role of surfaces and their terminations in defining new spectral features is provided to indicate the sensitivity of such measurements to changes in interfacial chemistry.

11:00 AM CH01.01.10
X-ray Diffraction Tomography for Investigating Li-Ion Batteries Under Operating Conditions Dorota Matras[1,2], Thomas Aston[3], Marta Mirolo[4], Isaac Martens[4], Jakub Drnec[4], Olof Gutowski[5], Simon Jacques[6], Jawwad Darr[3], Andrew Beale[3,6], Paul Quinn[2] and Antonis Vamvakeros[6]; [1]Faraday Institution, United Kingdom; [2]Diamond Light Source, United Kingdom; [3]University College London, United Kingdom; [4]European Synchrotron Radiation Facility, France; [5]Deutsches Elektronen-Synchrotron, Germany; [6]Finden ltd, United Kingdom

Li-ion batteries (LiBs) have become the preferred energy storage device choice for a variety of applications ranging from portable devices to (hybrid) electric vehicles, due to their relatively large energy density and life-cycle when compared to other competitive technologies. LiBs are though complex multi-component material systems and their performance directly depends on numerous parameters such as electro-chemical stability of the cell components and uniform current and temperature distributions for the desired operating conditions (voltage/current density), all of which are interlinked. A non-uniform current/charge distribution can have a negative impact on the performance of LiBs as it can lead to decreased capacity and power output, local temperature gradients and even to overcharge/overdischarge. Understanding how the local chemistry of the various system components is related to spatial gradients in the state of charge (SoC) and indeed capacity fade, is essential in order to optimise cell performance and design LiB materials with enhanced properties. However, investigating the evolving chemistry and the Li distribution in real-time is crucial to avoid relaxation problems coming from *ex situ* cell/material characterisation measurements.
Over the past decade, several studies focusing on *in situ*/ *operando* investigation of commercial LiBs, but most have been performed with conventional X-ray absorption-contrast computed tomography which provides limited/no chemical information in the reconstructed images [1]. In contrast, combining

scattering or spectroscopic techniques with tomography enables the extraction of local chemical and physical information within the interiors of intact materials and devices.
In this work, X-ray diffraction computed tomography was employed to study the state-of-charge induced chemical heterogeneities in commercial cylindrical LiBs in a spatially-resolved manner. More precisely, the (de)lithation processes under operating conditions and the effect of cycling rate on the heterogeneities within both electrodes were investigated. In both these studies [2,3], we were able to identify regions of uneven Li distribution which is bound to have an effect on the current and temperature distribution, potentially leading to capacity loss and/or cell failure. Finally, the obtained results demonstrated the importance of this chemical imaging technique as an invaluable diagnostic tool for real-word commercial batteries. This technique can applied for a variety of different experiments related to battery degradation mechanisms, such as *in situ/operando* abusing testing to capture internal temperature gradients through the crystallographic behaviour of both electrodes.

SESSION CH01.02: Spectrometry and Spectroscopy Techniques for Energy Materials
Session Chairs: Rosa Arrigo and Junjie Niu
Monday Afternoon, April 10, 2023
Moscone West, Level 3, Room 3022

1:30 PM *CH01.02.01
On Chip Electrochemistry Mass Spectrometry for Multiple Li Chemistries—from Batteries to N_2 Fixation Daisy Thornton[1], Bethan Davies[1], Artem Khobnya[1], Soren Scott[1], Ainara Aguadero[2], Mary Ryan[1] and Ifan E. Stephens[1]; [1]Imperial College London, United Kingdom; [2]ICMM, Spain

Gas evolution is ubiquitous in electrochemical energy conversion and storage; for instance in water electrolysis O_2 and H_2 evolution are desired, while in batteries, the same reactions are largely undesired and parasitic. On chip electrochemistry mass spectrometry offers much higher sensitivty than the prior state-of-the-art methods, typically based on differential electrochemistry mass spectrometry (DEMS).

In this contribution I will discuss how we have recently translated on chip electrochemistry mass spectrometry from aqueous systems to non-aqueous systems, both for probing (a) parasitic reactions in Li ion batteries and (b) ammonia production during Li mediated N_2 reduction.

The method allows quantitative pmol/s sensitivity to O_2, N_2, C_2H_4, CO_2 and NH_3 , all in real time. We have detected these products under conditions milder than previously reported. In this contribution I will discuss the mechanistic implications of our findings.

2:00 PM CH01.02.02
Highly Reliable Electrochemical Characterization of Electrode/Electrolyte Interface in Sub-Second Time Based on Impulse Response Analysis
Inyeol Yun, Jinpyeo Jeung and Yoonyoung Chung; Pohang University of Science and Technology, Korea (the Republic of)

Electrochemical analysis on electrode/electrolyte interface (EEI) is utilized in numerous research areas, such as batteries, skin electrodes, and biochemical sensors. Contact impedance, the most intuitive indicator of the electrochemical reaction between electrode and electrolyte, was generally extracted through electrochemical impedance spectroscopy (EIS). However, the EIS is too time-consuming to be implemented at the industry level [1]. Also, the long measurement latency leads to low reliability in time-variant measurement conditions, such as a human body and a microfluidic channel. Therefore, a contact impedance extraction method with a short measurement latency is required for ultrafast electrochemical analysis of EEI.
In this study, we propose a novel approach to extract contact impedance in an extremely short period (<1 sec) through an impulse response analysis. Our approach only measures an instantaneous response of EEI to an impulse input, and then extracts the contact impedance by analyzing the response with a unique algorithm. The extracted contact impedance exhibits a slight deviation of 6.4% with conventional EIS despite of its significantly short measurement latency. The ultrafast measurement enables to reliably extract contact impedance even on human skin, which has inhomogeneous characteristics with time. Furthermore, we demonstrated the impulse response analysis in a dynamic measurement condition which moves at high speed (500 mm/s) on a linear rail. The deviation rate of the impulse response analysis exhibits 5 times lower than EIS, which suggests that the impulse response analysis has robust characteristics in time-variant environments. The superiority and practicality of impulse response analysis will be of great help to numerous electrode-related research areas as well as the industry site by providing a concise and quantitative analysis of EEI.

2:15 PM CH01.02.04
Understanding Chemo Mechanical Interfacial Degradation Mechanisms in all Solid-State Batteries Using XRD-CT Partha P. Paul[1,2], Ji Hu[3], Robert Young[3], Alex Rettie[3], Marco DiMichiel[1] and Philip Withers[2]; [1]European Synchrotron Radiation Facility, France; [2]The University of Manchester, United Kingdom; [3]University College London, United Kingdom

As the transportation sector rapidly transitions from gasoline-driven to rechargeable battery-powered vehicles, there is an urgent need to develop more energy-dense batteries, with stable operation over long-term cycling. Using a solid-state electrolyte (SSE) offers the chance to exploit the significantly higher energy density of Li metal as an anode, compared to traditional intercalation anodes. However, interfacial stresses due to the non-uniform solid-solid contact at the anode/electrolyte interface can generate voids and cracks over cycling, as well as induce lithium plating [1]. Additionally, deleterious chemical and electrochemical reactions at the interface can exacerbate the interfacial instability, leading to crack propagation, metallic Li filling the voids, and eventually catastrophic failure of the battery [2]. Thus, understanding the nature of interfacial degradation mechanisms (chemical, electrochemical and morphological) is critical to achieving stable cycling with all solid-state batteries (ASSBs).
In this work, we employ synchrotron XRD-CT (X-ray diffraction computed tomography) to understand interfacial degradation in ASSBs under in-situ conditions. Specifically, we focus on the anode – SSE interface in symmetric Li | SSE | Li cells. We focus our study on the popularly used argyrodite (LPSCl) SSE. We scan the cells in the pristine, cycled and burned (cycled to failure) conditions. Using microcomputed X-ray tomography, we map and contrast the extent of cracking at the Li | LPSCl interface in Swagelok cells. Then, we scan the cells using XRD-CT to chemically map various species across the interface, including Li, LPSCl and Li_2S.
After registering the datasets together, we overlay the morphological microCT volume with the XRD-CT map, to correlate the presence of deleterious

interfacial products such as Li_2S. Additionally, we map the strains in the various chemical species, to correlate regions of strain heterogeneity with the size and extent of cracking, as well as the quality of interfacial contact between the SSE and Li anode in that region. We also investigate the effect of heat treatment of the SSE prior to cycling on the grain size, and correspondingly the extent of strain heterogeneities and cracking in argyrodite SSEs after moderate cycling. The non-destructive and fast nature of synchrotron X-ray characterization provides an ideal avenue to pursue *operando* characterization. Such non-destructive and multimodal characterizations are essential to understanding the interplay between various degradation modes, in turn informing strategies to mitigate them and enhance their cycling stability.

2:30 PM CH01.02.05
Tracking Electrochemical Active Material Transport with Simultaneous Neutron and X-Ray Tomography Jacob LaManna[1], Michael C. Daugherty[1], Youngju Kim[1,2], Daniel Hussey[1], Eli Baltic[1] and David Jacobson[1]; [1]NIST, United States; [2]University of Maryland, United States

In situ tracking of electrochemical active species is critical to understanding the complex transport mechanisms in electrochemical devices such as fuel cells, electrolyzers, and batteries. Many probes available to track electrochemical processes often require significant modifications to the devices to allow probe access to the reaction sites. These modifications can strongly influence the reaction by altering mass and charge transport, thermal gradients, and mechanical stresses. Additionally, the layered materials in electrochemical devices are not flat and can have a wavy interface which requires three-dimensional analysis to fully capture these interfaces. Two penetrating nondestructive probes that resolve three-dimensional structures are neutron tomography and X-ray tomography. Neutrons excel at detecting hydrogen and lithium while X-rays of sufficient energy to penetrate larger samples are sensitive to solid structures and high-Z components. The NIST-NeXT system combines these two probes together for truly simultaneous neutron and X-ray tomography that can gain greater information about the sample than either mode on its own. Recent advances in how NIST-NeXT data are analyzed has significantly reduced the acquisition time of a tomography scan. This reduction will produce scan times in the <15 minute range which is critical for tracking performance evolution in electrochemical devices. This talk will give an overview of the NIST-NeXT system with example studies from fuel cells, electrolyzers, and lithium-ion batteries to demonstrate the system's unique characterization capabilities for electrochemical devices.

2:45 PM CH01.02.06
Nano-FTIR Spectroscopy of the Solid Electrolyte Interphase Layer on a Thin-Film Silicon Li-ion Anode Andrew Dopilka[1], Yueran Gu[1,2], Jonathan M. Larson[1], Vassilia Zorba[1,2] and Robert Kostecki[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Si anodes for Li-ion batteries are notorious for their large volume expansion during lithiation and the corresponding detrimental effects on cycle life, however, the calendar life is the main roadblock for widespread adoption. During the calendar life aging, the origin of the impedance increase and capacity fade is attributed to the instability of the solid electrolyte interphase (SEI).[1] In this work, nano-FTIR spectroscopy and XPS depth profiling is used to characterize the structure and composition of the SEI on Si thin film electrodes that underwent an accelerated calendar aging protocol.
Nano-FTIR spectroscopy is a novel scanning probe technique in which a metallically coated atomic force microscope (AFM) tip is illuminated with a broadband infrared light source.[2] By operating the AFM in constant tapping mode, the background from the scattered light can be separated from the near-field response with lock in amplification. The result is FTIR spectra with high spatial resolution (ca. 20 nm) that match well with standard far-field and ATR-FTIR references.[2–5] Nano-FTIR is an ideal method to study the SEI because of its high spatial resolution, ultrahigh sensitivity, and specificity for identifying inorganic and organic SEI compounds.
We first evaluate the structure and composition of the SEI after different washing procedures with dimethyl carbonate (DMC). We find that brief washing (< 5 seconds) results in large chemical and topographic changes to the surface of the Si electrodes in comparison to non-washed electrodes. While the non-washed electrode is homogenous in terms of topography, IR imaging and nano-FTIR spectra, the washed electrode displays heterogeneity on multiple length scales demonstrating how brief washing can disrupt the delicate SEI layer and potentially result in misleading conclusions. This is further supported by XPS depth profiling experiments showing that the SEI layer thickness also decreases with increased washing time.
After establishing the undesirable effects of washing on the SEI layer, we focus on characterizing the initial SEI formation (non-washed) to compare it to the SEI after the accelerated calendar aging protocol which invovles a 12 hour hold at 0.05 V. From the characterization on the initial SEI formation, we identify Li ethylene dicarbonate (LiEDC), polyethylene oxide (PEO) and LiF as the major components of the SEI layer. After the accelerated aging protocol, we find that the amount of PF_6^- reduction products is much higher than the initial SEI suggesting that there is accumulation of salt related decomposition products during the aging process. Based on this result, we propose that PF_6^- mass transport into the SEI layer is a major source of parasitic reactions and could be prevented by increasing the fraction of the inorganic scaffold (e.g. LiF) in the SEI or improving the Li^+ transference number of the polymer like SEI species.

Acknolwedgements
This research was supported by the US Department of Energy (DOE)'s Vehicle Technologies Office under the Silicon Consortium Project directed by Brian Cunningham and managed by Anthony Burrell.

Improving the Accuracy and Reproducibility of Raman Spectroscopy for Graphitic Particles Andrew Pollard, Piers Turner, Keith R Paton, Elizabeth Legge and Konstantinos Despotelis; National Physical Laboratory (NPL), United Kingdom

As a key component of energy storage devices, electrodes containing graphitic particles must be accurately characterised to determine their material properties, properties which will affect the final performance of the device itself. Raman spectroscopy has long been a 'go-to' technique for measuring

carbon materials, as the resulting Raman spectra reveal many of the material properties, such as the level of disorder, strain, doping, particle lateral size and thickness. However, although this technique has been used for many decades, there are still glaring issues with reproducibility, as well as the quantification of the Raman peak metrics in relation to the material properties. As a non-destructive and rapid technique, these issues become a crucial barrier, when trying to use this technique for both academic research and as an industrial quality control tool.
Towards this effort, firstly we report the results of an international interlaboratory study (ILC) conducted under VAMAS. This study compared Raman spectroscopy data for an idealised graphitic material, that is a graphene layer grown using chemical vapour deposition, gathered from 17 participants across academia, industry (including instrument manufacturers) and National laboratories and will be used as the basis for the international standard ISO/TS 21356-2. By comparing reported Raman metrics with the measurements of the same regions made by the lead participant, variations in the reported peak intensity ratios and peak fits could be explored for both instrumentation and data analysis. Due to a lack of relative intensity calibration, the relative difference reported in the 2D- and G peak intensity ratios (I_{2D}/I_{G}) was up to 200%. It was also shown that the standard deviation for Γ_{2D} values reported by different software packages, was 15× larger for Lorentzian fit functions than for pseudo-Voigt functions. This study has shown that by adopting a relative intensity calibration and consistent peak fitting and data analysis methodologies, these large, and previously unquantified, variations can be significantly reduced, allowing more reproducible and comparable measurements of graphitic materials using Raman spectroscopy.
Secondly, we assess how Raman metrics measured for graphitic particles in powder form can be used to determine impurities and the limits of detection, namely for larger and undesired graphite particles that, in this case, have been deliberately added to a more homogeneous powder of smaller particles. When a sufficiently large number of spectra are acquired, it is found that by processing and classifying individual spectra, rather than the averaged spectrum, a reasonable estimate of the fraction of unexfoliated material can be obtained. These results highlight the care that must be taken when interpreting results of Raman spectroscopy measurements.

3:15 PM CH01.02.09
Probing Silicon Anodes in Lithium-Ion Batteries Using *In Situ* FTIR Spectroscopy Nathan R. Neale, Trevor R. Martin, Jaclyn Coyle and Maxwell Schulze; National Renewable Energy Laboratory, United States

We have been exploring the intrinsic chemical and electrochemical reactivities of silicon nanoparticles (Si NPs), the electrode binder and finished 3D electrodes using both ex situ and in situ attenuated total reflectance-infrared Fourier transform (ATR-FTIR) spectroscopies. We will first detail ex situ FTIR results that probe the solid reaction products from the chemical reaction of aprotic battery electrolyte and three purported components of the Si-based anode solid-electrolyte interphase (SEI): SiO_2 nanoparticles (NPs), lithium silicate (Li_xSiO_y) powders and Si NPs. We use FTIR and classical molecular dynamics/density functional perturbation theory to assess the solid products remaining with these model materials after exposure to electrolyte. These species represent the initial stages of SEI growth and predict they likely drive subsequent chemical and electrochemical reactions by controlling molecular interactions at the Si active material interface.
Additionally, we will present studies on poly(acrylic acid) (PAA), a commonly used binder for fabricating Si anodes, that show the evolution of PAA occurs via a cross-linking reaction during electrode curing. We will relate its chemical change to the final electrode properties and performance as well as local electrolyte structure in the 3D electrode. These studies are made possible using two types of in situ ATR-FTIR spectroscopy: thermal ATR-FTIR to probe the PAA cross-linking reaction, and ATR-FTIR spectroelectrochemistry of three-dimensional composite electrodes, a unique technique that probes the solvation dynamics of lithium ions at the silicon anode interface under electrochemical polarization. These latter studies reveal that PAA acts as an interfacial material that conducts lithium-ions, limits solvent molecule access to the Si surface, and stabilizes the electrode against parasitic lithium inventory loss at high state of charge for an extended period.

3:30 PM CH01.02.10
Operando Electrochemical XPS at the Electrode-Electrolyte Interface Roxy Lee and Robert Palgrave; UCL, United Kingdom

A major challenge in the development of reversible batteries is the huge irreversible capacity loss incurred during the first cycle, which is primarily due to electrolyte decomposition on the anode surface to form a solid electrolyte interface (SEI) layer. Thus, an in situ study on the behaviour of species at the electrode-electrolyte interface, in addition to proper characterisation of the SEI layer, is of great interest. One such emerging area with great prospect is that of in situ electrochemical X-ray photoelectron spectroscopy (XPS). A wealth of information for the top ~5 nm of a sample can be obtained using XPS, including identification and quantification of elemental surface composition, determination of oxidation state and local chemical environment. Additionally, the high-vacuum requirement of traditional lab-based XPS studies can be overcome using ionic liquid (IL) electrolytes, due to their negligible vapor pressure. Further beneficial properties of IL electrolytes, including a large electrochemical window, superior thermal stability and potential for greener chemistry make them exciting alternatives to organic electrolytes.

In this contribution, we demonstrate the unique information that can be obtained from operando electrochemical XPS. Cyclic voltammetry (CV) measurements were performed in tandem with XPS analysis, with the X-ray beam focussed on the electrode-electrolyte interface of the working electrode (WE) in a three-electrode electrochemical cell, for a variety of different systems containing IL electrolytes. We report on the binding energy shifts of characteristic signals from the electrode and electrolyte species with the applied electrochemical potential, and the evidence of electrochemical decomposition products as evidenced by the formation of new species. The techniques presented here may be applied to an extensive range of systems containing IL electrolytes and may bring new insights into complex electrochemical reactions at the electrode-electrolyte interface, ultimately helping us to design and develop reversible batteries for the future.

3:45 PM CH01.02.11
Understanding the Active Surface of a MnO_x@Ag Fuel Cell Catalyst Using Operando X-Ray Absorption Near-Edge Spectroscopy Johanna Schroeder[1,2], José A. Zamora Zeledón[1,2], Gaurav A. Kamat[1,2], Melissa E. Kreider[1,2], Lingze Wei[1,2], Dimosthenis Sakoras[2], Alessandro Gallo[2], Michaela Burkes Stevens[2] and Thomas Jaramillo[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The global drive toward the sustainable generation of fuels and the use of sustainable fuels is accelerating as the challenges posed by climate change become increasingly apparent. Hydrogen fuel cells or metal-air batteries using renewable electricity represent uniquely promising technology areas for this purpose.[1] The optimization of the kinetically hindered oxygen reduction reaction (ORR) is thereby one of the key components for a widespread use of such renewable energy conversion and storage technologies. Current state-of-the-art catalysts for hydrogen fuel cells are composed of expensive platinum. However, to reduce the material costs and increase the sustainability of the catalyst material, non-Pt group metals and non-critical raw material are of high interest. Due to stability limitations, non-Pt group metals are currently only employed in alkaline media. Bimetallic silver (Ag) catalysts are very promising non-critical raw materials for the ORR.
In our recent work Zamora Zeledón *et al.*[2] presented ultra-thin Mn films (maximum 1 nm) deposited on top of Ag bulk material prepared by physical vapor deposition that are substantially more active under ORR conditions at 0.8 V_{RHE} than single metal Ag and Mn thin films. Herein, we used operando X-ray absorption near-edge spectroscopy (XANES) to understand the surface dynamics of the highly active MnAg thin films. Applying a potential of 1.2 V_{RHE}, above the onset of electrochemical oxygen reduction, the pre-edge features in the Mn K-edge indicate a mixture of MnO_2 and Mn_2O_3 in oxygen and nitrogen saturated electrolyte. At 0.8 V_{RHE}, a potential within the ORR window, the Mn is more reduced. Notably, shifts in both the main edge and distinct

pre-edge features indicate that at 0.8 V_{RHE} the Mn is more reduced during ORR, namely, in oxygen vs. nitrogen saturated electrolyte. In terms of reversibility, consecutively applying 1.2, 0.8, and again 1.2 V_{RHE} revealed a non-reversible oxidation state change in oxygen in contrast to nitrogen saturated electrolyte. This could be explained by stability changes and a possible MnAg reconstruction. By coupling operando X-ray absoprtion spectroscopy (XAS) and electrocatalysis we are able to correlate activity changes to distinct changes in oxidation state. Those insights gained from operando XAS offer new directions for in situ stabilization or enhancement of electrocatalytic materials.

***In Situ* TEM Diagnosis Guided Designing of Electrode Materials for Better Battery** Chongmin N. Wang; Pacific Northwest National Laboratory, United States

Electron microscopy-based diagnosis, in particular in-situ TEM, appears to be one of the essential methods for gaining insights as how an electrode material failure, which can be used to guide battery materials development for creating new materials with enhanced battery performance. In this presentation, I will highlight recent progress on the development of in-situ TEM techniques, featuring integration of environmental electron microscopy with force and electrochemical process, which enable direct observation of structural evolution, phase transformation, coupling of electrochemi-mechanical effect and their correlation with mass and charge transport, providing insights as how active materials evolve that leads to fading and eventual failure of a battery. In particular, I will cover the current understanding of the interfacial process in an electrochemical cell and its correlation with the process such as Li dendrite growth, mossy Li formation, and cathode-air interfacial reaction. In perspective, the presentation will target to check what need to be done in terms of in-situ TEM to tackle the challenging science questions for advancing energy storage research.

11:00 AM CH01.03.02
Advanced Electrode Design with Homogenous Electric Field Distribution to Study the Electrochemical Li Deposition on Carbon Electrodes by Means of *In Situ* TEM Xin Wei, Michael Noyong and Ulrich Simon; RWTH Aachen University, Germany

A detailed understanding of the early stage Li dendrite formation as well as of the solid electrolyte interphase (SEI) formation at the electrode/electrolyte interface is indispensable in mitigating the degradation in battery performance and the safety issues for Li batteries, as well as in developing other energy materials. *In situ* electrochemical transmission electron microscopy (ec-TEM) is a powerful tool to investigate the Li deposition process in its very early stage during the electrochemical cycling of Li battery materials. It has been demonstrated so far that real-time observation of electrochemically induced Li nucleation, growth, and dendrite formation can be achieved with high spatial resolution on the glassy carbon as well as on metal (platinum or gold) electrodes *in situ* by using meanwhile commercially available microscale ec-TEM liquid cells. However, the so far reported ec-TEM cells feature inhomogeneous electric field distribution along the electrodes, which may cause unreliability of the measurement and set tight limits for the interpretation and the quantitative analysis. Thus, this persuasive characterization technique is still kept far from a “close to real” application scenario.
Here, we report an advanced electrode design enabling a homogenous electric field distribution for further microscopic quantitative characterization of the early-stage Li deposition in a closer approximation to the actual battery scenario. Similar to the commercially available chips, the designed ec-TEM chips are equipped with a semicircle carbon electrode as the working electrode surrounding two platinum wires in the same shape as reference and counter electrodes. The design is based on COMSOL 3D simulations, which demonstrate the electric field distribution and allow for a quantitative comparison of the designed chips with the commercially available ones. Experimental investigations on metal deposition from liquid electrolytes (Li and other reference materials) using the designed ec-TEM chips were performed and these analyses demonstrated the advancement and feasibility of the newly designed electrode configuration to approach true battery conditions. These designed ec-TEM chips facilitate the quantitative electrochemical characterization combined with the *in situ* TEM technique not only relevant for Li battery research but for any kind of electrochemical processes, where the deposition of active compounds from liquid electrolytes represents an elementary mechanistic step in the overall process.

11:15 AM CH01.03.03
New Frontiers in Electrochemical Device Characterization Enabled by AI-driven X-Ray Microscope Reconstruction Technologies Stephen Kelly, Hrishikesh Bale, Yulia Trenikhina and William Harris; Carl Zeiss RMS, United States

A clean energy future will rely heavily on electrochemical energy storage and conversion devices like batteries and fuel cells to shift away from carbon-based energy sources. These electrochemical devices are generally closed off from the outside world and operate under highly non-ambient conditions (e.g., liquid electrolytes, air-free or controlled gas environments, elevated temperatures, liquid / gas flows). The performance of these devices is largely driven by the 3D microstructures of the internal components and their evolutions. For example, the weaves of the gas diffusion layer in a polymer electrolyte fuel cell control the gas flow to the catalyst and electrolyte layers; breached layers in batteries due to lithium dendrite growth can lead to catastrophic failures and safety concerns. As such, imaging the internal microstructures and processes in these devices is important for observing and measuring device construction details and understanding how defects are distributed and change performance during operation. In particular, 3D imaging allows for analysis of features and parameters that can only be fully understood in 3D like porosity and tortuosity, and can also provide realistic microstructural input for 3D modelling and simulation approaches.

Within this scope, X-ray microscopy provides a unique method to image electrochemical devices because of the non-destructive nature of the technique. Modern X-ray microscopes also enable high resolution imaging inside relatively large objects – critical for in situ imaging of closed-form electrochemical devices like batteries and fuel cells. Advances in tomographic image reconstruction have allowed researchers to increasingly maximize the impact of X-ray microscopy data through higher image quality and enabling faster data acquisition schemes. Recently, artificial intelligence (AI) has been incorporated into these algorithms, dramatically increasing the performance and capability of the technique. Here, we apply multiple novel reconstruction technologies that leverage AI to dramatically improve the performance of laboratory-based X-ray microscopes, showing examples across multiple fields of electrochemical device research.

We show how AI-powered tomographic reconstruction can reveal new levels of detail in lithium-ion batteries and polymer-electrolyte fuel cells, and enable up to 10 times faster data collection at both the micrometer and nanometer length-scales. We additionally show how these technologies can be used to generate massive 3D images that allow researchers to evaluate, measure, and simulate the performance of these devices with the needed micrometer resolution across truly meaningful length scales of many millimeters of device volume. We additionally show how these technologies can be used to generate massive 3D images up to 100 times faster than conventional approaches allowing researchers to evaluate, measure, and simulate the performance of these devices with unprecedented precision and representivity. These capabilities shift the paradigm in volume analysis for electrochemical devices and give researchers unprecedented insight into the detailed microstructures that drive device performance, enabling new levels of understanding and helping to power the drive to a clean energy future.

11:30 AM CH01.03.04
The Impact of 3D Microscopy Strategies on Computational Analysis for Battery Research Yulia Trenikhina[1], Stephen Kelly[1], Sarah Reeb[2], Cheryl Hartfield[3] and William Harris[3]; [1]Carl Zeiss X-ray Microscopy, United States; [2]Math2Market, Germany; [3]Carl Zeiss Microscopy, LLC, United States

Rapidly progressing global warming and pricing of natural fuels are well-known reasons to search for renewable energy sources. Many nations are addressing global climate change by implementing legislation that favors electric vehicles (EV) and related infrastructure development. The idea of a greener vehicle with no harmful CO2 emission is attractive for most drivers. However, multi-hour charging times and limited distance range are the downsides that keep many car shoppers away from EVs.
Striving for the electrification of transportation sets up new, challenging EV battery standards. Fast charging ability (“fueling time”) and battery capacity (vehicle’s distance range) are the key metrics for Lithium-Ion Battery (LIB) performance. LIBs with graphite anode suffer from rapid capacity fade and Li plating at high charging rates. Degraded battery capacity limits the range of applications, and Li plating becomes a safety concern once conductive paths between anode and cathode are formed. Overpotentials in intercalation electrodes cause both of these effects during fast charging. Li ions diffusion limitation at high charging current is one of the problems that results in electrode polarization that causes overpotentials. There are two pathways to improve Li ion diffusion: to increase the rate of interfacial reactions and to reduce the tortuosity of Li ions paths. The first approach involves altering electrolyte composition and SEI properties. The second approach is concerned with the electrode architecture. The electrode microstructure is the result of a multi-step manufacturing process that is concerned with uniform distribution of the electrode components (active particles, binder and conductive additive) and constant thickness. These microstructures call for characterization methods that cover several orders of magnitude in the length scale from a nm up through micrometers and beyond. Particularly important parameters for fast charging performance are particle connectivity and size, electrode tortuosity, and surface area and, due to the nature of the parameters, only 3D techniques enable adequate characterization.
3D FIB-SEM tomography presents a powerful approach to 3D microstructural characterization of battery electrodes and, when combined with computational modelling packages, enables robust analysis, modelling, and design workflows for fast-charging applications. However, because FIB-SEM tomography operates on the slice-and-view principle, care must be taken in acquiring and analyzing the data to ensure accurate results.
In this study we explore how the 3D FIB-SEM tomography parameters such as slice thickness, slice thickness variation, slice-to-slice alignment, and signal-to-noise level influence resulting electrode microstructure characterization parameters. We control slice thickness, regularity, and alignment by using advanced FIB-SEM acquisition software like Atlas 3D that allows for nm precision. Then, tomography data is plugged into simulation software for the quantitative analysis and battery performance prediction by comparing the cell overpotential to the open-circuit voltage at different charge rates. This approach links electrode manufacturing parameters directly to the estimation of available capacity at various charging rates. Computational simulation of the battery performance based on realistic electrode properties provided by 3D FIB-SEM tomography reduces the need for battery assembly, testing and post-mortem analysis and streamlines the electrode architecture design for fast-charging applications. This work investigates the interplay between data collection approaches and computational output within this framework and provides guidance for ultimate success.

11:45 AM CH01.03.05
Formation and Impact of Nanoscopic Oriented Phase Domains in Electrochemical Crystalline Electrodes Revealed by Collocated 4D-STEM and EELS Mapping Wenxiang Chen, Xun Zhan, Renliang Yuan, Saran Pidaparthy, Arghya Patra, Kim Ta, Zhichu Tang, Hong Yang, Andrew Gewirth, Paul V. Braun, Elif Ertekin, Jian-Min Zuo and Qian Chen; University of Illinois Urbana Champaign, United States

We study the structural and compositional changes in primary cathode nanoparticles in the electrochemical phase transformation. We map the formation of oriented phase domains and the associated development of strain gradients quantitatively during ion insertion. A collocated four-dimensional scanning transmission electron microscopy and electron energy loss spectroscopy approach, coupled with data mining, enables the research. Results show that in the spinel cathode nanoparticles their phase transformation upon Mg^{2+} insertion leads to the formation of domains of similar chemical identity but different orientations at the nanoscale. The domain formation process follows the nucleation, growth and coalescence process, different from the conventional diffusion- or reaction-limited mechanisms. Furthermore, electrolytes have significant impacts on the transformation microstructure (‘island’ versus ‘archipelago’). Large strain gradients built up from the development of phase domains across their boundaries change the chemical diffusion coefficient in the cathode nanoparticles by a factor of ten or more. Our findings provide critical insights into the microstructure formation mechanism and its impact on ion insertion, suggesting another dimension of transformation structure control for energy storage materials.

SESSION CH01.04: Advanced Microscopy in Battery Research II

1:30 PM *CH01.04.01
Multi-Modal *In Situ* Liquid-Electrochemical Microscopy for Energy Applications Daan Hein Alsem[1], Tyler Mefford[2], Jongwoo Lim[3], Rui Filipe Serra Maia[4], Aram Yoon[5], Pawan Kumar[6], Deep M. Jariwala[7], See Wee Chee[5], William C. Chueh[2], Norman J. Salmon[1] and Eric A. Stach[7,1]; [1]Hummingbird Scientific, United States; [2]Stanford University, United States; [3]Seoul National University, Korea (the Democratic People's Republic of); [4]CoLAB NET4CO2, Portugal; [5]Fritz-Haber-Institut der Max-Planck-Gesellschaft, Germany; [6]imec, Belgium; [7]University of Pennsylvania, United States

In-situ liquid cell electron and x-ray microscopy has enabled the dynamic studies of electrochemical reactions in energy materials and is capable of, at the nanoscale, produce relationships between performance and the structure and chemical composition of these material systems. These fundamental relationships are critical to the development of better performing batteries, catalysts, and other energy materials. Together with the rapid increase of research in energy materials systems over the last decade and a half, in-situ liquid-electrochemical techniques have developed into more mature and more widely used characterization methods.

Here we will demonstrate how in-situ liquid-electrochemical transmission electron, X-ray synchrotron and scanning electron microscopy methods were used to study dynamics and structural changes of lithium-ion insertion/extraction in micron-scale Li_xFePO_4 battery particles, electrocatalytic behavior of β-Co(OH)2 platelet particles, and electrochemical oxidation of copper nanoparticles under electrolytic reduction conditions. These studies all yielded new insights into these materials systems that can directly provide guidance for development of improved energy systems.

New scientific hardware and method development has been crucial in enabling the exponential growth of in-situ nano-scale liquid cell microscopy/spectroscopy of electrochemical systems. Therefore, we will also discuss best-practice hardware and method design and development for these in-situ liquid-electrochemical microscopy experiments. Examples are how the potentiostat and holder connections should carefully consider different ground potentials and how the incorporation of real bulk-scale reference electrodes in these in-situ systems can yield quantitatively higher fidelity data. We will also show how heating the sample or illuminating the sample with light during these in-situ electrochemical experiments is starting to expand the new frontier of what can be achieved with these in-situ microscopy techniques.

2:00 PM CH01.04.02
Atomic Fortune-Telling—Forecasting the Future for *In Situ* Experimentation Steven R. Spurgeon[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

Mastery of dynamic materials and chemical processes depends on our ability to describe not just the present state of a system, but how it will evolve in the future. To better control phenomena ranging from radiation-induced defects to order-disorder phase transitions, we must both harness and anticipate how multi-modal data streams may change during a reaction. Surprisingly, there are few examples of machine learning-based forecasting models for transmission electron microscopy, one of the cornerstone platforms for in situ experimentation at high spatial and chemical resolution. Here I will describe our recent development of long short-term memory (LSTM) models, a kind of recurrent neural network, to predict phase transition points during in situ imaging and electron energy loss spectroscopy (EELS). I will describe how such models can be integrated into emerging automated microscopes to guide long-latency control parameters, laying the groundwork for *anticipatory* direction of complex reactions. Together, these developments show how artificial intelligence unlock richer, more controlled, and informative studies of dynamic processes in materials and chemical systems.

2:15 PM *CH01.04.03
Ionic Gradients at Active Battery Interfaces Revealed Through Time-Resolved Cryo-EM Nikita S. Dutta, Sang-Don Han, Mowafak Al-Jassim and Katherine L. Jungjohann; National Renewable Energy Laboratory, United States

Characterizing the structural and chemical evolution of battery interfaces during cycling and aging is critical to realizing longer device lifetimes. Cryogenic electron microscopy (cryo-EM) has greatly advanced our ability to study such interfaces at high spatial resolution without damaging sensitive organic or lithium-containing components. The temporal resolution, however, is limited by time-consuming traditional sample preparation techniques that allow structural changes to occur between electrochemical cycling and the later ex-situ freezing process. Here, we demonstrate a method to freeze active battery interfaces *in situ* on sub-second timescales, allowing the native structures and chemistry that arise at different points in cycling to be captured for cryo-EM study. We apply this technique to study the role of ionic gradients at charged nanostructured interfaces on formation and evolution of the solid-electrolyte-interphase (SEI) on silicon anodes. This allows us to capture diffuse features that form at the active interface, which otherwise relax too quickly to be studied with ex-situ sample preparation techniques. We discuss the potential to expand this technique to other electrochemical systems and advance characterization of broader energy materials.

2:45 PM CH01.04.04
***In Situ* and Ex-Situ 4D-STEM Characterization of Low *q* Scattering in Conductive Polymers Used for Li-Ion Battery Anodes** Hadas Sternlicht[1], Tianyu Zhu[2], Benjamin Savitzky[1], Chen Fang[2], Colin Ophus[1], Gao Liu[2] and Andrew M. Minor[1,3]; [1]National Center for Electron Microscopy, Molecular Foundry, Lawrence Berkeley National Laboratory, United States; [2]Energy Storage and Distributed Resources Division, Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States

Characterization of soft materials, such as polymers, using conventional transmission electron microscopy (TEM) techniques typically applied to harder materials (metals and ceramics), normally results in beam damage, while essentially providing no structural information. Four-dimensional scanning TEM (4D-STEM) captures the complete reciprocal space information while allowing for the practical evaluation of applied dose, addressing the challenges associated with the characterization of soft materials.

Conductive polymer binders provide electronic conductivity and mechanical support for Si-based composite anodes in Li-ion batteries. They moderate volume changes during electrochemical cycling and provide improved capacity retention. Promising polymer binders include poly(9,9-dioctylfluorene-co-fluorenone-co-methylbenzoic ester), abbreviated as PFM, and some of its derivatives.

In this work, spin-coated TEM samples of PFM were characterized using in-situ and ex-situ 4D-STEM to address the structure of the polymer chains at the nanometer length scale at different annealing conditions. The polymer exhibits stronger scattering at lower q values as compared to typical crystalline materials. Using 4D-STEM, we could discern between rotationally homogeneous and oriented lobes of low-q scattering, indicating semi-crystallinity associated with π-π stacking between the polymer chains. The orientation of the polymer chain alignment (and associated π-π stacking) was then mapped to reveal the granular morphology, where in this context a grain is defined as a region of continuous single orientation of the π-π stacking, which does not change abruptly. Finally, variations in the characteristics of the polymer, undergoing a gradual microstructural transition upon annealing, were determined, and associated with enhancement in the electrochemical and mechanical properties of the polymer.

3:00 PM CH01.04.05
4D-STEM Mapping of Thermal-Induced Nanodomains in Cathode Nanoparticles and Their Role in Facilitating Ion Insertion for Zinc-Ion Batteries Zhichu Tang, Wenxiang Chen, Zhiheng Lyu, Oliver Lin, Kaijun Yin, Cheng Zhang, Hong Yang, Jian-Min Zuo and Qian Chen; University of Illinois at Urbana-Champaign, United States

Electrochemical-induced phase transformation in electrode materials during ion insertion/extraction have been widely studied, including composition and phase domain heterogeneities. However, the role of preexisting nanodomains in electrode materials on their electrochemical performance has not been fully understood yet. Here, we use single-crystalline λ-MnO_2 nanoparticles as a model system to study the effect of thermal-induced lattice distortion and nanodomain formation on Zn-ion insertion/extraction. Through in-situ four-dimensional scanning transmission electron microscopy and electron energy loss spectroscopy, we investigate the formation mechanism of nanodomains in λ-MnO_2 crystals under heat treatment. Combining with electrochemical measurements, the results show that the domain walls can accommodate the strain caused by Zn-ion insertion and thus improve Zn-ion diffusivity in λ-MnO_2 nanoparticles. Our work pinpoints the distinctive impacts of nanodomains on the ion-diffusion process, providing guidance for the structure engineering of electrode materials.

3:15 PM *CH01.04.06

***In Situ* TEM – A Critical Analysis Technique for Understanding Energy Storage Systems** Nikhilendra Singh[1], Eric A. Stach[2], Timothy Arthur[1], James Horwath[2], Daan Hein Alsem[3] and Norman J. Salmon[3]; [1]Toyota Research Institute of North America, United States; [2]University of Pennsylvania, United States; [3]Hummingbird Scientific, United States

Advances in hybrid and electric vehicle technologies combined with a demand for green initiatives have motivated necessary diversification in energy storage research. To achieve customer expectations for hybrid and electric vehicles, new battery systems with higher energy densities, power densities and cycle life than the current state-of-art Lithium (Li)-ion battery are needed. Post Li-ion battery systems, especially those focused on the utilization of Li metal have recently come to the forefront of research. The ability to directly utilize Li metal anodes in rechargeable batteries presents itself as an ideal situation via the accessibility of a maximum possible theoretical specific capacity (3860 mAh/g) in comparison to commercially used anodes (e.g., graphite – 380 mAh/g). Hence, significant efforts in recent literature have targeted the development of robust Li metal anode systems.
One such system is Li-sulfur which has attracted attention due to its high theoretical capacity (1673 mAh/g) and potential low cost. However, this system is hindered by polysulfide dissolution and electrolyte decomposition at the Li metal anode. Among the various strategies which have been employed to overcome these hinderances, the use of solid-state electrolytes (inclusive of polymers, gels and conducting ceramics) stands out since the implementation of solid-state electrolytes can also serve as a mechanical barrier towards Li dendrite formation. However, solid-state electrolytes exhibit relatively lower ionic conductivities and display poor interfacial stability towards Li metal anodes. While advances in both liquid and solid-state electrolyte materials continue, comparatively little is known about the interfacial interactions between both types of electrolytes and Li metal. Hence, studies into understanding these interactions remains essential towards realizing Li metal battery technologies.
Here, we present select studies into the interfacial interactions between various liquid and solid electrolytes being considered for metal battery systems today. The studies will cover interfacial observations, nucleation and growth of the metal anode and the chemo-mechanical transformations within electrolytes and at their interfaces with metal anode materials. Tandem analytical ex-situ and in-situ studies via transmission electron microcopy (TEM) are used to reveal the interfacial interactions and failure modes between Li metal and commonly used liquid electrolytes, lithium thiophosphate solid electrolytes, the deposition and dissolution properties of Li metal from these electrolytes, and the effects of the deposition and dissolution properties on the bulk electrolyte structure. Additional work on non-Li metal anode systems will also be presented in a similar light. The presented studies allow for comparisons of metal anode deposition and dissolution properties for each electrolyte material and stand to help clarify interfacial, morphological and failure evolution mechanisms during battery cycling from them.
Further, in this presentation an emphasis will be laid upon the methodologies created, applied and advanced to carefully study solid-state battery materials in a TEM, where both sample preparation of extremely air-sensitive materials and microscope setup to ensure damage-free characterization are equally critical towards obtaining data clarity from ex-situ and in-situ TEM characterizations for battery materials. Additionally, this presentation will support the need for bridging length scales when analyzing energy storage system materials, to facilitate the correlation of model material studies done within a TEM and phenomenon observed in larger cells which stand the ability to be scaled up for commercial applications in current and future mobility systems.

Illuminating polysulfide distribution in lithium sulfur batteries: Shining light on polysulfides dissolution and movement through operando optical fluorescence microscopy Kofi Coke, Paul Shearing and Thomas S. Miller; UCL, United Kingdom

Lithium sulfur batteries are a particularly exciting developing battery technology, capable of impressive theoretical gravimetric specific capacities (1672 mA h g^{-1}), and energy densities (2567 Wh kg^{-1}). However, their performance is plagued by the polysulfide shuttle effect – perhaps the most critical issue to solve to enable the wider proliferation and commercialisation of lithium sulfur batteries. This is where lithium polysulfide charge carriers generated at the cathode diffuse towards the lithium metal anode and undergo parasitic reactions, leading to active material loss, anode degradation, and rapid cell failure. Development of strategies to mitigate this effect make up a large proportion of current Li-S research, but current methods of characterising the prevalence of polysulfide shuttle either provide limited detail or are prohibitively time consuming. New methods utilising optical fluorescence microscopy and rotating-ring disc electrode study are presented, allowing facile operando characterisation of the shuttle effect.
Through the use of optical fluorescence microscopy alongside an otherwise inert polysulfide selective fluorescent dye, the intermediate polysulfides formed throughout cycling are made to fluoresce, and can thus be directly visualised. Through analysis of recordings of polysulfide movement, the kinetics of their dissolution and subsequent diffusion towards the anode, and the effectivity of mitigation strategies, are then easily quantified. Further, localised polysulfide concentration within the electrolyte can be approximated from the fluorescence intensity.
Additionally, using a rotating-ring disc electrode analogous to a Li-S cell (fitted with a sulfur/carbon disc and lithium ring), the laminar flow of redox materials produced will provide a known 'collection efficiency' of lithium polysulfides reacting with the anode, with the resultant current at the ring serving as a proxy for the extent of the shuttle reaction. This allows facile assessment of the efficacy of measures taken to protect the anode from these parasitic reactions, as well as the ability to get mass transport parameters such as diffusion coefficients, alongside kinetic parameters such as rate constants.
With these methods of rapidly characterising the occurrence of the polysulfide shuttle effect in lithium sulfur batteries, one can rapidly determine the efficacy of measures taken to mitigate the effect, such as polysulfide trapping methods in the cathode, electrolyte, or separator, and additives capable of protecting the lithium anode through SEI formation.
These methodologies serve as an ideal platform for the further development of polysulfide shuttle mitigation strategies, as they allow rapid determination of efficiency.
The work could also be of key benefit to industry. The speed and ease of the two techniques means they could easily be integrated into industrial lithium sulfur research and development, and the potential time saved in using these techniques over cycling to cell failure will be of particular interest to industry; which in turn will help to the commercialisation of lithium sulfur batteries of course of substantial benefit to consumers and to the world.

Advancing Liquid-EM Techniques and Workflows for Operando Studies of Energy Materials Madeline J. Dressel Dukes, Stamp Walden, Kate Marusak, Tim Eldred, Nynke Krans, Yaofeng Guo, Alan Franks and John Damiano; Protochips, Inc., United States

The need for clean, renewable energy has driven the expansion of research focused on new materials for electrocatalysts, fuel cells, and batteries. These materials need to be plentiful, inexpensive, and have high energy capacity operating lifetimes to power a growing consumer market that is seeking alternatives to fossil-based fuel sources [1].

Operando transmission electron microscopy techniques enable dynamic, real-time imaging of a material's nanoscale processes as they occur within their functional environment [2]. A key objective in applying operando TEM to energy materials is the opportunity to observe a catalyst or battery material under its native operating conditions. Enabling researchers to simultaneously follow structural and morphological changes and correlate those to the material’s electrochemical behavior. Operando studies that utilize liquid-EM, in which a sample is encapsulated in a liquid environment between electron transparent membranes, has enabled researchers to study reactions as they occur in a liquid, electrolyte environment [1]. This technique has enabled researchers to better understand the mechanistic pathways that can result catalyst deactivation [3,4] battery capacity fading [5-7] and identify targets within these materials to improve their performance [8,9].

Successful operando liquid-EM experiments are challenging due to many factors, beginning with experiment design and workflow, and culminating complex analysis of multiple streams of large, often cumbersome, datasets. Here, we have set out to address and develop hardware and software tools which mitigate some of the most common challenges associated with operando liquid-EM electrochemical studies. Combining expertise in in-situ hardware and MEMs based sample support design, with AXON, Protochips’ recently introduced software platform, we have developed a holistic, workflow-driven approach to address key challenges and pain points associated with in-situ and operando TEM studies. New hardware and MEMs-based features integrated into the Protochips’ liquid-EM solution, Poseidon, include the ability to perform electrochemical studies beyond room temperature, and improved stabilization of electrochemical signals for correlation with bulk studies. Streamlining the operando-TEM experience, the AXON software family, utilizes machine vision and learning algorithms for improved stabilization and tracking of dynamic samples, accurate dose quantification and management, consolidation of experimental parameters and metadata, and an intuitive, free-to-use, visual data analysis tool, AXON Studio.

As operando TEM techniques continue to grow in popularity within the larger energy materials sector, there is a growing need for in-situ hardware and software solutions that permit users with minimal expertise in electron microscopy to undertake and obtain high-quality, robust, reproduceable datasets that can be shared and independently interpreted by colleagues and collaborators to further the shared goal of developing the next generation of renewable energy materials.

Imaging Phase Segregation in Nanoscale Li_xCoO_2 Single Particles Elliot J. Fuller[1], David Ashby[1], Celia Polop[2], Elena Salagre[2], Bhuvsmita Bhargava[3], Yueming Song[3], Enrique Vasco[4], Joshua Sugar[1], Paul Albertus[3], Tevfik Onur Mentes[5], Andrea Locatelli[5], Pilar Segovia[2], Miguel Ángel Gonzalez-Barrio[6], Arantzazu Mascaraque[6] and A. A. Talin[1]; [1]Sandia National Laboratories, United States; [2]Universidad Autónoma de Madrid, Spain; [3]University of Maryland, United States; [4]Consejo Superior de Investigaciones, Spain; [5]Sincrotrone Trieste S.C.p.A., Italy; [6]Universidad Complutense de Madrid, Spain

Li_xCoO_2 (LCO) is a common battery cathode material that has recently emerged as a promising material for other applications including electrocatalysis(*1, 2*) and as electrochemical random access memory (ECRAM)(*3*). During charge-discharge cycling LCO exhibits phase transformations that are significantly complicated by electron correlation. While the bulk phase diagram for an ensemble of battery particles has been studied extensively, it remains unclear how these phases scale to nanometer dimensions and the effects of strain and diffusional anisotropy at the single particle scale. Understanding these effects is critical to modeling battery performance and for predicting the scalability and performance of electrocatalysts and ECRAM. Here we investigate isolated, epitaxial $LiCoO_2$ islands grown by pulsed laser deposition (PLD). After electrochemical cycling of the islands, conductive atomic force microscopy (c-AFM) is used to image the spatial distribution of conductive and insulating phases. Above 20 nm island thicknesses, we observe a kinetically arrested state in which the phase boundary is perpendicular to the Li-planes; we propose a model and present image analysis results that show smaller LCO islands have a higher conductive fraction than larger area islands, and the overall conductive fraction is consistent with lithiation state. Thinner islands (14 nm), with a larger surface to volume ratio, are found to exhibit a striping pattern which suggests surface energy can dominate below a critical dimension. When increasing force is applied through the AFM tip to strain the LCO islands, significant shifts in current flow are observed, and underlying mechanisms for this behavior are discussed. The c-AFM images are compared with photoemission electron microscopy (PEEM) images which are used to acquire statistics across hundreds of particles. The results indicate that strain and morphology become more critical to electrochemical performance as particles approach nanometer dimensions.

Understanding Disparate Atomic Arrangements at Interfaces in Palladium Nanocrystals During Hydrogen Absorption and Desorption Daewon Lee[1,2], Sophia Betzler[1,2], Colin Ophus[1], Mark Asta[1,2] and Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Solute-induced phase transformations are essential in energy material applications, including hydrogen storage and lithium-ion batteries. Solute intercalation into a host material generally leads to significant lattice expansion and lattice mismatch strain. Specific interphase boundary structures develop to compensate for the lattice mismatch strain, and dictate the phase transformations. Revealing the interfacial atomic arrangements and their formation mechanisms is pivotal to the understanding of solute-induced phase transformations. Hydrogen-induced phase transformations in palladium (Pd) is a classical study model. The palladium hydride (PdH_x) comprises a hydrogen-poor α and a hydrogen-rich β phases. The structural transformations between α and β phases are well explained at the bulk level; however, the dynamic atomic arrangements at the interphase boundaries during the hydrogen-induced phase transformations have not been achieved.

We utilize the advanced high-resolution *in-situ* liquid cell TEM (LCTEM) to directly observe hydrogen-induced phase transformations in individual Pd nanocrystals at the atomic level. We loaded the Pd nanocubes in an aqueous solution into the liquid cell. The molecular H_2 is generated inside the liquid cell *via* water radiolysis from electron beam irradiation. The hydrogen absorption in the Pd nanocrystals accompanies the propagation of a unique interfacial structure with a spatially broadened interphase boundary where both β- and α-PdH_x exist and lattice planes tilt. In contrast, the hydrogen desorption proceeds with the movement of an atomically sharp interface with edge misfit dislocations. Furthermore, we conduct a systematic study on the effects of Pd nanocubes with different sizes on the hydrogen-induced phase transformations. We observe distinctly different interfacial atomic structures and phase propagation dynamics and intermediate structures, indicating size-dependent lattice strain relaxation mechanisms. We perform theoretical calculations to understand the observed disparate interface structures during hydrogen-induced phase transitions in Pd nanocrystals. The insights from this work deepen our understanding of solute-induced phase transformations and may benefit materials/device development for renewable energy technologies.

GaSb for High-Performance Alkali Metal-Ion Battery Anodes Young-Han Lee, Do-Hyeon Kim, Jeong-Myeong Yoon and Cheol-Min Park; Kumoh National Institute of Technology, Korea (the Republic of)

Over the last decade, electric vehicles (EVs) that employ lithium-ion batteries (LIBs) have been successfully commercialized, and their market has rapidly expanded. However, EV batteries still require significant improvements in energy and power density, fast-charging capability, and high safety to be more competitive with combustion engine vehicles. It is challenging to fulfill all of these requirements using conventional LIBs. Therefore, new high-performance electrode materials for LIBs are highly required. Furthermore, sodium-ion batteries (SIBs) and potassium-ion batteries (PIBs) are promising next-generation rechargeable battery systems because Na and K are abundant (deposits of Na and K are approximately three and two times larger than that of Li, respectively) and are environmentally harmless.
This study introduces a high-energy-density GaSb compound anode and optimized nanocomposite fabrication route for superior alkali metal (M)-ion batteries (M= Li, Na, K). The GaSb compound was synthesized by a simple thermal synthesis method, and its electrochemical performance for alkali M-ion battery anodes was investigated. In addition, the reaction mechanisms of GaSb with Li, Na, and K-ions were clearly investigated using state-of-the-art analytical tools. To obtain optimized GaSb anodes, two nanocomposites of the chemically modified GaSb/reduced graphene oxide (rGO) and mechanically modified GaSb/amorphous carbon (a-C) are suggested. The GaSb/a-C shows better electrochemical performance than that of GaSb/rGO nanocomposite anode. Furthermore, the GaSb/a-C nanocomposite anode exhibits higher electrochemical performance than those of conventional carbonaceous anodes. The high-performance of GaSb/a-C was attained by three-step nanoconfinement and stabilization of GaSb nanocrystallites uniformly embedded in the C matrix, which was thoroughly demonstrated. Based on the electrochemical performance, the proposed GaSb/a-C nanocomposite can be a promising alternative anode material for alkali M-ion batteries.

***Operando* SAXS and Synchroton Based X-Ray Analysis for Insights into Se Reaction Mechanisms Confined in Ordered Mesoporous Carbon for Li-Se Batteries** Yelim Kwon, Junwoo Yu, Won-Sub Yoon and Ji Man Kim; Sungkyunkwan University, Korea (the Republic of)

Increasing demand for advanced rechargeable batteries, especially in an electric vehicle market, requires further progress to increase energy density. Lithium-selenium (Li-Se) battery is one of the promising candidates for next-generation rechargeable batteries due to their high energy density and good kinetics. However, there is the primary problem to be commercialized, which is called shuttle effect. It is caused by the dissolution of polyselenide from Se cathode into the electrolyte in the repetitive charging and discharging, resulting in capacity fading.
Herein, we report on ordered mesoporous carbon (OMC) to confine Se (Se/OMC) to suppress the shuttle effect by providing a sufficient capability for adsorbing dissolved polyselenide.[1] It shows improved electrochemical performances, like higher capacity, better cycle retention, and lower resistance. *Operando* small-angle X-ray scattering (SAXS) is a powerful technique to analyze the structure dynamics of mesoporous materials in real-time conditions during electrochemical reations. [2,3] *Operando* SAXS, an innovative investigation on the behaviors of selenium species in the nanopores of OMC materials, combined with ex-situ analysis by synchrotron-based X-ray absorption fine structure (XAFS), X-ray photoelectron spectroscopy (XPS), and high-resolution transmission electron microscopy (HRTEM) allows us to understand the role of mesopores and the reaction mechanisms of selenium in OMC.

Electrochemical Li Reaction Mechanism of Ge and High-Performance Ge Nanocomposite Anodes for Li-Ion Batteries Do-Hyeon Kim, Young-Han Lee, Jeong-Myeong Yoon and Cheol-Min Park; Kumoh National Institute of Technology, Korea (the Republic of)

Rechargeable Li-ion batteries (LIBs) are representative and continuously developing energy storage systems owing to their wide applicability in electric vehicles and portable electronics. Conventional rechargeable LIBs are typically composed of carbon-based graphite anodes and Li–transition metal oxide cathodes and exhibit good cyclic behavior owing to their distinctive Li intercalation reaction. However, the reversible capacity of LIBs is low owing to the low theoretical Li storage capacity of the electrodes (graphite anode: 372 mAh g^{-1} and $LiCoO_2$ cathode: ~140 mAh g^{-1}). Because the cathode materials are limited to Li–transition metal oxides, research on increasing the capacity of LIBs has focused on anode materials. Among the alternative anode materials for high-capacity LIBs, Li-alloy-based group-IV elements (Si, Ge, and Sn) have been actively studied because they can store many Li ions, thereby affording high theoretical Li storage capacities. However, these group-IV elements pose a fatal problem in that their capacity decreases during cycling due to the significant volume change during the continuous cycles. Among the group-IV elements, Ge is a highly researched anode material for LIBs owing to its high theoretical Li storage capacity and higher electrical conductivity compared to that of Si. However, Li reaction mechanism of Ge have not been

definitively established due to the formation of various and complicated Li-Ge alloy phases during lithiation/delithiation.
In this study, the electrochemical Li reaction mechanisms of nanocrystalline Ge were elucidated by applying various cutting-edge *ex situ* techniques, namely, X-ray diffraction, extended X-ray absorption fine structure, X-ray absorption near edge structure, and high-resolution transmission electron microscopy. Moreover, Ge-based nanocomposites (Ge/C and Ge/Al_2O_3/C) were synthesized using a simple one-pot mechanical solid-state method to enhance the electrochemical Li storage characteristics of Ge. The Ge/Al_2O_3/C comprising nanocrystalline Ge with Li-inactive Al_2O_3 and C matrices exhibited superior electrochemical performance compared to that of Ge/C. Thus, Ge/Al_2O_3/C is suggested as a new Ge-based nanocomposite anode material for high-performance LIB anodes. Furthermore, the roles and effects of the Li-inactive Al_2O_3 and amorphous C matrices were revealed using various analytical tools. We anticipate that the electrochemical Li reaction mechanism of Ge and the resulting high-performance nanocomposite anodes will be highly useful in investigating high-performance Ge-based anodes for LIBs.

5:00 PM CH01.05.05
STEM-Based Techniques to Characterize Nanoscale Point Defects Formed Under Molten Salt Corrosion Sean Mills[1,2], Ryan Hayes[1], Steven Zeltmann[1], Raluca Scarlat[1] and Andrew M. Minor[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Extreme nuclear reactor environments require materials to maintain their integrity all while a range of processes act in unison to degrade their performance. Integral features of these processes are that defects produced under irradiation directly limit or accelerate the corrosion rates. Moreover, in molten-salt reactor environments, previous experimental work has shown that Cr dealloying is strongly coupled to the microstructure evolution of these alloys. Connecting corrosion attack with alloy microstructure such as grain boundaries and accumulating point defects is imperative to understanding underlying mechanisms. However, the trends associated with varying salt chemistry, temperature, and irradiation dose are not intuitive, and a mechanistic understanding of the associated thermodynamics and kinetics remains unknown. A close inspection and tracking of point defects such as vacancies and interstitials would be essential for the understanding of material behavior under complex molten salt corrosion environments. The recent developments in 4D-STEM with high-speed direct electron detectors and atomic resolution STEM allow mapping vacancy distributions at the nanoscale and their associated strains, both of which have far-reaching implications for detailed analysis of complex irradiation / corrosion damage.

This work aims to understand, through experiments and modeling, the mechanisms that govern corrosion in LiF-NaF-KF eutectic salts (FLiNaK), and how they are correlated to microstructure evolution in the metal alloy. Here, implement techniques including 4D-STEM strain mapping and high-resolution STEM-EDX/EELS elemental mapping combined with computational modeling based on density functional theory to analyze the migration of these point defects with respect to local changes in composition around corrosion pores. Using this approach, we explore the defect map surrounding boundaries and interfaces where rapid transport occurs during a series of diffusional process. At elevated temperature, formation of a passive oxide layer is suited to protecting the metal-salt interface, however, oxide layers formed in oxygenated molten salt environments are neither stable nor protective. It is understood that Cr tends to leach into the salt, in combination with the breakdown of these protective layers, and the reaction is accelerated at discrete sites such as surface pitting and further corrosion in a creviced region obtained from microscopic SEM observations of the sample surface and the cross-section. Moreover, alloying elements (Cr oxidants) are selectively removed via a redox reaction to form metal halides which may act as a mechanical barrier to continued corrosion attack. Phase field modeling has shown that these microstructural coupling trends vary for selective dissolution from a binary (e.g. Cr dissolution from NiCr). Further, we conduct simultaneous EDX-STEM and 4D-STEM mapping in situ at elevated temperatures to track time / temperature sensitive corrosion behavior within an isolated salt-filled pore. Concentrations and distributions of point defects that form by surface diffusion or by bulk lattice diffusion in response to Cr migration and leaching at the metal-salt interface are measured. This extensive study fundamentally improves the understanding of the complex corrosion and irradiation processes and provides a new pathway for engineering materials designed in future nuclear energy systems. The project is part of FUTURE Energy Frontiers Research Center (EFRC), which aims to study how the coupled extremes of irradiation and corrosion work in concert to modify the evolution of materials by coupling experiments and modeling that target fundamental mechanisms.

5:00 PM CH01.05.06
Interfaces in Lithium-Ion Batteries—Advanced Chemical and Morphological Characterization of the Solid Electrolyte Interphase Gilles Bonneux[1,2], Nicolas Cachot[1,2], Kun Feng[3] and Frank U. Renner[1,2]; [1]Hasselt University, Belgium; [2]imec, Belgium; [3]Umicore, Belgium

As the market share of electric vehicles (EVs) and mobility is expected to rise immensely over the next decades, the demand for improved energy storage technologies is currently at an all-time high. Li-ion batteries attract most attention due to their high stability alongside excellent volumetric and gravimetric energy density. One of the most important factors influencing liquid-electrolyte battery performance and lifetime is the solid-electrolyte interphase (SEI), formed at the interface between anode and electrolyte. A stable SEI is critical towards the cyclability of the cell, as its formation process leads to the (irreversible) immobilization of lithium ions inside this layer. This is especially the case for Si-based anodes, as their large volume changes during cycling will damage the integrity of the SEI layer. SEI reformation after each cycle eventually leads to undesired capacity fading. Beyond silicon-based anodes, metallic Li could be considered as the ultimate anode material due to its exceptional theoretical capacity and lowest electrochemical potential. However, many challenges surround its practical application in both liquid electrolyte and all-solid-state batteries. Due to the high reactivity of Li metal, reactions and degradation processes taking place at the interface often have a strongly negative impact on the battery stability and performance. In addition, dendrite formation issues are well known, even for solid-state electrolyte systems.

In-depth study of these interfaces often relies on advanced characterization methods for the investigation of their morphology, mechanical properties and chemical composition. However, due to the complex nature and reactivity of these interfaces, this is often challenging. Alongside real electrode samples, planar model systems with a well-structured interfacial region could provide supporting information and a better understanding of the processes taking place at the surface. By combining cross-sectional electron microscopy (FIB-SEM) with surface sensitive imaging (AFM), the morphology of the interface region can be investigated in detail. Compositional analysis of the SEI and (buried) electrode surface can be achieved with XPS/HAXPES. By combining multiple x-ray energies, the chemical environment can be probed at various depths, which allows non-destructive profiling. The ultimate goal of this study is to integrate these results, providing a deeper look into the early stages of SEI formation and reduction processes taking place at Si-based materials (Si/SiOx or Si/C composites) and metallic Li anode interfaces. This knowledge could lead to advancements of current state-of-the-art battery systems and even provide further insights towards new generation Li-ion battery technologies.

5:00 PM CH01.05.07
Raman *In Situ* Monitoring of Concentrated Solutions for Copper-Based Redox Flow Batteries Pier Carlo Ricci[1], Stefania Porcu[1], Giampaolo

Lacarbonara[2] and Catia Arbizzani[2]; [1]Univ Cagliari, Italy; [2]Alma Mater Studiorum - Università di Bologna, Italy

Nowadays the scientific community is at the forefront of the fight against climate change, exemplified by the targets set in the Paris Accord, and the goal of a zero-carbon, sustainable economy. These goals can be only achieved with a higher share of renewable energy, which being mostly of an intermittent nature, require innovative energy storage solutions deployable at large scale. A vast capacity of stationary energy storage must be created, and redox flow batteries (RFB) are one of the best technological solutions to provide it. However, multiple hurdles have to be overcome to make such deployment possible; they are of different nature, ranging from technical aspects related to performance (e.g. long cycle life or electrolyte composition optimization) to economic ones (e.g., the need to reach a competitive levelized cost of energy and to raise vast capital sums), and from environmental issues (e.g., toxicity and recyclability) to the security of supply (e.g., dependence on critical raw materials from outside of the EU or on a shallow market dependent on the production of a by-product of a non-related material).
Within the project CUBER (financed by the EU community grant number 875605) we are developing to validate in a relevant environment, a low-cost and scalable stationary energy storage technology, based on redox flow battery systems, with a proven superior environmental performance based on a non-critical and earth-abundant material (copper).
One of the main problems related to the developing of this new class of battery is the solubility problem of the high concentrated solutions.
In this regards the spectroscopic characterization and Raman measurement, in particular, can be very useful to deep understand the presence and the nature of the residues.
The stability of the solution was studied and verified with in-situ monitoring of the solution as a function of time and temperature. The measurements were acquired with BW-TEK: i-Raman® Plus, fiber-coupled Raman system with excitation at 1064 nm to avoid luminescence. The system permits to monitor of the presence of CuCl2 Raman features in the solution and helps in the definition of the temperature at which the first residues are observed. The samples were kept at 60 °C for 12 hours, then it is cooled down with different cooling rates. Remarkably, the highest temperature before the Raman feature of CuCl2 was observed depending on the cooling rate. If a slow rate is utilized, it seems that the stability is preserved for a wider temperature range, while for a faster cooling rate the precipitate was observed for higher temperatures.
The laboratory setup consists of a controlled thermal bath (40 °C) and a continuous flux obtained with a peristaltic pump at room temperature. We utilize two Raman probes, one at the beginning of the path and a second probe that monitors the effect of thermal shock.
The results confirm the possibility to verify the presence of residues and monitoring the system without the necessity to stop the flow and /or sample the solution.

Gallium-Based Nanocomposites for High-Performance Lithium-Ion Batteries Jeong-Myeong Yoon, Do-Hyeon Kim, Young-Han Lee and Cheol-Min Park; Kumoh National Institute of Technology, Korea (the Republic of)

With the development of various portable devices and electric vehicles, the importance of rechargeable batteries is increasing day by day. Among these rechargeable batteries, lithium-ion batteries are dominating the market due to their superior energy density and long cycle life. However, graphite, currently the most commonly used LIB anode material, has a relatively slow rate-capability and a limited theoretical capacity (LiC_6: 372 mAh g^{-1}). Li-alloy-based materials, such as Si, Sn, Ge, P, and Sb have high theoretical capacities and are therefore being researched as alternatives to graphite. However, these materials have a poor cycling behavior by the large volume changes during repeated cycling. Therefore, the search for high-capacity Li-alloy-based anode materials for LIBs that can overcome these shortcomings is highly required.
Among these materials, gallium (Ga) has unique characteristics such as low melting temperature and fluidity. It can also alloy with Li and forms Li_2Ga (762 mAh g^{-1}) phase, ensuring a high theoretical capacity. Nevertheless, Ga-based anodes are easily agglomerated during lithiation/delithiation due to its low melting temperature (29.8 ºC) and show a poor cycling behavior. In this study, various Ga-based nanocomposites were fabricated by a simple solid-state method and was applied as high-capacity anodes for LIBs. Among the various Ga-based nanocomposites, a Ga-based nanocomposite with Li-inactive metal carbide and amorphous C matrices was fabricated. The Ga-based nanocomposite with diverse matrices shows an enhanced reversibility with Li, high capacity retention of 525 mAh g^{-1} after 200 cycles, and fast rate capability of 401 mAh g^{-1} at 3C rate. Furthermore, the reaction mechanism between the Ga-based nanocomposite with Li was investigated thoroughly using various cutting-edge analytical tools.

Fabrication of Sulfide-Based Polymer-in-Ceramic Solid Electrolytes for All Solid-State Batteries and its Distinct Ionic Conductivity Characteristics Minjae Kim, JunHyeok Seo, Jinsol Im, Jinhyeok Ahn and Kuk Young Cho; Hanyang University, Korea (the Republic of)

There is a continuous increase in the demand for safe and high energy density lithium secondary batteries to cope with exploding needs from the mid-and large-sized batteries for electric vehicles and energy storage systems (ESS). Therefore, new electrode materials, such as lithium metal, high-nickel ternary cathodes, sulfur cathodes, and silicon anodes, have been investigated for post-lithium batteries that enable high energy density. Meanwhile, replacing the conventional liquid electrolyte with a solid-state electrolyte improves the batteries' safety and it is categorized as all solid-state batteries (ASSBs).
In this work, we present stable solid-state electrolyte systems for ASSBs using the sulfide-based electrolyte that demonstrates high ionic conductivity over 1 mS/cm. We could successfully obtain thin free-standing solid-state electrolytes with the polymer-in-ceramic composite approach. We propose a model composite system that can be fabricated and investigated in the open-air atmosphere. The model composite system provides optimum fabrication conditions for the moisture-sensitive solid-state electrolyte. In addition, we, for the first time, confirmed different ionic conductivity behavior with the applied pressure for the fabrication compared to the solid-state electrolyte made only from sulfide inorganic particles. Our result shows that much unexplored in the thin, free-standing solid-state electrolyte requires detailed investigation.

Prevention of the Transition Metal Crossover from High-Nickel NMC Cathode Using Ceramic-Coated Separator with the Ion-Trapping Ability JunHyeok Seo, Minjae Kim, JuYeon Im and Kuk Young Cho; Hanyang University, Korea (the Republic of)

Nickel-rich lithium nickel-manganese-cobalt oxide cathodes (NMC) are gaining significant attention in both lithium-ion batteries (LIBs) and lithium metal batteries (LMBs) as high-energy cathode material due to the material's relatively high capacity. However, nickel-rich NMC cathodes suffer from capacity fade during electrochemical cycling due to the degradation resulting in transition metal dissolution from the cathode. This migrates to a lithium metal anode and forms a solid electrolyte interface (SEI). In addition, the deposited metals have been proposed to catalyze further electrolyte solvent reduction, resulting in additional trapping of lithium ions at the anode in the form of the salts that comprise the degradation products. Thus, preventing the transition

metal movement to the lithium metal anode surface is important.
In this study, we designed a new ceramic-coated separator (CCS) using an inorganic particle demonstrating ion-trapping ability. We investigated various parameters that influence ion-trapping performances. The results show that sophisticated control of the surface modification of the inorganic particle allows significant improvement in the prevention of transition metal crossover to anode surface leading to enhanced electrochemical performances of the LMB. Our research suggests that preventing the migration of transition metal ions to the lithium metal anode surface is essential to improve LMB performance.

***In Situ* Probing of the Interfacial Forces at Play on Catalytic Gold Surfaces** Leo Sahaya Daphne Antony[1], Loriane Monin[1], Mark Aarts[2] and Esther Alarcon-Llado[1]; [1]AMOLF, Netherlands; [2]imec, Belgium

Electrocatalysis is one of the green energy technologies which employs the use of chemical reactions to convert an unwanted feedstock into a useful energy product. The most common electrocatalysts under an investigation like Pt, Au, Cu etc. are both expensive and unpredictable due to the dynamic nature of their surface morphologies during catalysis. The recent emphasis on the surface structure of catalyst due to the electrode-electrolyte (solid-liquid) interface highlights the complexity of the surface under study and the differences that arise due to electrolyte compositions. Probing catalytic surfaces in the solid-liquid interface can provide useful information about the surface structure and composition of different ionic species (adsorbed on the catalyst surface).
In this work, we highlight the use of the in-situ Electrochemical-AFM technique to observe the local changes on gold catalyst surfaces during catalysis. In addition to local topographical information, our scanning probe also maps the local nano-mechanical properties of the catalyst under study. We measure the adhesion force between the probe and the Au catalyst under applied potentials in electrochemical conditions. These in-situ adhesion force measurements can then be exploited to learn the work of adhesion which provides useful information about the electrostatic, Vander Waals, and Electric Double Layer forces under play on the catalyst surface. To highlight the important differences in the catalytic system, we study the behavior of both polycrystalline gold film on Si substrates and single crystalline gold nano-triangles on ITO substrate in sulfate-based electrolytes. This work further highlights the nanoscopic and microscopic inhomogeneity of the solid-liquid interface structure.

5:00 PM CH01.05.18
Cobalt Coated 460FC-Based Metallic Interconnects for Solid Oxide Fuel Cell Dong-Heon Han, Seung-Ju Oh, Jae Uk Yoon, Insun Woo, Hyun-su Park, In-Seo Park, Woong Heo and Jin Woo Bae; Korea University of Technology and Education, Korea (the Republic of)

Solid oxide fuel cells (SOFCs) show excellent fuel efficiency, power reliability, lower emission, and inexpensive operating cost, as compared to other electrochemical devices. Recently, 460FC-based Fe-Cr alloy have been developed as metallic interconnect for SOFCs. However, serious problems caused by the diffusion of Cr and the growth of Cr-based oxide of 460FC-based Fe-Cr alloy during oxidation at high temperature reduce the power efficiency of SOFC. Co-based oxide layer can improve the oxidation properties of metallic interconnects at high temperature due to inhibiting the diffusion of Cr and retarding the growth of Cr-based oxide during oxidation at high temperature. Here, Co protective layer was deposited on 460FC-based Fe-Cr alloy by the electroless plating method and then oxidized at high temperature. The oxidation characteristics of Co-coated 460FC-based Fe-Cr alloy at high temperature was analyzed and compared with non-coated 460FC-based Fe-Cr alloy using X-ray photoelectron spectroscopy (XPS), focused ion beam-scanning electron microscope (FIB-SEM)/energy dispersive spectroscopy (EDS), X-ray diffraction (XRD) and area specific resistance (ASR). The Co protective layer of Co-coated 460FC-based Fe-Cr alloy was thermally oxidized to Co_3O_4 during oxidation at high temperature, which shows lower resistance than Cr-based oxide. It is confirmed that the presence of continuous Co_3O_4 layer inhibited the diffusion of Cr and retarded the growth of Cr-based oxide effectively during oxidation at high temperature. Therefore it is believed that the oxidation properties of metallic interconnects at high temperature is enough to apply to the SOFC.

5:00 PM CH01.05.19
Development of High-Resolution STEM Methods to Map Diffusional Transport of Point Defects Produced via Kirkendall Diffusion Dongye Liu[1], Sean Mills[2,1] and Andrew M. Minor[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

In nuclear reactors, irradiation damage tolerance can be increased by utilizing interfaces as vacancy sinks. Degradation mechanisms at interfaces can involve complicated defect production and evolution. Specifically, Kirkendall void formation has been attributed to the imbalance diffusion between two species of atoms, and as a result, this is counteracted by a flux of vacancies across the metal-metal interface, accumulating locally at grain boundary or dislocations to form voids. Current methods for probing accumulation and mobility of these vacancy-type point defects are largely based on bulk measurements (X-ray diffraction (XRD) and positron annihilation spectroscopy (PAS)) that do not provide the spatially resolved information necessary to track the early stage of interdiffusion at a bi-metal interface. 4D-STEM and high-resolution STEM methods have the potential to provide details on the formation of point defects by identifying changes in lattice parameters at the nanometer scale. This spatially resolved method is especially important for determining the influence of pre-existing microstructural features, such as grain boundaries or dislocations, and their role on defect kinetics. In this study, we consider a thin film bimetallic diffusion couple to track changes in vacancy concentration and Kirkendall void formation *in situ* at elevated temperatures. A Cu-Ni bimetal is utilized as an ideal specimen (both phases are miscible and no intermediate phase is expected to form) to correlate vacancy concentration fluctuation with Kirkendall void formation under designed in situ heating program. With high-resolution EDS, we track real-time motion and diffusivity/concentration of the solute atoms. 4D-STEM measurements map the local change in lattice parameter across the bimetallic interface, with custom patterned “bullseye” condenser apertures that are used to improve the accuracy of the lattice parameter mapping. DFT modeling is used to connect the divergence between solute induced lattice strain and vacancy-defect concentration. This extensive study fundamentally improves the understanding of interfaces in engineering materials (eg. Coating, welding joints, etc.) designed in future nuclear energy systems.

5:00 PM CH01.05.21
The Investigation of Well-Defined Structure and Grain Boundary on Nanocrystals Using Atomic Resolution TEM Seungkyu Kim[1,2], Jinsil Jang[1] and Myoung Hwan Oh[1]; [1]Korea Institute of Energy Technology, Korea (the Republic of); [2]UC Berkeley, United States

In past, identifying the mechanism of particle formation nearby ordered structures has been a challenge because there was no way to control the GB on nanocrystals. Recently our research group developed a process to control the grain boundary and defects on nanocrystals. Within these nanocrystals, we have succeeded in controlling the number, size, and orientation of the individual GBs, which is distinguished from disordered defects in polycrystalline materials. Therefore, observation of a responsive material to which energy is transferred and capturing the unknown variables according to the existence of defects/grain boundaries is essential to find out noble reaction pathways.

Herein, we study the grain boundary (GB) phase transition of nanocrystals with real-time monitoring atomic resolution TEM imaging. We aim to fabricate a well-defined core-shell structure sample capable of being a phase transition (ordered structure from disordered) by an external source (e.g. electron beam, heat), and enough to be confirmed atomic dynamics during TEM imaging. The formation of GB can be the matrix in which the reaction takes place. Observation of phase transformations according to external sources in GB can serve as a fundamental model for understanding nanostructure–property relationships. From this perspective, capturing unknown variables in defects/grain boundary formation enables the exploration of catalytic activity and noble reaction pathways for the electrochemical CO2 reduction reaction using TEM.

5:00 PM CH01.05.22
Preparation and Characterization of Highly Durable and Effective TiO_2-Based Pt Catalyst Support for Polymer Electrolyte Membrane Fuel Cell
Yongsug Tak, Jisu Kim, Chanmi Park, Eungjun Lee and Yonghun Yoon; Inha University, Korea (the Republic of)

Polymer electrolyte membrane fuel cells (PEMFCs) attracted attention as next-generation energy conversion devices since they use hydrogen as fuel and produce only water. PEMFC electrodes are mainly composed of a precious Pt metal and a carbon support which has large surface areas and high electrical conductivities. However, carbon materials such as carbon black, graphene, and carbon nanotubes can affect the electron transport environment and Pt catalyst stability. During the operation of PEMFC, carbon support corrosion can be caused by the high potential above 1.2 V at the cathode during start-up/shut-down and it will lead to the loss of Pt nanoparticles which results in the severe performance degradation. Metal oxide was prospectively suggested because it is stable in oxidizing atmospheres. Among them, TiO_2 has excellent chemical, electrochemical, and thermal stabilities. Furthermore, strong interaction between Pt and TiO2 can bring a higher electron density on Pt which can result in higher stability and enhanced catalytic activity for oxygen reduction reaction (ORR). However, it has two main drawbacks as a Pt catalyst support, low electron transfer and small surface area.
To overcome low electrical properties, TiO_2 was firstly doped with nitrogen. N-doped TiO_2 (TiON) produces Ti^{3+}-enriched TiO_{2-x} phases and the characterization with TEM, HR-PXRD, and XPS suggested that it affect the electrical structure and charge transport properties. Pt/ N-doped TiO_2 cathode enhanced electrochemical activity and improved durability. Secondly, Pt/Nb-doped TiO2 have a smaller Pt 4f binding energy than that of Pt/C and the H_{UPD} desorption and PtO reduction peaks in half-cell CV measurements supported higher stability. Nevertheless, modified TiO_2 with N or Nb are still lower electrically conductive than carbon materials. Hybridization of doped TiO2 with highly conductive materials can be a candidate for Pt support and pristine graphene was selected because of its high electrical conductivity, large surface area, and mechanical strength. Graphene was also doped with nitrogen. N-doped graphene (NG) exhibited higher electrical conductivity and catalytic activity and strengthened the chemical bonding between the support and catalyst, leading to the prevention of catalyst aggregation and the uniform distribution of platinum nanoparticles on the graphene support. NG-TiON hybrid support was analyzed with TEM, XRD, XPS and TG, and the investigation of electrochemical ORR activity and durability of Pt-supported with NG-TiON showed high stability and corrosion resistance with a performance degradation rate of only 9 % after 5,000 accelerated durability test cycles while the performance of Pt/C decreased 83 %. However, low surface area is an intrinsic drawback of TiO_2, compared to carbon.
In this study, the electrical conductivity of TiO_2 was controlled with Nb-doping, and SiO_2 precursor was added with a nonionic surfactant in the hydrothermal preparation of TiO_2 particles from precursors. It was expected that SiO_2 contributes to increase the surface area with the maintenance of TiO_2 structure and electrical properties by suppressing the agglomeration of TiO_2 during heat treatment. The effect of SiO_2 on the surface area of Nb-doped TiO_2-SiO_2 support was investigated by the addition of different amount of SiO_2 presursors. Pt supported Nb-doped TiO_2-SiO_2 were analyzed with X-ray photoelectron spectroscopy (XPS) and transmission electron microscopy (TEM), and their electrochemical properties were investigated with potentiostat/galvanostat and electrochemical impedance spectroscopy (EIS). Performance of Pt/ Nb-doped TiO_2-SiO_2 catalyst as a cathode in a single-cell system will be reported.

5:00 PM CH01.05.23
Synthesis Towards TiO_2/Graphene Nanocomposites to Enhance the Energy Storage Capability and Stability of Sodium-Ion Batteries Ahmed Al-Kamal[1], Christof Schulz[1,2] and Hartmut Wiggers[1,2]; [1]Institute for Energy and Materials Processes – Reactive Fluids, Germany; [2]Center for Nano integration Duisburg-Essen, Germany

Lithium-ion batteries (LIB) are widely used for powering electric vehicles, cell phone devices, and stationary energy storage because of their long cycle life and high energy density. However, due to the limited availability and high cost of lithium and lithium-ion storage materials, the demand is raising concerning the use of other materials to store energy. Sodium-ion batteries (SIB) could be used to replace LIBs because of the low cost of sodium and its virtually unlimited availability [1]. However, the drawbacks of SIBs are Lower energy density compared to LIBs, and the larger Na^+ ion radius of (1.02 Å) compared to Li^+ (0.76Å), leading to an immediate structure change during Na^+ insertion and extraction that may cause gradual capacity fade. Suitable combinations of cathode and anode materials can provide similar energy densities of SIBs and some types of LIBs. Regarding the anode, developing long-term stable, environmentally friendly, and abundant active materials is of particular interest. Titanium dioxide (TiO_2) has been selected because it is low-cost and non-toxic and features a moderate sodium insertion/extraction voltage (~0.7 V vs. Na/Na^+), which efficiently avoids sodium plating on the anode and provides a suitable working voltage when coupled with a cathode material [2]. However, TiO_2 has poor ionic and electronic conductivity limiting its performance and practical capacity. Therefore, integrating ultrafine TiO_2 into a highly conductive and stable graphene matrix achieves exceptional rate capacity and durability [3]. Herein, we report a facile and direct self-assembly method of TiO_2/graphene nanocomposites with a controllable graphene loading to enhance the capacity and stability performance of TiO_2-based materials. The TiO_2/graphene with a graphene loading of 20 and 30 wt. % was tested as an anode in SIBs. With the outstanding conductivity enhancement and synergetic effect between TiO_2 nanoparticles and graphene sheets, the nanocomposites exhibited excellent electrochemical performance with a higher reversible capacity of 281 mAh g^{-1} at 0.1C as compared to pristine TiO_2 (155 mAh g^{-1}) at the same rate. In addition, the nanocomposites could deliver a high reversible capacity of 154 mAh g^{-1} after 500 cycles at 10 C and a high average rate capability performance of 158 mAh g^{-1} up to 20 C. Overall. The formation of TiO_2/graphene composites prevents the agglomeration of the nanoparticles and provides a high specific surface area, thus leading to an increase in the electrochemical activity of the anode materials. In addition, different in-situ and ex-situ techniques were used to study the mechanism of sodium storage in an anode structure. The synthesized route of the nanomaterials and their outstanding performance provide a new strategy to synthesize advanced nanomaterials for Na-ion batteries applications.

Two Microscopes Are Better Than One – A Unique New Inspection Tool For Advanced Characterization by *In Situ* Combination of AFM and SEM Hajo Frerichs, Lukas Stuehn, Sebastian Seibert, Marion Wolff and Christian H. Schwalb; Quantum Design Microscopy GmbH, Germany

Combining different analytical methods into one instrument is of great importance for the simultaneous acquisition of complementary information. Especially the in-situ combination of two of the most powerful microscopy techniques – scanning electron microscopy (SEM) and atomic force microscopy (AFM) – enables completely new insights in the micro and nano-world. [1,2] In this work, we present a unique inspection tool that seamlessly combines SEM and AFM for inspection and process control of Micro- and Nanostructures. Due to the self-sensing piezoresistive cantilever technology used for the AFM scanner the cantilever deflection signal can be measured completely electrical and allows for simultaneous acquisition of SEM and AFM data directly at the region of interest. We will present a variety of novel case studies to highlight the advantages this new tool for interactive correlative in-situ nanoscale characterization for different materials and nanostructures.

First results will focus on semiconducting $BaTiO_3$-based ceramics with positive temperature coefficient of resistivity (PTCR) that currently gain increased attention due to their application as cabin heater in electrical vehicles. We use electrostatic force microscopy (EFM) in combination with the SEM in order to precisely analyze the grain boundary potential barriers of different $BaTiO_3$-based samples. [3] The grain boundaries were located by backscatter electron detection (BSE) and afterwards measured with in-situ EFM. The barriers were shown to be significantly thinner and more pronounced as the amount of SiO_2 was increased from 0 to 5 mol%. These results can be directly correlated with electron backscatter diffraction (EBSD) measurements to link the AFM and SEM data to the crystallographic microstructure of the different samples.

In addition, we will present first results for the in-situ characterization of nanowires that will be used for energy harvesting applications. The SEM enables the easy location of individual or multiple nanaowires, whereas the in-situ AFM allows the characterization of topography, surface roughness, mechanical, and electrical properties of the nanowires.

Based on the broad variety of applications regarding the inspection and process control of different materials and devices, we anticipate that this new inspection tool to be one of the driving characterization tools for correlative SEM and AFM analysis in the future.

Operando Multi-Modal Synchrotron Study on Self-Discharge Behaviors of Li-S Batteries Pu Zhang[1,2], Molleigh Preefer[2], Johanna N. Weker[2] and Yi Cui[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Lithium-sulfur batteries (LSBs) are the next-generation energy storage alternative to traditional Li-ion batteries (LiBs). An LSB can pack twice the energy (550 Wh/kg for LSB vs. 260 Wh/kg for LiB), costs ~1000x less (sulfur: $46/ton vs. cobalt used in LiB: $50,097/ton), and has fewer harmful environmental impacts. If commercialized, LSBs could power long-lasting mobile devices EVs and replace LiBs for grid energy storage. However, during battery charging and discharging, intermediate-state chemicals, known as polysulfides, form and dissolve into the electrolyte, freely move inside an LSB and form by-products, shortening the LSB lifetime. Moreover, while the battery is not being used, these polysulfides continue to cause energy loss that amounts to over 50% of energy loss per month. This energy loss during resting, also known as self-discharge, is more prominent in LSBs than in LiBs.

Much of the attention has been focused on novel electrolytes and coatings to minimize polysulfide diffusion during cycling. However, the polysulfide diffusion kinetics during resting has not been thoroughly explored. Previous studies on minimizing self-discharge used electrochemistry before and after resting to estimate the polysulfide diffusion rate during resting. While electrochemistry is the gauge of the battery bulk performance, the behaviors of the particles locally could serve as direct evidence for fundamental properties in LSBs, such as polysulfide diffusion kinetics. The morphological, structural, and chemical changes required to understand the sulfur species' behavior during cycling could be applied to study the batteries during resting. I will discuss the operando findings conducted via Transmission X-ray Microscopy, X-ray Diffraction, and X-ray Absorption Spectroscopy. This multi-modal operando synchrotron study will guide the better design of Li-S batteries for longer cycle life and calendar life.

Tightly Coupled Experiment-Theory X-Ray Absorption Spectroscopy Characterization of Carbon Electrode in Vanadium Redox Flow Batteries Wenyu Sun[1], Namhoon Kim[1], Liwen Wan[1], Aaron Hollas[2], Qian Huang[2], Vijayakumar Murugesan[2], David Reed[2], Edwin Thomsen[2], Tony Van Buuren[1] and Jonathan Lee[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Pacific Northwest National Laboratory, United States

Vanadium redox flow batteries (VRFBs) are promising solutions to stationary grid energy storage given their advantages towards high efficiency, scalability, safety, near room temperature operation, and the ability for independent sizing of power and energy. Because VRFBs operate on redox couple reactions of V^{2+}/V^{3+} and VO_2+/VO^+ on the carbon electrodes, thorough understanding of the surface functionality of the carbon electrodes and their propensity to degradation during electrochemical cycles is prerequisite for the design of future VRFBs with extended lifespans. In this talk, we will present a tightly coupled experiment-theory approach based on X-ray absorption spectroscopy (XAS), to characterize the carbon electrodes prepared under different conditions and identify relevant functional groups that may give rise to unique spectroscopy features. A series of atomic models were created for different functional groups, including hydroxyl, carbonyl, methyl and carboxyl on representative carbons with either sp2 or sp3 bonding environment. The interactions between functionalized carbon and various solvated V complexes were explicated modeled using density functional theory. A library of carbon K-edge XAS were collected for all distinct carbons with different functional groups before and after interacting with solvated V complexes. Here we will demonstrate how these simulated spectra can be used to deconvolute the ex-situ measured experimental spectrum of carbon electrodes immersed in different solutions and cycled at different stages, and to determine the active species appeared on the carbon electrons that may dictate their performance.

Simultaneous Mapping of Hydration and Temperature in Proton Exchange Membrane of Fuel Cells Using Magnetic Resonance Imaging Darshan

Chalise and David Cahill; University of Illinois at Urbana-Champaign, United States

The efficiency of a proton exchange membrane (PEM) fuel cell is partly determined by the mobility of protons in the PEM, which depends on the hydration and temperature of the membrane. Due to the ability to provide non-invasive 3D images, spin-lattice relaxation time (T1) and spin-spin relaxation time (T2) contrast magnetic resonance imaging (MRI) of protons in PEMs has been suggested as methods to map hydration in the fuel cells. In this work, we show that while T1 and T2 imaging may be used to map hydration in PEMs under isothermal conditions, proton T1 and T2 are also functions of temperature. Different levels of hydration can have identical T1 and T2 values for different temperatures. Therefore, for PEM fuel cells, where current densities are large and thermal gradients are expected, T1 and T2 relaxation times cannot be used for mapping hydration. The chemical shift of the mobile proton is, however, a strong function of hydration but not temperature. Therefore, chemical shift imaging (CSI) can be used to map hydration. We further show, T1 and T2 imaging cannot be used for temperature mapping even when CSI has decoupled the information on hydration as same T1 or T2 can correspond to different temperatures for the same hydration. The diffusion coefficient, on the other, increases with both temperature and hydration. Therefore, CSI followed by direct imaging of diffusion via pulsed field gradients can be used for individual mapping of hydration and temperature in PEMs.

DFT Modeling of Solid State NMR—From Electronic Structure to Measurement of Acidity and Basicity of Oxide Materials Farahnaz Maleki and Gianfranco Pacchioni; University of Milano-Bicocca, Italy

Today one of the most powerful spectroscopic techniques available for the structural characterization and detailed investigations of solid materials is solid-state nuclear magnetic resonance (NMR). Density functional theory (DFT) calculations of NMR properties, in combination with experimental measurements, can provide reliable results for spectral assignments. Recently, we have studied DFT calculations of ^{17}O NMR chemical shift in zirconia surfaces and nanostructures. Our results showed that the ^{17}O NMR chemical shift is a sensitive probe of the coordination and electronic nature of zirconia surfaces or nanostructures.

On the other hand, solid state NMR spectroscopy is in principle a useful tool for probing the acidity and basicity of solid catalysts. We have studied the surface basicity in a series of alkaline earth metal oxides, by means of DFT calculations of the ^{17}O NMR chemical shift. The changes in the ^{17}O NMR chemical shift of the anions on the surface after adsorption of BF_3 and $B(OCH_3)_3$ exhibit a linear correlation with several other properties of the adsorbed molecules.

The ^{31}P NMR chemical shift of adsorbed trimethylphosphine, $P(CH_3)_3$, has been used to identify the presence of different facets in oxide nanocrystals and to study the acid–base properties of the adsorption sites. The NMR signal of adsorbed $P(CH_3)_3$ molecules has been studied for various oxide surfaces, facets, different coverages, and for both stoichiometric and reduced surfaces to titrate Lewis acid sites with ^{31}P NMR. The order of Lewis acid strength for oxides where cations have the same +IV oxidation state is $SnO_2 > TiO_2 > ZrO_2 > CeO_2$.

9:30 AM CH01.06.06

Impact of Aging Inverse Vulcanized Copolymeric Cathodes on Li-S Cell Performance Lisa Djuandhi and Neeraj Sharma; University of New South Wales, Australia

Lithium-sulfur(Li-S) cells possess a high theoretical capacity (1672 mAh g^{-1}) however they suffer from poor capacity retention over electrochemical cycling due to the dissolution and precipitation of redox active lithium polysulfides.[1] To minimize Li-S cell capacity loss, adsorptive cathode matrices such as porous carbons that physically confine redox species are typically used to impede detrimental effects from polysulfide migration.[2-5]

Besides physical confinement, strategies to improve Li-S cell capacity retention have also been reported by using copolymeric sulfur cathodes such poly(S-*r*-DIB).[6, 7] The copolymeric hydrocarbon moiety is a central part of cathode rational design despite ambiguity on the role of covalent carbon-sulfur crosslinks and factors governing degradation during cell operation. As such, despite promising effects, it is unclear whether copolymeric cathodes have reached their limits to improve the Li-S cell system and whether there is any scope in further optimization.

This work provides comprehensive analysis of the effects to Li-S cell capacity through aging poly(S-*r*-DIB) cathodes. The aged cathodes resulted in significant improvements in capacity retention (ca. 99%, 20th cycle @0.1C) compared to without aging (ca. 70%, 20th cycle @0.1C). This implies evolution of the cathode material upon aging and that different mechanistic effects are in play. Most pertinently, ^{7}Li NMR on aged cathodes revealed a stronger Li affinity to copolymeric hydrocarbons over non-hydrocarbon components, similarly observed in low molecular weight poly(S-*r*-limonene), which has also been demonstrated to produce superior benefits to cell capacity retention.[8] The developed NMR approach provides an unprecedented level of spatial and dynamic insight not only for copolymers but possibly for any organic electrode material, setting a new standard in the analysis of organic electrodes.

Understanding Interfacial Phenomena in Battery Systems—Addressing the Measurement Challenges Sofia Marchesini[1], Benjamen Reed[1], Helen Jones[1], Lidija Matjacic[1], Timothy E. Rosser[1], Yundong Zhou[1], Barry Brennan[1], Mariavitalia Tiddia[1], Rhodri Jervis[2,3], Melanie Loveridge[3,4], Scott A. Brown[5], Stuart D. Robertson[5], Rinaldo Raccichini[1], Juyeon Park[1], Andrew J. Wain[1], Gareth Hinds[1], Ian S. Gilmore[1], Alexander G. Shard[1] and Andrew J Pollard[1]; [1]National Physical Laboratory, United Kingdom; [2]University College of London, United Kingdom; [3]Harwell Science and Innovation Campus, United Kingdom; [4]University of Warwick, United Kingdom; [5]University of Strathclyde, United Kingdom

In the quest to reach Net Zero targets, the development of improved energy storage systems plays a key a role. However, Lithium-ion batteries suffer from stability issues that lead to capacity loss with time and use. Huge research efforts are being dedicated to improving the performance of existing lithium-ion systems, as well as pursuing new battery chemistries as viable alternatives. This challenge requires improved understanding of how battery systems work, as well as why their performance degrades with use, from the macroscale down to the nanoscale.

With most reactions occurring at surfaces and interfaces during battery operation, techniques that allow these surfaces to be characterised for both in operando and post-mortem settings are critical. However, the measurement of such complex and heterogeneous systems is not trivial and still lacks standards and guidelines for data collection and interpretation, which can lead to a lack of trust in the data. Without reliable materials characterisation data, accurate conclusions cannot be made and therefore the research and development of improved batteries will be hindered.

In this talk, I will demonstrate the measurement challenges for key post-mortem surface analysis techniques, namely focused ion beam scanning electron microscopy (FIB-SEM), X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, and time-of-flight secondary ion mass spectrometry (ToF-SIMS). I will describe the current best practice for these techniques and, specifically, I will provide key recommendations to improve the reproducibility of measurements, to enable both academia and industry to better understand the degradation mechanisms for these electrodes and aid in the development of better lithium-ion batteries.

Furthermore, I will show examples of typically used spectroscopy techniques (Fourier transform infrared and Raman spectroscopy) when applied to studying new electrolytes for use in magnesium battery applications in operando, during electrochemical cycling. The development and validation of “minimally-invasive” test protocols for in operando testing allows direct measurement of the material changes under realistic operating conditions, rather than ex-situ after battery teardown. To this end, the changes in the electrolyte during electrochemical cycling can be studied, which we have demonstrated can be used to study the mechanisms of plating and stripping.

Addressing the metrology challenges in the analysis of battery electrodes both in operando and ex-situ is key for the battery community and will ultimately lead to the improvement of existing battery systems and enable the transition to post lithium-ion technologies.

Multilength Scale *In Situ* Analysis of Nanomaterials at Johnson Matthey/Diamond Light Source Manfred Erwin Schuster; Johnson Matthey, United Kingdom

Studying nanostructured materials with atomic resolution by (scanning) transmission electron microscopy (S)TEM is nowadays routinely carried out to reveal their structural and electronic properties. These are considered key to understanding reactivity. A much deeper and more robust level of understanding of reaction mechanisms can be achieved by imaging catalyst dynamics in their catalytic active state usually at elevated temperatures and pressures in a liquid or gas environment. This approach is at the heart of the research at Johnson Matthey to design improved catalytic materials.
In this contribution I will showcase experiments carried out with a DENSsolution Climate gas flow system used in JMs aberration corrected ARM200F electron microscope located within the electron Physical Sciences Image Center (ePSIC) at the UK synchrotron facility Diamond Light Source. I will discuss a recent development which enables us to utilize our TEM in-situ gas cell at the nanoprobe beamline I14 of the DLS [1]. This capability allows us to carry out multilength scale in-situ experiments by combined TEM and nanoprobe XANES, thereby linking dynamics observed on a nm- scale with those at the um scale.
I will show examples of advanced characterisation developed and applied to materials relevant in Power to gas technologies.

Atomic Scale Imaging of Li Vacancies in a Li-Ion Battery Cathode Material via Multislice Electron Ptychography Dasol Yoon, Yao Yang, Dong Ren, Hector Abruna and David A. Muller; Cornell University, United States

Understanding Li diffusion remains challenging for the development of battery materials, especially due to the difficulties associated with simultaneous imaging of both light and heavy elements at the atomic scale. In this talk, we demonstrate the power of multislice electron ptychography on four-dimensional scanning electron transmission microscopy (4D-STEM) dataset, which allows atomic-scale imaging and depth sectioning of light and heavy elements at the same time. The depth sectioning reveals Li vacancies within a lithium nickel manganese cobalt oxide (NMC-111) cathode material and opens up possibilities of better understanding the Li diffusion mechanism.

Multislice electron ptychography solves the multiple scattering problem by retrieving phase information using a 4D-STEM dataset. This technique is enabled by a fast high-dynamic-range electron microscope pixel array detector, which records a full distribution of momentum transfer at every probe position—unlike conventional detectors such as annular detectors [1]. This allows us to image both light and heavy elements at a resolution of < 20 pm in a dose-efficient manner [2, 3]. In some cases, the lateral resolution is no longer limited by instrumental errors, such as lens aberrations, but by fundamental thermal fluctuations of atoms [3]. Another major advantage of using multislice ptychography is that it retrieves a three-dimensional atomic structure. By iteratively solving the electrostatic potential of the sample at each slice along the depth direction, we are able to discover Li vacancies embedded in the cathode material.

***Operando* Visualization of Perovskite Structural Transformation Using Transmission Electron Microscopy for Light Emitting Diode Application**
Lan L. Nguyen, Martial Duchamp and Yeng Ming Lam; Nanyang Technological University, Singapore

Halide perovskite light-emitting diode (LED) has gained significant interest due to its cheap fabrication process, color tunability, and color purity [1]. Despite considerable achievements in the field, perovskite LEDs commercialization is still met with considerable challenges such as short-term stability, high driving voltage and intensity inhomogeneity [1-3]. Among these factors, high driving voltage is challenging to tackle as it is needed to inject and confine carriers for radiative recombination and can thus not be reduced [1]. As a result, perovskite LEDs often operate at a voltage above the perovskite bandgap, thereby, inducing electrochemical degradation and ionic migration that shorten the device lifetime [1]. Therefore, understanding degradation mechanisms of perovskite LEDs is imperative to design effective solutions to lower the driving voltage and impede degradation.
To facilitate our comprehension of perovskite degradation in LED, transmission electron microscopy (TEM) provides an invaluable tool for showing direct

observations of degradation pathways. A few *operando* TEM studies of perovskite devices were performed and showed interesting mechanisms. Jeangros et al. demonstrated the nanoparticle formation at the perovskite–hole TL interface at forward bias and void formation at perovskite–electron TL interface at reverse bias [4]. Amorphization of perovskite was also observed and was reversible under low heating [5]. Commonly, devices for *operando* TEM were prepared using focused ion beam which may introduce unwanted degradation from air exposure during sample transferring process and ion beam damage [4]. To solve these challenges, we devise a novel design of horizontal arrangement of different layers of perovskite LED that is fabricated directly on MEMS chips using electron beam lithography. Together with a hermetic set-up, the MEMs chips are transferred directly into TEM for *operando* measurements to preserve perovskite structural integrity. Non-exposure to air is shown to improve perovskite stability under electron beam, allowing for observation of degradation with minimal beam damage. Low-dose bright field images are recorded, denoised and reconstructed to follow perovskite structural alteration during LED operation.

This new perovskite LED design also creates new possibilities for tuning transport layers using sputtering and atomic layer deposition. The use of such techniques is previously minimized as ionic bombardment from sputtering and high temperature in ALD may damage perovskite [6, 7]. Additionally, our design allows for easy removal and redeposition of perovskite, eliminating the need to fabricate a new lamella-on-chip device for each *operando* measurement. All in all, the new LED configuration promises to ease preparation process for *operando* TEM measurement and provide opportunities for new material exploration.

Operando Investigation of Energy Storage Material Across Multiple Length Scale by Electron Microscopy Yuzi Liu[1], Xinwei Zhou[1], Likun Zhu[2], Wenquan Lu[1] and Zonghai Chen[1]; [1]Argonne National Laboratory, United States; [2]Indiana University Purdue University Indianapolis, United States

Lithium-ion battery is one of the most needed energy storage technologies and being used from portable electronics to electric vehicles. However, the capacity and energy density of current battery materials cannot meet the requirement for long lasting applications or long-range driving. In order to impove the performence and understand the fading mechanism of energy storage materials, various charicterizations were employed to study the working mechanism of the energy storage materials in real time. *In situ* characterization methods such as X-ray diffraction, X-ray absorption spectroscopy, coherent X-ray diffraction imaging and analytical scanning/transmission electron microscopy (S/TEM) were used to monitor materials evolution during electrochemical cycling. In the assembled battery device, the dimensions of the materials ranges from nanometers (single primary particles) to micrometers (secondary particles and some single crystal Si, Ge and ternary cathode material). The investigation at each length scale provides valuable insights about the battery materials. Electron microscopy is a versatile tool to study materials in wide range of length from atomic scale (S/TEM) to mesoscale (Scanning Electron Microscopy). We employed TEM and FIB-SEM to study structure and composition evolution of single particle Li-ion battery during electrochemical cycling. The all-solid state single particle battery was built in FIB-SEM. The morphology changes of micrometer-sized single particles during lithiation and delithiation was directly observed. The crystal structure transformation was investigated by S/TEM for fundamental understanding of how the materials fail from atomic level. The lithium dendrite evolution on electrolyte, electrodes and the mechanical contact between the electrolyte and electrodes along with electrochemical testing were studied to provide constructive solution for building battery with better performance.

This work was performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, and supported by the U.S. Department of Energy, Office of Science, under Contract No. DE-AC02-06CH11357.

11:45 AM CH01.06.12
***Operando* Electrochemical Atomic Force Microscopy of Model Electrocatalysts** Andrew Akbashev; Paul Scherrer Institute, Switzerland

Operando studies of model electrocatalysts can provide precise potential-dependent quantities that are vital for accurate assessment of theoretical models and predictions. The structural evolution of materials under highly oxidizing conditions represents a particular challenge for *operando*experiments. To gain the necessary insight into the surface behavior, one should combine advanced *in situ* characterization techniques with well-defined materials that can be directly compared to computational models.

In this talk, I will discuss how epitaxial oxide films can be used as model systems for real-time tracking of materials' evolution during electrocatalytic water splitting (OER). Specifically, I will show how *operando* electrochemical atomic force microscopy (EC-AFM) can be used to record tiny changes in the surface morphology during anodic corrosion of the perovskite $SrIrO_3$ surface. In the experiments, we employ epitaxial films of $SrIrO_3$ with a sharp step between the film and substrate, which allows us to precisely track the dissolution rates. The degradation of $SrIrO_3$ electrocatalyst was found to follow different potential-dependent leaching and dissolution profiles in acidic and basic electrolytes.

Ultimately, our work shows that (1) Sr leaching precedes perovskite dissolution by up to 0.8 V, leading to a wide voltage window of stability where water oxidation occurs on a Sr-depleted surface without significant corrosion; (2) the overall stability of perovskite oxides during electrocatalysis can be substantially improved by suppressing A-site leaching.

Ambient-Pressure X-Ray Photoelectron and Absorption Spectroscopy to Study Electrode Materials Under Working Conditions Verena Streibel; Technische Universität München, Germany

The combination of ambient-pressure X-ray photoelectron spectroscopy (APXPS) and X-ray absorption spectroscopy (XAS) has revolutionized our understanding of working functional interfaces by providing access to both the composition and chemical state of electrode materials under reaction conditions. This line of research has been enabled by technological advances on the analytical side and the development of tailored electrochemical cells compatible with spectroscopic requirements.[1] In the present contribution, we will discuss the development of XPS from a purely ultra-high vacuum (UHV)-based technique towards being able to collect spectra while catalytic reactions proceed at surfaces under (close-to) atmospheric conditions. The focus will be on electrochemical studies of electrode materials, especially those materials that are catalyzing the oxygen evolution (OER) and CO$_2$ reduction (CO2RR) reactions.[2–5] We will highlight the capabilities, advantages, and challenges of the developed electrochemical cell types and discuss the insights that have been generated using these approaches. Importantly, we will describe how a detailed understanding is commonly obtained by tightly integrating operando experimental observations with computational spectroscopy, i.e. by comparing measured spectroscopic fingerprints with first-principles simulated spectra.[6] While these experiments have so far mainly been performed at synchrotron end stations, multi-colored APXPS systems are starting to become available as lab systems with the advantage of providing flexible daily access for rapid feedback during material development processes. Within the German excellence cluster *e*-conversion, we have recently ordered a powerful and versatile lab-based APXPS system, available for user operation from summer 2023. Our APXPS features a vertically mounted electron analyzer, operable in gas phase or vapor environments of up to 100 mbar, while also being perfect for probing samples in contact with 'open' liquids. Three monochromatized X-ray sources (1.5 - 5.4 keV) allow us to probe surfaces as well as buried solid|solid, solid|liquid, and hybrid interfaces. A dedicated gas-phase manipulator enables *operando* experiments of heterogeneous (photo)catalysts in different gas atmospheres at a wide range of temperatures. A second, electrochemical manipulator features an 'open-liquid' three-electrode electrochemical cell, continuous electrolyte flow capabilities, and versatile connections for custom-made cells. In addition, surfaces and interfaces can be illuminated to investigate photo(electro)catalytic processes and modified photoelectrode properties or degradation processes. In this respect, we will discuss the possibilities and challenges of such lab-based systems. We will conclude with an outlook on future developments within the field of APXPS to study energy materials.

***In Situ* X-Ray Absorption Study of Electrocatalytic Carbon Dioxide Conversion to Multicarbon Organic Liquids at High Single-Product Faradaic Efficiency and Low Over-Potentials** Tao Xu; Northern Illinois University, United States

The conversion of carbon dioxide (CO2) to storable multi-carbon (with two or more than two C-C bonds) organic liquids by electrocatalytic reduction of CO2 provides a promising and value-added route to mitigate the greenhouse gas emission. Here, we present a family of carbon-supported transition and non-transition metals-based electrocatalysts with varing sizes that can electrochemically reduce CO2 to C2 and C3 liquid organic compounds with high single-product selectivity at relatively low potentials. The reaction mechanism is extensively studied by in-situ synchrotron X-ray absorption techniques that identify the dynamic evolution of the catalytic center. (Nature Energy, 2020, *5*, 623-632)

2:15 PM CH01.07.03
Probing Lattice Oxygen Oxidation in Electrocatalysts by Resonant Inelastic X-Ray Scattering Jan Bosse[1,2] and Andrew Akbashev[1]; [1]Paul Scherrer Institute, Switzerland; [2]ETH Zürich, Switzerland

Oxygen evolution reaction (OER) is the main bottleneck in water electrolysis. Under OER conditions, oxide electrocatalysts undergo structural degradation and can become amorphous. Lattice oxygen oxidation was proposed as a possible cause for the observed amorphization. However, because lattice oxygen oxidation is notoriously challenging to probe, its unambiguous detection in oxide electrocatalysts has been elusive so far.

I will show how oxygen oxidation can be detected in single-crystalline (model) oxide electrocatalysts using high-resolution resonant inelastic X-ray scattering (RIXS). For this, I will present the case study of perovskite materials where the emergence of oxidized oxygen depends on the transition metal and extent of oxygen intercalation. Finally, I will discuss how lattice oxygen oxidation is related to the degradation of oxide electrocatalysts during OER.

2:30 PM CH01.07.04
Unraveling Charge Carrier Dynamics in Cu3N Photocathodes Using In-Operando Transient Absorption Measurements During Photoelectrochemical CO2 Reduction Finn Babbe[1,1], Mohammed Ebaid[1,1], Noah Bussel[1,2], Jason K. Cooper[1,1], Shaul Aloni[1,1] and Adam Schwartzberg[1,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

A crucial challenge for the next century will be the generation and storage of renewable energies at relevant scales. A stepping stone for this is the generation of artificial fuels by electrochemical CO2 reduction into more useful products by utilizing solar energy as a source. An emerging semiconductor system for this is Cu3N, which has a 1.8 eV direct bandgap, high optical absorption coefficient, p-type doping, and high carrier mobility. Within this study, high-quality thin films are grown by direct nitridation of copper films sputtered on FTO covered glass substrates. Prepared thin films exhibit grains of up to a few micrometers and are phase pure as shown by X-ray diffraction (XRD) and Raman. Tested in a potassium bicarbonate solution (KHCO3) with potassium persulfate (K2S2O8) as an electron scavenger, simulating the charge transfer into a CO2 molecule, the electrodes initially show a low photocurrent. However over the course of a few hours of continued chronoamperometry measurements under 1 sun illumination the photo-current increases up to 3 mA/cm^2. Scanning electron images after the photo-electrochemical (PEC) testing show a restructured surface with voids and pits. In operando-Raman and in-operando Incoming Photon Conversion Efficiency measurements as well as ex-situ XRD and X-ray photoemission measurements show that no secondary phases or metallic copper forms. This indicates that the improved performance is inherent to the Cu3N electrodes. To investigate this behavior in more detail, we combined photo-electrochemical testing with ultra-fast pump-probe spectroscopy in the visible range. The transient absorption (TA) spectra exhibit four peaks related to two direct bandgap transitions from an unstrained Cu3N phase and a strained Cu3N phase shifted towards higher energies. Within the first hour of the prolonged PEC testing, the carrier lifetime increases from 70 ps to 150 ps indicating a reduction of non-radiative recombination. After this, the lifetimes continuously drop over 6 hours concurrently with an increased TA signal and measured photocurrent. The higher TA signal shows a higher carrier concentration within the semiconductor after excitation, while shorter lifetimes and increased current show an increased carrier injection efficiency into the electrolyte. TA measurements further indicate that carriers generated in the strained phase only contribute to the generated photocurrent indirectly by carrier diffusion into the lower bandgap unstrained materials within the first 5 ps. In summary, the combination of photo-electrochemical and transient absorption measurements allows direct insights into the charge carrier dynamics under operational conditions showing the charge carrier generation, transport, recombination, and injection into the electrolyte. Thus paving the way for the rational design of efficient and selective PEC systems.

2:45 PM *CH01.07.05
The Structure of the Electrical Double Layer on Suspended Graphene in Contact with Salt Solutions Miquel B. Salmeron[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The structure of interfacial water near suspended graphene in contact with aqueous solutions of Na_2SO_4, NH_4Cl and $(NH_4)_2SO_4$ was studied using confocal Raman spectroscopy, sum frequency vibrational spectroscopy (SFVS) and Kelvin probe force microscopy (KPFM). SO_4^{2-} anions were found to preferentially accumulate near the interface at open circuit potential (OCP), creating an electrical field that orients water molecules below the interface, as revealed by the increased intensity of the O-H stretching peak of fully H-bonded water. No such increase is observed with NH_4Cl at OCP. The degree of orientation of the water molecules as well as the electrical double layer strength increased further when positive voltages are applied. We show that preferential anion-accumulation at the interface at OPC is driven by segregation from the solution bulk, and is not driven by electrostatic effects nor by formation of specific chemical bonds, which is impeded by the large energy required to desolvate sulfate anions. The first water layer in contact with graphene has dangling O-H bonds that point to the graphene with an intensity that remains unchanged in both with salt concentration and with increasing positive potentials. However the first water layer undergoes a chemical interaction with graphene at negative values that decreases the intensity of the dangling bond peak and redshifts its frequency, pointing to orbital hybridization between dangling H and graphene.

3:45 PM CH01.07.06
Many-Body Contributions to X-Ray Spectroscopy and Relevance to Interfacial Characterization David Prendergast, Subhayan Roychoudhury and Ana Sanz-Matias; Lawrence Berkeley National Lab, United States

X-ray spectroscopy is an invaluable tool for the analysis of materials, their surfaces and interfaces. However, studies of functional materials, especially in interfacial contexts, are likely to explore atomic and electronic structure that does not have a pre-existing set of standard spectra, due to the limited, nanoscale dimensions of the interfacial zone or due to the transient nature of its state under operando conditions. Therefore, first-principles simulations can be a vital component in the design of such experiment, either for predicting possible spectral outcomes or interpreting existing measurements. We report on recent advances in the use of a Slater determinant many-electron representation for X-ray transition amplitudes to provide more accurate estimates and more facile interpretation of X-ray absorption, emission and resonant inelastic scattering spectroscopies. The same approach can also provide atom-by-atom interpretation of Electron Energy Loss Spectra (EELS). Applications will be presented in various materials contexts of relevance to energy conversion processes.

4:00 PM CH01.07.07
Real-Time Probing of Interfacial Processes in Oxygen-Evolving Oxide Catalysts Tzu-Hsien Shen and Vasililki Tileli; EPFL, Switzerland

Operando characterization techniques are indispensable for understanding the catalysts evolution during operation. Electrochemical liquid-phase transmission electron microscopy (ec-LPTEM) grants the capability of real-time imaging of electrochemically-induced processes in liquid media. Herein, we describe the advancements of ec-LPTEM towards studying the solid-liquid-gas interfacial processes occurring on Co-based oxide oxygen evolving catalysts [1]. By performing real-time measurements, we can associate the potential-dependent variation of the local contrast to the effects that precede the electrocatalytic reaction such as electrowetting and redox-induced reactions. Further, through optimization of the microcell, we report on the direct probing of the evolution of molecular oxygen by *operando* electron energy loss spectroscopy (EELS). Similar experiments on IrO_2 particles indicate the capability to separate the contribution of different components in the EEL spectra, providing qualitative maps of O_2 and liquid electrolyte, and demonstrating that ec-LPTEM is a promising technique for probing interface phenomena in a range of electrocatalytic processes [2].

4:15 PM CH01.07.08
Operando pH Imaging to Investigate the Influence of the Micrometer-Scale Morphology on CO_2 Gas Diffusion Electrode Performance Annette Boehme[1], Aidan Fenwick[1], Rohit Bhide[2], Cassidy Feltenberger[2], Shane Ardo[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]University of California, Irvine, United States

We developed an experimental technique to map the local in situ pH value around operating CO_2 reduction gas diffusion electrodes with confocal laser scanning microscopy and two fluorescent ratiometric dyes. This allowed us to demonstrate that microcavities on the order of 5 µm on the surface of copper CO_2 reduction gas diffusion electrodes serve as local hotspots with enhanced activity for CO2 reduction, including multicarbon products.
Fluorescent confocal laser scanning microscopy is a very powerful tool because it allows to map an entire macroscopic sample in three spatial dimensions with sub-micrometer resolution. In combination with pH-sensitive fluorescent dyes, it offers the unique opportunity to probe the pH value within microstructures on the surface of a sample of interest such as an active gas diffusion electrode. As pH probes, we use two different commercially available ratiometric fluorescent photoacids with different sensing mechanisms. The first dye we use is 6,8-dihydroxypyrene-1,3-disulfonic acid disodium salt (DHPDS). Its pH sensing capacity is connected to proton-transfer reactions in its electronic ground state to perturb its absorption spectrum. We excite it with lasers at 458 nm and at 488 nm and collect the signal separately for both excitations between 405 nm and 754 nm. The ratio between the two signals is a measure for the local pH value and is independent of the local dye concentration. It is sensitive to pH values between 6 and 10. To extend the accessible pH range, we implemented a measuring protocol for a second novel pH probe, 8-aminopyrene-1,3,6-trisulfonic acid trisodium salt (APTS). Its sensing mechanism relies on quenching of its thermally equilibrated electronic excited state by direct proton transfer to aqueous OH^{-}. We excite this probe at 458 nm and collect the emission signal separately in the range 480-550 nm and 551-754 nm. The ratio between the two signals is sensitive to pH values between 11.2 and 14. This work presents the demonstration of APTS as a probe for the local pH value for the first time. By combining both probes DHPDS and APTS, we can cover pH values between 6 and 14 with a gap between 10 and 11.2.
We developed an experimental setup that uses these two dyes to probe the local pH value around an operating CO_2 reduction gas diffusion electrode made of carbon paper with a 300 nm copper catalyst layer. The pH-sensitive dyes are diluted in 100 mM KHCO3 electrolyte which is pumped through an electrochemical cell optimized for use with confocal microscopy. The pH is monitored under operation of the CO_2 reduction gas diffusion electrode with current densities as high in magnitude as 200 mA/cm^2. We can create three-dimensional maps of the pH value by collecting of the fluorescent emission from the focal point of the laser and scanning the laser beam over the sample. Using this technique, we could gain valuable insight into the influence of microstructures on the CO_2 reduction performance of a gas diffusion electrode. We demonstrated that narrow trenches in the electrode surface are local hotpots with enhanced CO_2 reduction activity and selectivity.

We expect that these insights will help inform the design of advanced gas diffusion electrodes for CO_2 reduction with enhanced efficiency and multicarbon product selectivity. Furthermore, the developed technique can potentially be used in other electrochemical applications where the pOH value plays an important role and could be extended to additional fluorescent dyes.

Mechanism Exploration of Hydrogen Evolution Reaction on Platinum Single Atom Catalyst Using Electrodeposition Technique Sohui Kim[1], Mansu Kim[2] and Dongmok Whang[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Northwestern University, United States

Due to global climate change and the energy crisis, the demand for low-cost, high-efficiency catalysts for hydrogen generation reaction (HER) is increasing. Platinum is the most suitable metal as the HER catalyst and has excellent catalytic activity compared with other transition metals. However, it is essential to reduce the amount of use in the catalyst due to its high cost and scarcity. The synthesis of Pt single atom catalyst is promising strategy to maximize atomic utilization efficiency and decrease the Pt content. In recent years, the research on Pt single atom catalyst has been actively conducted because of low platinum content and excellent catalytic activity per unit mass. However, it is tricky to synthesize highly uniform Pt single atom catalysts and interpret the distinguished catalytic activity of Pt single atom because Pt clusters or small nanoparticles could be unavoidably formed, and it led to remain obscure in interpreting the mechanism of Pt single atom catalyst. In this study, we developed a fast and facile method to synthesize single Pt atoms on carbon support (Pt SA/C) using electrodeposition technique. Pt particle formation was concisely controlled from Pt single atom to Pt nanoclusters (~2 nm) to Pt nanoparticles (3-5 nm). The very uniform Pt SA/C was identified through HR-TEM and XPS analysis, which is distinguished from the existing Pt single catalyst in which some platinum nanoclusters are coexist. The Pt SA/C displays excellent HER activity with a mass current density of 81.11 Amg_{Pt}^{-1} which is overwhelmingly superior catalytic activity compared to the recent research works. the HER mechanism on Pt SA/C was interpreted using DFT calculation and CO stripping analysis. In this study, the finely dispersed Pt SA/C was synthesized using the electrodeposition technique and the unique catalytic activity and HER mechanism were identified.

5:00 PM CH01.08.02
Synthesis of Highly Monodispersed Iron Oxide Nanocrystals in Various Well-Defined Sizes and Morphologies and Elucidation of the Reaction Mechanism Agnes Weimer[1,2], Artur Feld[1,2], Andreas Kornowski[1], Naomi Winckelmans[3], Jan-Philip Merkl[1], Hauke Kloust[1], Robert Zierold[1], Christian Schmidtke[1], Theo Schotten[4], Maria Riedner[1], Sara Bals[3] and Horst Weller[1,4,1]; [1]University of Hamburg, Germany; [2]Hamburg University, Germany; [3]Electron Microscopy for Materials Science, Belgium; [4]Fraunhofer-CAN, Germany

Magnetic nanoparticles are of significant interest and immense importance for research as well as technological application. These nanoparticles exhibit fascinating magnetic properties, including blocking temperature, coercivity, saturation magnetization, magnetic domain size, and exchange coupling effects, which are affected by size, shape, and crystal structure. [1–3]
For these outcomes, a new synthetic route was developed[4], based on the thermal decomposition of iron oleate. The oleate was synthesized by use of a novel precursor system - Fe(II)CO_3 and Fe_2(III)$(CO_3)_3$. The method allows the synthesis of highly monodisperse nanocrystals (NC) in various well-defined sizes and morphologies on a gram scale. Furthermore, the elaborated synthetic route accomplished a strict kinetic separation of the formation of iron oleate from the generation of reactive pyrolysis products and the subsequent nucleation during the synthesis.
Size and shape control was achieved by varying the concentration of the ligand oleic acid and the non-coordinating solvent 1-octadecene, the temperature and reaction time, so that octapod-shaped NC in a size range of 20-80 nm and cubic NC with sizes from 20-60 nm could be synthesized. With dilution, the size of the nanoparticles decreases significantly, while at higher concentrations, they become larger.
The octapod star-shaped morphology, formed shortly after nucleation as a kinetically favored product, could be characterized by a comprehensive structure analysis using transmission electron microscopy (TEM) and electron energy loss spectroscopy tomography (EELS-tomography). As a result of thermodynamic control they transformed into cube-shaped structures due to metamorphosis in 4 phases.
Furthermore, the hydrophobic NCs were transferred into water and encapsulated with a polystyrene shell, based on the seeded emulsion polymerization technique[5], providing biocompatibility and water solubility. This enables the way for a broad spectrum of applications.
Especially iron oxide nanocrystals can be used to effectively remove micro polystyrene particles via adsorption from water showing potential advantages of this particles for removing environmental pollutants by an environmental-friendly procedure.[6]
Finally, the goal is to optimize this synthetic approach so that it is biobased and sustainable. One way to do this would be to use bacteria[7] to produce particles via biomechanisms. However, such production methods using bacteria allow poor control of shape and size, so in the future, it would be purposeful to adapt the method presented here to a biologically synthesized strategy.

Advanced Electrocatalyst for Efficient Water Splitting Tao Jiang, wenjing zhang and Poul Norby; Denmark Technical University, Denmark

Transition metal sulfides for electrocatalysis have been a hot topic in recent years, because of their high intrinsic activity and excellent electrical conductivity, they have become one of the candidates for basic OER industrial catalysts. Herein, We have successfully synthesized iron-sulfur-doped nickel foam by organic solvent thermal method. We optimize the adsorption behavior of active intermediates at the interface, by inducing interfacial electron rearrangement of Ni and Fe_3O_4,Notably, The obtained catalyst exhibits remarkable OER catalytic activity, requiring only an overpotential of 297 mV to stably drive the OER reaction to a current density of 10 mA cm^{-2}. When applied for the total water splitting reaction, it exhibits excellent catalytic activity and excellent stability, and a current density of 10 mA cm^{-2} can be obtained at 1.57 V.

Additive-Driven Alternative Redox of Iron Oxides for High-Capacity and Reversible Aqueous Batteries Sathya Narayanan Jagadeesan; Worcester Polytechnic Institute, United States

Aqueous alkaline iron (Fe) batteries (AIBs) are promising energy storage systems because of the distinctive merits of Fe materials, including high abundance, low cost, nontoxicity, and multiple valent states. Conventional AIBs relying on a conversion storage mechanism at the Fe anode have limited faradaic efficiency and storage capacity due to the formation of electrochemically inert Fe_3O_4 upon discharging $Fe(OH)_2$ in the alkaline solution. Herein, we report the study of the redox behavior of iron (II, III) oxide materials containing α-FeOOH and Fe_3O_4 in NaOH solution with a low concentration silicate introduced to enable the one-charge transfer $Fe(OH)_2$/FeOOH reaction in the AIB anode and mitigate Fe_3O_4 formation. The system with silicate added exhibits an enhanced storage capacity and cycling life. Supported by experimental evidence, molecular dynamics simulations reveal that silicate additives strongly interacted with $Fe(OH)_2$ surface, inhibiting the water transport and favoring $Fe(OH)_2$/FeOOH over $Fe(OH)_2/Fe_3O_4$ conversion. This study paves a path to realizing green battery systems for efficient energy storage.

Lithium Phosphate Covered Reduced Graphene Oxide as Anode Material for Lithium-Ion Batteries Wei-Yi Huang, Wen Sun and Che-Ning Yeh; National Tsing Hua University, Taiwan

The solid electrolyte interface (SEI) formed between anode materials and the electrolyte is important for the cycling performance of the lithium-ion batteries, which promotes much research effort on studying the effect of SEI on the performance of the batteries. However, the complicated structures and chemical compositions of the SEI layer make it a complex component to understand. Therefore, investigating a specific component in the SEI can provide helpful guidelines to the design of electrolytes and artificial SEI. In this work, we chose lithium phosphate (Li_3PO_4), one of the attractive solid electrolytes, as an artificial SEI and studied the electrochemical performance of Li_3PO_4 covered reduced graphene oxide (r-GO) as anode materials for lithium-ion batteries. R-GO was produced by reducing graphene oxide using a hydrothermal process. Rather than typical coating methods such as sputtering or chemical vapor deposition, the process we chose for coating lithium phosphate layer on r-GO is through wet chemical synthesis. Since the formation of SEI occurs at all the interface between anode materials and the electrolyte instead of only the surface of the anode materials, wet chemical synthesis ensures high surface coverage of lithium phosphate on r-GO. The role of lithium phosphate on the electrochemical properties of SEI was investigated by studying the cycling performance and electrochemical impedance spectroscopy (EIS) of lithium phosphate covered r-GO as anode materials. This work provides insights for the design of artificial SEI which could effectively passivate the electrode, thereby improving the safety and cycle life of the lithium-ion batteries.

Investigating *In Situ* Corrosion Dynamics During CO_2 Reduction Using Inductively-Coupled Plasma Mass Spectrometry Katherine Yan, Kyra Yap, Gaurav A. Kamat, Adam C. Nielander, Michaela Burkes Stevens and Thomas Jaramillo; Stanford, United States

There is a critical need to develop new technologies for the sustainable production of carbon-based fuels and chemicals. The electrochemical CO_2 reduction reaction (CO_2RR) provides a path to meet this need, offering opportunities to use renewable electricity to drive the conversion of CO_2 into products such as ethylene, ethanol, and methane. A challenge limiting the implementation of CO_2RR is catalyst stability during reduction. Greater fundamental understanding is needed to uncover the governing physical and chemical factors as well as mechanisms of degradation in CO_2RR operating conditions. Catalysts of interest for CO_2RR include Ag and Au, but one particularly interesting catalyst is Cu, as it can form C_{2+} products. Changes to the Cu surface morphology can favor the formation of certain products.

The goal of this research is to quantify dynamic corrosion of Cu CO_2RR electrocatalysts. Specifically, we aim to probe the relationship between degradation rate and catalyst morphology changes and applied potential. Cu electrocatalyst degradation in CO_2RR conditions was examined in varying electrolyte pH, gas environments to isolate the effects of hydrogen evolution and CO_2RR, and potentiostatic conditions in Faradaic and non-Faradaic regions to determine the effect of catalysis. Atomic force microscopy (AFM) was used to characterize the electrode surface pre- and post- electrolysis by distinguishing nanostructures on the electrode surface and calculating surface roughness, which was found to be dependent on applied potential. While AFM allows for examination of the resulting morphology of electrode surfaces due to various experimental conditions, the use of inductively coupled plasma mass spectrometry (ICP-MS) enables on-line studies for quantifying catalyst degradation. Using a flow cell allows for simultaneous application of a potential and/or current density while sending electrolyte effluent to the ICP-MS to detect corroded catalyst species in trace amounts (low ppb level), coupling the examination of reaction and corrosion kinetics. On-line ICP-MS data indicates that during CO_2 reduction in potassium bicarbonate electrolyte, Cu degrades at negative applied potentials. Greater fundamental understanding of Cu morphology changes and degradation during CO_2RR conditions can help to steer selectivity towards desired products and improve catalyst performance. The use of on-line ICP-MS studies accelerates corrosion studies by enabling real-time measurements during reaction conditions. Elucidating the factors that drive catalyst degradation enables the assessment of the lifetime and long-term stability of electrocatalytic devices.

Asynchronous-to-Synchronous Transition of Li Reactions in Solid-Solution Cathodes Nikhil Sharma, Luize S. Vasconcelos and Kejie Zhao; Purdue University, United States

The composition dynamics regulate the accessible capacity and rate performance of rechargeable batteries. Heterogeneous Li reactions can lead to nonuniform electrochemical activities and amplify mechanical damage in the cell. Here, we employ *operando* optical microscopy as a laboratory tool to map the spatial composition heterogeneity in a solid-solution cathode for Li-ion batteries. The experiments are conducted at slow charging conditions to investigate the thermodynamic origins. We observe that the active particles charge asynchronously with reaction fronts propagating on the particle surfaces during the first charge, while subsequent (dis)charge cycles transition to a synchronous behavior for the same group of particles. Such transition is understood by computational modeling, which incorporates the dependence of Li diffusivity and interfacial reaction rate on the state of charge. The optical experiments and theoretical modeling provide insight into the reaction heterogeneity of porous electrodes and electrochemical conditioning for layered oxide cathodes.

Anisotropic Mechanical Properties of Single Crystalline NMC Cathode Materials for Li-Ion Batteries Nikhil Sharma and Kejie Zhao; Purdue University, United States

Nickel manganese cobalt oxides (NMC) are state-of-the-art cathode materials for Li-ion batteries. The layered lattice structure of NMC exhibits highly anisotropic strains upon Li intercalation, leading to particle fracture and interfacial delamination of the active particles from the conductive matrix. Such mechanical degradation becomes a crucial issue in pursuing high Ni-content and Co-free cathodes. Notably, the experimental information regarding the anisotropic mechanical properties of NMC cathodes is missing in the literature. In this study, we measure the stiffness constants of single crystalline NMC cathodes using environmental nanoindentation. The correlative measurements of the elastic stiffness and the lattice orientations allow us to fully determine the stiffness matrix. Furthermore, we compare the effective elastic indentation modulus, hardness, and fracture toughness of different NMC compositions. The complete information on the mechanical properties of NMC cathodes will enable accurate computational modeling and assist in designing and manufacturing durable rechargeable batteries.

Machine Learning for High Throughput Characterization of Oxide Nanoparticles Min Gee Cho[1,2], Mary Scott[2,1], Katherine Sytwu[1,2], Catherine Groschner[2] and Luis E. Rangel DaCosta[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Nanomaterials exhibit new properties that do not exist in the bulk state and have infinite potentials to be applied to key industrial technologies in the future, such as nanocatalysts, sensors/optical devices, and energy storage/conversion devices. A recent research trend is to control the size and shape of nanoparticles to increase the activity of catalysts of noble metals such as platinum and palladium, so that specific active sites are exposed on the surface a lot. As mentioned above, the catalytic activity is different depending on the surface facet. However, despite the development of nanoparticle synthesis, the individual particles cannot be perfectly identical. Each individual has a slightly different size and shapes even if the nanoparticles are synthesized under the same synthesis conditions. For this reason, there is a limitation in directly correlating the surface structure of nanoparticles with catalytic activity.
In this study, we focused on this point and imaged hundreds of thousands of individual nanoparticles with a high-resolution transmission electron microscope (HRTEM), and put these images into a trained neural network to extract key features of nanocrystals and obtain statistical distributions. Achieving the goal of developing a pipeline for the characterization of nanocrystals with high-throughput microscopic data requires machine learning analysis. We used a convolutional neural network (CNN), a machine learning technique that analyzes data on a pixel-by-pixel basis. It was possible to more consistently measure the gradient of the surface facet of nanoparticles and the atomic-scale patterns, which were difficult to distinguish by the human eye. In previous studies, materials with large atomic numbers, such as platinum or gold, have been frequently studied. Here, we study Co3O4 nanocrystals for their great potential as cost-effective energy-related materials. The key challenge is that we are analyzing high-resolution TEM images with lower contrast. In this study, we started by developing a method for synthesizing cobalt oxide with sizes and shapes. We prepared the cubic-shaped Co3O4 nanoparticles with different sizes and with different degrees of truncation of the corner and the convexity of the face. After synthesizing several different samples of cobalt oxide nanoparticles, tens of thousands of sizes and shapes of each nanoparticle sample were imaged and analyzed using transfer learning to obtain a statistical distribution from the TEM images. In this process, we are able to compare the data preparation process with and without human intervention and compare how it affects the prediction performance of machine learning.
In this study, we trained a neural network and used the trained neural network to find an optimized labeling strategy to segment particles and backgrounds in TEM images. After achieving accurate detection of particles, we classified the segmented particles to obtain a population of nanocrystals using a Random Forest classifier or K-means clustering algorithm. Through machine learning, we were able to uncover not only nanocrystal shapes consistent with existing knowledge about nanocrystal systems but also microscopic properties of nanocrystal surfaces that are difficult to recognize with the human eye. This will become a pipeline that can be used for the development of new materials in the future.

Developing Redox Booster Materials to Increase the Capacity of Non-aqueous Redox Flow Batteries Sara Amin; National Science Foundation, United States

Redox flow batteries are a promising energy storage system for renewable energy-powered grids. However, relatively low energy density has been achieved by these systems thus far, due to a combination of low active-material solubility and high-viscosity of concentrated electrolytes. These challenges can be mitigated by using solid active materials as boosters in a redox-targeting flow battery (RTFB) system. Cobalt hexacyanoferrate (CoHCF), a Prussian blue analog (PBA), is a promising candidate for this application, however, its redox-intercalation chemistry in non-aqueous flow battery systems is not well established. Understanding the mechanism behind these electrochemical processes of PBA in the non-aqueous solvent is crucial to developing better-performing high-capacity redox flow batteries.

Here, we report PBA-modified electrodes using various substrates including glassy carbon, ITO glass, and, FTO glass, prepared by the dispersion drop-cast method. Voltammetry of the PBA-modified electrodes was performed under various conditions that are analogous to those of an operating, nonaqueous RTFB. We will describe the custom electrochemical cell that is used as a platform to investigate RTFB electrolyte/booster interactions, along with results from the investigation of CoHCF and its interaction with the NFRB active-material, vanadium bis-hydroxyaminodiacetate (VBH).

5:00 PM CH01.08.14
Design Novel Polymer Materials for Advanced Redox Flow Battery Technology Hyung-Seok Lim, Sujong Chae, Litao Yan, Guosheng Li, Ruozhu Feng, Yongsoon Shin, Zimin Nie, Bhuvaneswari Sivakumar, Xin Zhang, Yangang Liang, David Bazak, Vaithiyalingam Shutthanandan, Vijayakumar Murugesan, Soowhan Kim and Wei Wang; Pacific Northwest National Laboratory, United States

Redox flow batteries are considered a promising technology for grid energy storage. However, capacity decay caused by crossover of active materials is a universal challenge for many flow battery systems, which are based on various chemistries. In this work, we demonstrate a new gel polymer interface (GPI) consisting of crosslinked polyethyleneimine with a large amount of amino and carboxylic acid groups introduced between the positive electrode and the membrane. The GPI functions as a key component to prevent vanadium ions from crossing the membrane, thus supporting stable long-term cycling. Cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) measurements were conducted to investigate the effect of GPI on the electrochemical properties of graphitic carbon electrodes (GCFs) and redox reaction of catholyte. Results from inductively coupled plasma mass spectrometry (ICP-MS), Fourier-transform infrared (FTIR) spectroscopy, and energy-dispersive X-ray (EDX) spectroscopy proved that the GPI is effective in maintaining the concentration of vanadium species in their respective half-cells, resulting in improved cycling stability because of it prevents active species from crossing the membrane and stabilizes the oxidation states of active species. X-ray photoelectron spectroscopy (XPS) and ^{1}H nuclear magnetic resonance (NMR) spectra demonstrated that the cross-linked GPI is chemically stable for 100 cycles without dissolution of polymers and swelling in the strong acidic electrolytes.

Unraveling Metal-to-Metal Hydride Phase Transformation at the Atomic Level Using *In Situ* Tem Techniques Gopi Krishnan and Joerg Jinschek; Technical University of Denmark, Denmark

In our quest for a solution to drive the decarbonization of our society and economy, hydrogen shows unique properties as a zero-emission fuel, energy storage solution, and chemical feedstock. However, compact storage remains a scientific and technological challenge.

Safely storing hydrogen e.g. in the solid form of metal hydrides, has many advantages, but further improving its storage properties requires a thorough understanding of the metal-to-metal hydride phase transformation at the atomic level. Although many techniques have been applied to understand these phase transformations, in-situ visualization of the transformation process with the high spatial resolution is essential for a quantitative understanding. For example, stress/strain, defects, and intermediate phase evolution during metal-to-metal hydride phase transformation are crucial to interpret the hydrogen sorption properties.

In this study, we use MgTi thin film as a model system to test, understand, identify and resolve metal-to-metal hydride phase transformation via in situ transmission electron microscopy (TEM). MgTi thin films were prepared via magnetron sputtering, and a focused ion beam (FIB) was used for TEM sample preparation. We observed the Mg to MgH_2 phase transformation by following the bulk plasmon resonance shift in electron energy loss spectroscopy (EELS) and the transition from hexagonal to the tetragonal structure by selected area electron diffraction (SAED). The local strain was measured using HRSTEM, and hydrogen atoms in the MgH_2 matrix were identified using integrated differential phase contrast imaging (iDPC). To confirm experimental findings, the accuracy of strain measurement is validated by geometric phase analysis, and the interpretation of iDPC contrast is supported by image simulation.

Microscale Evaluation of the Lithium Content in Lithium-Ion Battery Cathode Materials in the Scanning Electron Microscope Jonathan D. Lee[1] and Shangshang Mu[2]; [1]Gatan, Inc., United States; [2]EDAX, United States

Lithium (Li) ion-based electrochemical cells have been widely adopted due to their capacity for energy storage and low mass. However, due to a lack of characterization techniques that allow microscale analysis of the Li content, understanding of lithium plating and dendrite growth, and solid electrolyte interphase formation remain a major obstacle in the development of improved Li-based cells.

Commonly, microanalysis by energy dispersive X-ray spectroscopy (EDS) in the scanning electron microscope (SEM) is used for detection and mapping of elemental distribution, however, this remains unfeasible in commercially important materials consisting of elements with low atomic number ($Z < 4$), including Li [1, 2]. However, recently the composition-by-difference method (CDM) was shown to be a viable method for determining the Li content quantitatively at the microscale, with an accuracy of ~1 wt. % and was demonstrated in lightweight structural alloys [3] and metal oxides [4]. CDM uses quantitative analysis of the EDS and backscatter electron (BSE) signals to calculate the lithium content indirectly. In this study, we extend the CDM approach to Li-ion battery cathode materials including lithium nickel manganese cobalt oxide particles (NMC).

High-grade NMC 811 particles of nominal composition $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ were analyzed (MSE Supplies). A sample of the NMC 811 was prepared by embedding the powder in epoxy before a cross-section was prepared by broad-beam argon milling (PECS™ II system, Gatan, Inc.). The sample was held at a temperature of 0 °C during the milling process and, subsequently, a 2.0 nm carbon coating was deposited (PECS™ II system, Gatan, Inc.). The sample was transferred under vacuum conditions to a conventional field emission SEM and compositional analysis was performed using the Cipher™ system (Gatan, Inc.). Quantitative BSE analysis was performed and evaluated according to the modified electron approach [5] with a screening factor of 0.7. Quantitative EDS analysis at select locations within NMC particles was performed revealing O, Ni, Mn, and Co with little-to-no variation within or between particles that were analyzed; no other elements were found to be present above the minimum detection level. The Ni:Mn:Co ratio was determined experimentally to be 8.07:1.00:1.01, consistent with the nominal 8:1:1 ratio of this NMC. The lithium content from 6 different NMC particles was determined using Cipher and the mean lithium concentration was determined to be 22.5 at. % (5.7 wt. %) within ~1.5 wt. % of the nominal composition value of 7.3 ± 0.3 wt. %.

This is a significant step forward in the analysis of battery materials as, for the first time, the charge state of a cathode material is determined in a conventional SEM—where 25 at. % Li corresponds to an uncharged battery state with NMC 811 cathode.

Direct Observation of Rutile-TiO_2 Recrystallization Under Electron-Beam Irradiation Silu Guo, Hwanhui Yun, Sreejith Nair, Bharat Jalan and K. A. Mkhoyan; University of Minnesota, United States

Radiolytic damage of materials under electron beam irradiation has been a significant problem in transmission electron microscopy over the years with particular severity in beam-sensitive materials such as zeolites and MOFs [1]. Despite the prevalent theory of bond breakage mechanisms in materials due to electron beam irradiation [2], there has not been a solid study showing how a material undergoes radiolytic damage. In particular, the detailed stages in which a material experiences crystalline-to-amorphous phase transition have not been explored at atomic level. Here, we present a scanning transmission electron microscopy (STEM)-based study on the electron-beam-induced structural modification of rutile-TiO_2. We reveal that rutile-TiO_2 undergoes degradation and recrystallization through radiolytic reactions, including a motion of the TiO_6 octahedra building blocks upon 200 keV electron beam irradiation exposure. Through atomic-resolution imaging, for the first time, we were able to directly visualize the bond breakage and reconstruction processes during the radiolysis. By combining atomic-resolution STEM imaging with energy dispersive X-ray spectroscopy and electron energy loss spectroscopy, we have explored both chemical and electronic structures of TiO_x during the reactions. This enables us to unveil a detailed radiolytic mechanism for the structural modifications of the material. Elucidating the degradation and recrystallization process of rutile-TiO_2 under electron-beam irradiation allows us to develop potential solutions for characterizing beam-sensitive materials and design novel synthesis techniques guided by electron beam.

Transition Metal Ion Doping on ZIF-8 for Enhanced the Electrochemical CO_2 Reduction Reaction Jin Hyuk Cho and Sooyoung Kim; Korea University, Korea (the Republic of)

The electrochemical reduction of CO_2 to diverse value-added chemicals is a unique, environmentally friendly approach for curbing greenhouse gas emissions while addressing sluggish catalytic activity and low Faradaic efficiency (FE) of electrocatalysts. Here, zeolite-imidazolate-frameworks-8 (ZIF-8) containing various transition metal ions—Ni, Fe, and Cu—at varying concentrations upon doping were fabricated for the electrocatalytic CO_2 reduction reaction (CO_2RR) to CO without further processing. Atom coordination environments and theoretical electrocatalytic performance were scrutinized *via* X-ray absorption spectroscopy and density functional theory calculations. Upon optimized Cu doping on ZIF-8, $Cu_{0.5}Zn_{0.5}$/ZIF-8 achieved a high partial current density of 11.57 mA cm^{-2} and maximum FE for CO of 88.5% at –1.0 V (vs. RHE) with a stable catalytic activity over 6 h. Furthermore, the electron-rich sp^2 C atom facilitated COOH* promotion after Cu doping of ZIF-8, leading to a local effect between the Zn–N_4 and Cu–N_4 moieties. Additionally, the advanced CO_2RR pathway was illustrated from various perspectives, including the pre-H-covered state under the CO_2RR. Our findings expand the pool of efficient MOF-based CO_2RR catalysts, deeming them viable alternatives to conventional catalysts.

Experimental and Theoretical Studies on the Effect of Microstructure and Mechanical Properties of LLZO Md Zakariya Mohayman[1,2], Akihiro Kushima[1], Nan Li[2] and Tongjun Niu[2]; [1]University of Central Florida, United States; [2]Los Alamos National Laboratory, United States

All-solid-state lithium batteries are considered an ultimate choice for energy storage systems due to their high energy density and safety. Unlike conventional lithium-ion batteries, solid-state batteries do not rely on the flammable organic electrolyte and are expected to prevent lithium dendrite penetrations, which lead to the use of lithium metal anode further enhancing the energy density. However, the practical implications of solid-state batteries are limited due to poor mechanical stability and complex electro-chemo-mechanical reactions at the interface between solid electrolyte and metal anode. Garnet-type $Li_7La_3Zr_2O_{12}$ (LLZO) is one of the promising solid electrolytes for all-solid-state lithium batteries due to its low activation energy, high ionic conductivity, and high chemical stability against metal lithium enabling safe cycling of Li anodes. Although LLZO has a much higher modulus than lithium metal, penetrations of lithium are still observed in LLZO electrolytes leading to premature failures of the batteries. This is particularly evident at the grain boundaries involving nano-scale events of grain-boundary fracture, lithium deposition/penetration, and crack nucleation/propagation. Therefore, it is important to understand the fundamental mechanical properties of LLZO at the nanoscale and the influence of microstructures and loading conditions. In this work, nano-indentation and micro-pillar compression tests were performed to evaluate the mechanical properties of LLZO and clarify the effect of microstructures. In addition, *ab initio* simulations were conducted to evaluate the change in the mechanical strength of LLZO at different lithium concentrations which may occur during the charge/discharge process and at or near the grain boundaries. The insights obtained in this work provide a fundamental understanding of the mechanical properties and nano-mechanics of LLZO solid electrolytes, contributing to the development of all-solid-state lithium battery technology.

5:00 PM CH01.08.21
Development of Metal Sulfide/Oxide Decorated N, S-Doped Carbon Prepared by the Coordinated Polymer Obtained Using a New Synthetic Method Kyubin Shim, Sungwoo Park, Hyun Woo Kim and Hae Jin Kim; Korea Basic Science Institute, Korea (the Republic of)

Recently, hybrid organic-inorganic materials have received much attention in both industry and academia. [1,2] In particular, three-dimensional (3D) porous coordination polymers as a carbon precursor gives many advantages, such as rich active sites, high porosity, etc. [3] Among them, the metal-ion coordination polymers composed of metal center linked to each other through organic chains are useful to prepare the catalytic materials.
Here, we synthesized a Mn^{2+} coordinated polymer bonded by a sulfur atom with acetate counter ions (Mn-DTOGA) by an imine formation reaction. Then, from calcination of the Mn ion-coordinated polymer (700, 800, and 900 ^oC), MnS/MnO decorated N, S-doped carbon nanoparticles (MnS/O-SNC) are then prepared for the practical applications of catalytic reactions.
The prepared Mn-DTOGA and MnS/O-SNC structures are characterized using various physical, chemical, and electrochemical analyses such as FT-IR, MALDI-TOF, XRD, SEM, TEM, etc. The electrochemical measurements were conducted with a 0.070 cm^2 glassy carbon electrode with an Ag/AgCl reference electrode and a Pt wire as a counter electrode. The as-prepared electrode using the materials was tested for the electrochemical oxidation of hydrogen peroxide (H_2O_2) in a 1.0 mM H_2O_2 solution.
The Mn-DTOGA reveals a homogeneous sphere shape having a diameter with an average size, estimated to be ~500 nm. The MnS/O-SNC is also a spherical shape with a particle size of around 350 nm. Among catalysts prepared at different calcination temperatures the MnS/O-SNC (900 ^oC) shows the best performance in H_2O_2 catalytic oxidation. The XPS analysis demonstrates that the MnO decorated outward N, S-doped carbon nanoparticles mainly function for H_2O_2 oxidation. The decomposition potentials of H_2O_2 (1.0 mM) on the catalyst modified electrode are observed to be +0.40 V. The sensor prepared catalytic materials displays two dynamic ranges with a detection limit of 0.08 (± 0.02) μM.
Conclusively, we designed a new synthesis way to synthesize a coordination polymer as a precursor for carbon catalysts. From calcination of the coordinated polymer, MnS/MnO decorated S, N-doped carbon (MnS/O-SNC) nanoparticles were successfully obtained and examined for catalytic oxidation of H_2O_2. We confirmed that the catalytic performance of the oxidation reaction was mainly related to MnO decorated outside the SNC particles. The results show that it can provide a new direction for further study on catalyst design for the practical applications of catalytic reactions.

Orange Peel Biomass-derived Carbon Supported Cu-Electrocatalysts Active in the CO_2-Reduction to Formic Acid Izuchika Nduka[1], Tanvir Miah[1], Palmarita Demoro[2], Federica Deluca[2], Salvatore Abate[2] and Rosa Arrigo[1]; [1]University of Salford, United Kingdom; [2]University of Messina, Italy

Introduction: The use of carbonaceous materials in sustainable energy applications such as catalysis and electrocatalysis is deemed important (1). The production of these carbon materials from biomass waste is being thought to increase the economic value of the waste especially in emerging markets. Of the biomass wastes that have been explored, citrus waste is of utmost interest because of all the numerous useful chemical compounds it possesses, ascorbic acid is currently being used as both a capping agent and a reducing agent in the synthesis of Cu nanoparticles active in CO_2 electroreduction (2). In our study, we have explored a green approach towards the production of C-supported Cu electrocatalysts active in CO_2 reduction to formic acid. Using orange and lemon peels as a C-support precursor and as a source of reducing agent for Cu, we synthesized some Cu nanoparticles (Cu-O and Cu-L) by means of microwave irradiation and studied their performances in the electrochemical reduction of CO_2. The performances were correlated to the structural characteristics of these systems determined by means of scanning electron microscopy (SEM) and x-ray photoelectron spectroscopy (XPS) at the $Cu2p_{3/2}$, C1s, and O1s core levels.
Results: The Cu2p3/2 XPS spectra showed the presence of Cu(I) and Cu(II) species and two satellite peaks which we think are related to sulphate Cu species derived from the precursor used, and they remained partially unreduced under the synthesis conditions for the Cu-L; for the C1s XPS spectra, the peaks seen suggests that for Cu-L, some of the original peel remained unaltered after the hydrothermal synthesis; and for the O1s spectra, peaks belonging to both Cu(I)-O particles and O species on the C support were present. In contrast, Cu-O presents Cu(I) species together with a more graphitized C matrix. On evaluating the electrocatalytic performance of both Cu-O and Cu-L on CO_2 reduction, we find that the Cu-O-derived electrodes outperformed Cu-L-derived electrodes in terms of activity as well as selectivity towards CO_2 reduction products (with a maximum Faraday efficiency to formic acid of 30%) and stability, thus providing a more favourable structure for application in electrocatalysis. Taken together, these findings show that the chemical composition of the peels play an important role in determining the chemical speciation in the samples of both the Cu nanostructures and the C support.
Conclusion: In conclusion, not only have we demonstrated the viability of directly utilizing citrus waste to produce useful material in a green fashion, but we have also provided a rational strategy for tailored synthesis of Cu electrocatalyst from biomass derived precursors active in the electroreduction of CO_2. Whilst our work focused on CO2 reduction, our findings can generally be applied to the preparation of orange peel derived c-supported metal

electrocatalysts for other electrocatalytic reactions of relevance in energy conversion and storage.

Electrochemical Impedance Spectroscopy Combined ETEM Study of Solid Oxide Material Gadolinium Doped Ceria (GDC) Zhongtao Ma, Waynah L. Dacayan, Christodoulos Chatzichristodoulou, Kristian S. Mølhave and Søren B. Simonsen; Technical University of Denmark, Denmark

In response to climate change it is necessary to develop sustainable fuel production and storage technologies. Solid oxide electrolysis/fuel cell has recently become a research hotspot due to their high energy conversion efficiency [1]. However, its degradation mechanisms at high working temperatures are still unclear, advanced characterization methods are necessary to be further developed, especially *operando* techniques.

Electrochemical impedance spectroscopy (EIS) is a classic technique in electrochemistry, and one of its advantages allows *operando* characterization on a running system without causing damage to the research object [2].

In this work we are combining an Environmental TEM [3], and a heating and biasing TEM holder connected to a potentiostat for performing EIS in the TEM. This combination allows us to mimic the operation conditions of a solid oxide electrolysis/fuel cell. In addition, combining simultaneous EIS signal, one can investigate the structural/compositional evolutions and their effect on the electrochemical performance.

We have investigated the feasibility of performing EIS in ETEM. An electrolyte-electrode barrier layer material, mixed ionic and electronic conductor $Ce_{0.9}Gd_{0.1}O_{1.95-\delta}$ (GDC), which is widely used in the composite electrodes of the SOEC and SOFC cells [4], was chosen as a test sample. Our preliminary results are consistent with the documented data in terms of ionic conductivity, electronic conductivity, activity of surface-gas exchange reactions, and chemical capacities, which verified the reliability of the EIS-TEM test.

We believe the correlative EIS-TEM method will be crucial for understanding the electrochemical processes at nanoscale such as degradation in electrolysis cells, fuel cells and batteries.

Dynamics of an Oxide Fuel Cell Catalyst Revealed by Operando X-Ray Scattering Jason J. Huang[1], Yao Yang[1,2], Jacob Ruff[1], Hector Abruna[1] and Andrej Singer[1]; [1]Cornell University, United States; [2]University of California, Berkeley, United States

Furthering understanding of the catalytic mechanism in the oxygen reduction reaction (ORR) is critical to advancing and enabling fuel cell technology. In this work, we use operando synchrotron diffraction and resonant elastic X-ray scattering (REXS) to investigate the interplay between the structure and oxidation state of a Co-Mn oxide catalyst, which shows an impressive ORR activity in alkaline fuel cells. REXS was used to simultaneously observe the dynamic changes in the structure and valence state of both Co and Mn under steady state (constant applied potential) and non-steady state (cyclic voltammetry). Under steady-state conditions, an irreversible structural phase change is observed at low potentials, along with an accompanying reduction in both Co and Mn valence. With fast diffraction data collection enabled by a synchrotron source, we resolved periodic changes in the lattice parameter aligned with the cyclically applied potential. When cycled through low potentials, the catalyst exhibited a reversible rapid increase in strain. Through this work, we gained a greater understanding of the ORR mechanism in Co-Mn oxide catalysts and demonstrated the unique capabilities of combining structural and chemical characterization in REXS.

9:00 AM CH01.09.05

Combining *In Situ* Mass Spectroscopy and Active Learning for Rapid Development of Pre-Treatment Protocol for Electrocatalysts Aniket Sandip Mule[1,2], Kevin Tran[3], Ashton Aleman[1,2], Gaurav A. Kamat[1,2], Weike Ye[3], Shijing Sun[3], Michaela Burkes Stevens[2] and Thomas Jaramillo[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Toyota Research Institute, United States

Electrocatalysts are materials that speed up an electrochemical reaction. In the last few decades, researchers have observed that activation or "pre-treatment" protocols, such as electrochemical cycling, can significantly modify the structure and the performance of electrocatalysts. However, the mechanistic details of such a structure modification remain poorly understood. Consequently, a pre-treatment protocol is often chosen arbitrarily. To gather insight into the underlying mechanism and accelerate the optimization of the pre-treatment protocol, we employ a two-fold strategy: 1) systematic design of experiments (DoE) and 2) in-situ characterization of electrocatalysts to obtain time-resolved data. Commercially available Pt/C electrocatalysts for oxygen reduction reaction (ORR) were chosen as a model system. First, a central composite design based on multiple parameters (> 6) was applied to generate different pre-treatment protocols. The protocols were then investigated using a custom-made experimental setup that provided simultaneous and real-time information about the electrochemical performance and the stability of the catalyst. Specifically, an electrolyte saturated with O_2 or N_2 was guided through a flow cell to perform electrochemical experiments (pre-treatment or ORR). The flow cell outlet led to an inductively-coupled plasma mass spectrometer (ICP-MS) that monitored the in-situ dissolution of the electrocatalyst. Modifying parameters in the pre-treatment protocol showed a sizeable impact on charge transfer and dissolution during ORR. For example, increasing the upper potential from 1.5 V to 2.5 V decreased the charge transferred and increased dissolution during ORR by a factor > 2. Additionally, during pre-treatment and ORR, the dissolution occurred primarily when the potential was swept from oxidizing currents to reducing currents. Furthermore, our DoE-based approach unraveled the interaction between different parameters. Thus, the data obtained from in-situ ICP-MS by applying a DoE-based approach provided mechanistic insight and enabled efficient training of the active learning algorithms. We then exploited such machine learning models to identify characteristics of an ideal pre-treatment protocol that lead to maximum activation of an electrocatalyst. Finally, we also provide strategies to rapidly extend our parametric space to evaluate the effect of additional parameters (*e. g.*, electrolyte flow rate) and transfer our knowledge to different systems (*e. g.*, compositions of catalysts). Therefore, besides advancing the fundamental knowledge of electrocatalyst behavior, our study provides a framework for the accelerated development of pre-treatment protocols for new electrocatalysts.

***Operando* Correlative Studies of Evolving Cu Nanocatalysts for CO_2 Electroreduction** Yao Yang[1], Sheena Louisia[1], Sunmoon Yu[1], Hector Abruna[2] and Peidong Yang[1]; [1]University of California, Berkeley, United States; [2]Cornell University, United States

In an era of shifting the energy paradigm from fossil fuels to renewable energy, CO_2 reduction reaction (CO_2RR) emerges as a promising approach to covert greenhouse gas into valuable chemical fuels and close the carbon cycle for a sustainable energy supply. Since Cu remains the sole element for CO_2RR to multicarbon products (C_{2+}), significant efforts have been devoted to developing Cu electrocatalysts with higher selectivity and activity. However, the complex nature of active sites and the intrinsic structures under reaction conditions have remained largely elusive due to the lack of *operando*/*in situ* methods.[1-3]
In our previous studies, we reported that small Cu nanoparticles (sub-10 nm NPs) showed superior C_{2+} superior C_{2+} selectivity, relative to the larger sized Cu NPs, especially at low overpotentials.[4,5] In this work, we present a comprehensive *operando* correlative study of dynamic evolution of a family of monodisperse Cu NP ensemble electrocatalysts under CO_2RR.[1] *Operando* electrochemical liquid-cell scanning transmission electron microscopy (EC-STEM) and 4D-STEM resolves microscopic dynamic morphological and structural evolution at the nm scale. Correlated *operando* high-energy-resolution fluorescence detected (HERFD) X-ray absorption spectroscopy (XAS) reveals dynamic macroscopic changes in valence states and coordination environment. Statistical analysis of interparticle dynamics was probed by *operando* resonant soft X-ray-based resonant soft X-ray scattering (RSoXS).[2] The *operando* correlative strategies, described herein, elucidates the longstanding enigmatic nature of Cu active sites for selective CO_2 electroreduction. The strategy described herein can serve as a general platform to resolve the electrocatalytic interface of nanoparticle catalysts under real-time operating conditions across multiple time and length scales, thus serving the fundamental understanding necessary to development of many other electrochemical reactions for renewable energy technologies.

9:30 AM BREAK

10:00 AM CH01.09.07
Gas-Phase Reactions of Metal-tmhd Compounds—New Insights from Microreactor Studies Using Synchrotron Radiation Sebastian Grimm[1,2], Patrick Hemberger[3] and Burak Atakan[1,2]; [1]University of Duisburg-Essen, Germany; [2]Center for Nanointegration (CENIDE), Germany; [3]Paul Scherrer Institute, Switzerland

Metal-β-diketonate complexes are widely used as precursors for thin film deposition in the fields of catalysis, microelectronics and functional materials for energetic applications.[1] This is mainly because of their superior physical and chemical properties such as the volatility and inertness, which can be customized by changing the β-diketonate group attached to the respective metal center.[2]
When used in deposition processes, often gas-phase reactions are the initial decomposition step, but gaseous intermediates can lead to unwanted film morphology and unsatisfactory purity or a depletion of the precursor by side reactions, and consequently a reduction in growth rate. A precise understanding of the decomposition mechanism, especially the sequence of bond dissociation steps, is important for improving and modelling such a processes.
Consequently, the analysis of the initial stages of growth is important and requires sensitive analytical techniques with sufficiently low detection limits for elusive gas-phase species. Because of limitations in experimental techniques, it was until recently not possible to detect most of the postulated intermediate species; their temperature-dependent kinetics often remained unknown.[3]
We have overcome some of these challenges and demonstrated for various metal-organic precursors, that by using a microreactor coupled to a very mild ionization source, aided by numerical simulation, we are capable to detect and characterize elusive species, especially metal-containing intermediates with short lifetimes below 50 µs.[4]
Building up on previous work on acetylacetonate complexes, we present insights into the reactions of 2,2,6,6-tetramethyl-3,5-heptanedionate (tmhd) compounds. The vacuum pyrolysis of aluminium and zirconium 2,2,6,6-tetramethyl-3,5-heptanedionate, $Al(tmhd)_3$ and $Zr(tmhd)_4$ is investigated here. In brief, the precursor is sublimed, subsequently transported by helium carrier gas, and expanded through a pinhole into a resistively heated 1 mm inner diameter SiC-microreactor of 10 mm length. Species leaving the reactor are ionized by tuneable vacuum ultraviolet (VUV) synchrotron radiation, and characterized by imaging photoelectron photoion coincidence spectroscopy (i^2PEPICO) and mass spectrometry at the Swiss Light Source. We recorded photoionization efficiency curves (PIE) and threshold photoelectron spectra (TPES) at photon energies of 6.3-11.5 eV, which give us direct evidence for the characterization of reactive intermediates and products.
In the experiments, hydrocarbons, oxygenated and metal-containing species were detected and characterized unambiguously in the gas-phase at temperatures from 450-950 K, which provides insights in the underlying decomposition mechanisms. Most importantly, we detected and characterized metal-bis(diketo)acetylacetonate-H, $M(C_{11}H_{19}O_2)(C_{11}H_{18}O_2)$ as major initial decomposition product in the gas-phase at temperatures above 650 K, which subsequently forms $M(C_{11}H_{19}O_2)(C_{10}H_{15}O_2)$ by a methyl loss. Additionally, several hydrocarbons and oxygenated species were detected and assigned as decomposition species for the first time, i.e. H-tmhd ($C_{11}H_{20}O_2$), $C_7H_{11}O_2$, pinacolone ($C_6H_{12}O$), the tert-butyl radical (C_4H_9), which afford the formation of metal-containing intermediates. The temperature-dependent formation mechanisms of the assigned species will be discussed and compared to previous results on M(acac) precursors.

Nanoscale Characterization for Understanding Performance Limitations in Water Splitting Photoelectrodes Lukas Wolz[1], Harishankar Balakrishnan[2], Guanda Zhou[1], Ian D. Sharp[1], Achim Hartschuh[2] and Johanna Eichhorn[1]; [1]Technische Universität München, Germany; [2]Ludwig-Maximilians-Universität München, Germany

Photoelectrochemical water splitting is a promising route for efficient conversion of solar energy into chemical fuels. In this context, economically viable photosystems are often based of semiconductor thin films which are polycrystalline or nanostructured with highly complex architectures e.g. with boundaries between differently orientated grains, different crystal facet orientations, as well as locally varying composition or phase. These nano- to micrometer properties often control critical processes, such as efficiency and stability, of the macroscale system. To understand the impact of nanoscale properties on the macroscopic performance, we aim at resolving local structural, chemical, and optoelectronic heterogeneities and at elucidating their effect on light-driven processes.

In this work, we use a correlative approach to elucidate the nanoscale properties of polycrystalline BiVO$_4$ thin film photoelectrodes. Mapping of the local charge transport properties by photoconductive atomic force microscopy reveals the tolerance to grain boundaries.[1] Interestingly, scanning nearfield infrared microscopy shows strongly varying absorption from VO$_4$ stretching modes between grains and at grain boundaries which correlate with the heterogeneities in the local photoconductivity across the polycrystalline thin films. Furthermore, local temperature-dependent current-voltage spectroscopy show that the low intrinsic bulk conductivity of BiVO$_4$ limits the electron transport through the film, and that the transport mechanism can be attributed to space charge limited current in the presence of trap states.[1] Performing the same measurements in-situ in controlled gas-phase environment reveals the influence of chemical interactions of adsorbed oxygen and water on charge transport and interfacial charge transfer.[2] For BiVO$_4$, we demonstrate that adsorbed oxygen acts as a surface trap state for electrons, which enhances the built-in potential and depletes the BiVO$_4$ layer. Overall, combining insights from different nanoscale techniques generates a comprehensive picture of charge separation, transport, and transfer at the nanoscale. The gained nanoscale understanding of energy materials enables the rational design of durable and efficient solar fuel devices.

A Multitechnique Approach for The Investigation of Reaction Mechanisms in Cu-Zeolite Catalysts Gloria Berlier; University of Turin, Department of Chemistry, Italy

Heterogeneous catalysis is involved in the vast majority of industrial chemical processes, with a growing attention to sustainability, energetic and environmental aspects. To develop a sustainable and cleaner technology, based on new or optimized solid catalysts, a comprehension of the working principles of heterogeneous catalysis is a prime requirement. Spectroscopies play a pivotal role in this complex subject, addressing some of the main challenges: i) determine the nature and distribution of the catalytically active sites; ii) unveil the underlying catalytic mechanisms; iii) define structure/properties relationship (activity, selectivity and stability); discriminate between active sites and spectators in reaction conditions [1].
This contribution focuses on the use of *in situ* and *operando* vibrational and electronic spectroscopies (infrared, Raman, UV-Vis, X-ray absorption and emission) for the characterization of heterogeneous catalysts for selective redox reactions, *i.e.* the Selective Catalytic Reduction of NO$_x$ with NH$_3$ (NH$_3$-SCR) and the direct conversion of methane to methanol (DMTM) [2,3]. Cu-exchanged zeolites are among the most studied catalysts for both reaction, in relation to the reversible Cu^{2+}/Cu^{+} redox cycle and to the ability of Cu^{+} ions to active O$_2$ in specific conditions. In particular Cu exchanged chabazite (Cu-CHA) is the catalyst of choice for NH$_3$-SCR, due to high activity and good hydrothermal stability. The high symmetry of the CHA framework coupled to the intrinsic structural definition of Cu counterions implies that this system is also an ideal playground for spectroscopy and computational studies [3,4,5]. Some of the most recent and relevant results obtained on the Cu-CHA catalysts by applying advanced spectroscopic techniques together with complementary computational studies will be discussed, with particular focus on the fundamental knowledge related to the different techniques and the importance of a holistic multitechnique approach. This will include advanced data analysis, such as the wavelet transform (WT) analysis and machine learning (ML)-assisted fitting of the extended X-ray absorption fine structure (EXAFS) spectra [4,6], and experimental methodologies such as Modulation Excitation (ME) spectroscopies [7].

11:00 AM *CH01.09.10
Understanding Catalyst Deactivation via Electron Microscopy Qian He; National University of Singaproe, Singapore

In textbooks, a catalyst is often defined as: "a substance that makes a chemical reaction happen faster without being changed itself". However, in practice, all catalysts deactivate for one reason or another [1]. As a powerful tool to probe local structural and chemical information about practical catalysts at atomic resolution, Electron Microscopy (EM) can be used to follow the evolution of catalysts under reaction conditions to provide insights into the deactivation mechanisms. This not only can help us to develop catalysts with better stability but also can shine a light on the nature of the active sites. This is often a challenging task due to the structural complexity of practical catalysts, which can make it difficult to correlate the observed results with catalytic performance. Although many in situ/operando EM techniques [2] have been developed, it can still be challenging to reproduce the reaction environment for many industrially important reactions.

In this presentation, we will give a few examples of using identical location electron microscopy to understand the deactivation of catalysts used for gas-phase and electrochemical reactions, that are still difficult to reproduce with the current in situ techniques. The first example is the study of Au catalysts used for the low-temperature water gas shift (LT-WGS) reaction, which can be used for the PEMFC applications. Both the nature of the active sites and the deactivation mechanism have been under debate. Flytzani-Stephanopoulos *et al.* [3] suggested that the cationic Au was the active site, and hence the deactivation was due to sintering. Hardacre et al.[4] suggested that the interface between the metallic nanoparticle and the support are the active sites and the deactivation was due to the loss of the interfaces via "dewetting". Our identical location EM studies [5] showed that the loss of cationic Au happens at the early stages of the reaction and can only be partially responsible for deactivation, while the deactivation at a later stage of the reaction was likely due to dewetting.

Another story is about CO2 reduction reactions (CO2RR) via Cu catalysts, which are the best catalysts to produce C2+ products but are also known to show morphological instability. Understanding the mechanisms of these morphology changes can help us to further optimize the catalysts. Current views as to why this occurs include copper redox reaction or intermediates adsorption inducing the morphological restructuring and leading to the fac

Status, Challenges and Advanced Characterization Needs of Automotive Solid State Batteries Alvaro Masias; Ford Motor Company, United States

Lithium ion battery technology has improved continuously since its introduction in 1991. In the last decade, the automotive sector has experienced a huge revival of interest in electrification as the continuously growing energy density of the lithium ion battery has enabled more and more practical vehicle designs. However, the rate of improvement of lithium ion battery technology maybe slowing down and to support the mass adoption of electrification, superior battery technologies are being pursued the world over.

Lithium solid state batteries hold great promise as a next generation battery chemistry for automotive electrification. Through the enablement of advanced anodes such as majority silicon or lithium and the replacement of flammable liquid solvents, solid state batteries are believed to offer opportunities for improvements in energy and safety. However this chemistry family has a wide range of maturity and scale challenges when compared to conventional liquid lithium ion.

This presentation will describe how the current status of solid state batteries compares to liquid lithium ion for the automotive market. We will also highlight the most pressing materials and characterizations challenges of the solid state battery class from the perspective of an automotive manufacturer and discuss some advanced characterization techniques of active study such as the usage of fluorophores and neutron reflectometry.

2:00 PM CH01.10.02
Using Correlations to Reveal Fine Details on Structural Disorder in Solid-State Electrocatalysts Rodney Smith; University of Waterloo, Canada

Transition metal ions in undercoordinated sites, such as edge-sites in layered double hydroxides or adjacent to oxygen vacancies in perovskites, have long been envisioned as catalytically relevant sites for electrochemical reactions such as the oxygen evolution reaction. Direct analysis of such defect chemistry in solid state electrocatalysts is impeded by the low concentrations of defects relative to bulk sites, multitude of viable defects in any given material, potential for dynamic changes during catalysis, and fundamental limitations inherent in every characterization technique. We pursue experimental evidence for strained, distorted, or defective coordination environments in common electrocatalysts such that we can systematically identify and rule out specific features as catalytically relevant sites to guide efforts to design improved catalysts. Our strategy is to combine systematic variations in synthesis with comprehensive characterization. Synthetic strategies are developed to prepare series of samples that, ideally, are dominated by changes in a single type of structural disorder. The structure, properties, and electrochemical parameters extracted from diverse techniques are then comprehensively compared to each other to identify useful structure-property and structure-structure correlations. These correlations can provide chemical insights that cannot otherwise be attained. This talk will demonstrate how this strategy enabled identification of distortions and unreported coordination environments in iron-nickel hydroxide,[1,2] and defects such as interstitial protons and associated iron vacancies in hematite photoanodes.[3,4]

3:15 PM *CH01.10.05
Imaging Characterization Challenges and Solutions for Advanced Battery Development Zhao Liu; Thermo Fisher Scientific, United States

Lithium battery is an energy storage system with highly complex microstructures covering multiple length scales, namely from millimeters to nanometers. The performance of the battery is dependent on the battery microstructures. Therefore, accurately characterizing the battery microstructure at different length scales is critical for interpreting battery performance, which ultimately advances battery technology.

Imaging characterization via electron microscopy, including SEM, FIB-SEM, and TEM, has been recognized as an effective approach to studying battery microstructure. However, it is challenging to capture the materials at the full-length scale and also correlate each data set. In addition, some materials are beam-sensitive and air sensitive, making it challenging to observe the structure at its native state.

In this talk, I will discuss a comprehensive approach to studying the battery structure at multiple length scales in 2D and 3D. In addition, solutions such as cryogenic FIB and TEM, inert gas sample transfer, and dose management approach to observe the battery materials are their native state will also be discussed.

3:45 PM CH01.10.06
Lithium Excess-Driven Redox Imbalance Between Cationic and Anionic Redox Causes Electro-Chemo-Mechanical Failure in High-Energy Layered Cathode Materials Hoyoung Jang, Donggun Eum and Kisuk Kang; Seoul National University, Korea, Korea (the Republic of)

Despite the high-energy density of lithium- and manganese-rich layered oxides (LRLOs) provided through the high-voltage anionic redox chemistry, critical issues such as capacity fading, voltage decay, and hysteresis have limited their real-world applications. As an elegant solution, O2-type LRLOs were recently reported to mitigate these voltage issues via reversible transition-metal (TM) migration during the successive charging and discharging; however, these materials still suffer from capacity degradation during long-term cycling. Repetitive mechanical stress and failure, one of the prevailing degradation factors for other layered oxide electrodes, has also been proposed as the origin of the capacity fading even in LRLOs. Nevertheless, in-depth studies on the mechanical behavior in LRLOs, particularly with respect to the extent of high-voltage oxygen redox, remain elusive. Herein, a series of O2-type LRLOs were designed and synthesized to investigate the evolution of the bulk structures as a function of varying oxygen-redox capabilities and to examine their effects on persistent electrochemical degradation. We demonstrate that the generation of bulk microcracks in the particles is strongly coupled with repeated lattice evolution and structural distortions during the high-voltage oxygen redox. These internal cracks lead to the formation of an electrochemically inactive phase near the cracks, which is followed by capacity fading as extended cycling occurs. Based on these results, we propose redox engineering strategy via Ni redox buffer to increase the ratio of cationic to anionic redox activity and thereby mitigate severe lattice disruption, achieving improved capacity retention during long-term cycling. These findings clarify how the oxygen redox in LRLOs is highly correlated to the mechanical degradation (and consequently capacity fading) and provide a general design principle towards genuine high-energy cathode materials.

Fundamental Studies on Enhanced Redox Performance of Alkaline Iron Batteries by Silicate Additives Sathya Narayanan Jagadeesan; Worcester Polytechnic Institute, United States

Iron oxides or hydroxides are highly desirable "green" battery electrodes owing to their abundance, multiple oxidation states, low cost, and environmental beneficence. However, their low storage capacity and poor cycling life have been lingering concerns due to the substantial hydrogen evolution on charging and the formation of inactive spinel phase on discharging. Herein, we report a fundamental physicochemical study of the redox behavior of iron (II, III) oxide materials containing goethite (α-FeOOH) and magnetite (Fe_3O_4) in an alkaline solution. Also, an unprecedented discovery of how the low concentration of sodium silicate (Na_2SiO_3) electrolyte additive improves the conversion of $Fe(OH)_2$ into FeOOH through a one-electron-transfer reaction by mitigating the formation of Fe_3O_4.
The phase information is provided by *in operando* synchrotron X-ray diffraction (XRD) during the redox cycling. X-ray photoelectron spectroscopy (XPS) and electrochemical measurements revealed the iron-oxide/silicate interaction that introduces diffusion limitation of oxygen species on the surface of the electrode, thus favoring the FeOOH formation. As per the classical molecular dynamics (CMD) simulations, the addition of Na_2SiO_3 results in increased Na ions in the solvation shell. Theoretical calculations (DFT) also supported that the $(SiO_3)^*$ adsorption is more energetically favored than the $(OH)^*$ on the $Fe(OH)_2$ surface. Moreover, this new battery chemistry enables the high capacity and reversibility of the iron electrode, which could contribute to developing new alkaline battery systems built on non-critical materials for sustainable energy storage.

Variable-Temperature Hall Study in High Performance Perovskite and Kesterite Films Using High Sensitivity Parallel-Dipole-Line Hall System
Chaeyoun Kim[1], Oki Gunawan[2] and Byungha Shin[1]; [1]KAIST, Korea (the Republic of); [2]IBM Research, United States

High sensitivity Hall effect system capable of measuring wide range of sample resistance, carrier density, mobility and temperature is critically needed for development of many advanced electronics material. We recently developed a high-sensitivity variable temperature Hall measurement system based on rotating parallel dipole line (PDL) magnet. The PDL system is an emerging AC field Hall system that has played a key role in the recent discovery of carrier-resolved-photo Hall effect [1]. This variable temperature Hall system allows us to study the mobility scattering mechanism and extracting the donor or acceptor level of the material. We demonstrated these applications in several high-interest materials such as high performance kesterite (CZTS) and perovskite solar absorber films. For example, we extracted the CZTS acceptor level of 210 meV, very close to the theoretical prediction of 217 meV level associated with Cu_{Zn} antisite acceptor level. [1] O. Gunawan et. al., Nature 575, 151 (2019).

Synthesis, Characterization and Electrochemical Analysis of Porous Carbon/Tungsten Oxide Composites Bishnu Bastakoti and John Bentley; North Carolina A&T State University, United States

Over the years, the development of sustainable and renewable energy storage systems has accelerated because of the need to preserve natural resources and control energy consumption. Non-conventional energy devices, such as batteries, supercapacitors, and fuel cells, have been utilized in hybrid vehicles and portable electronic devices where chemical energy is converted to electrical energy via electrochemical reactions. Here, we synthesized mesoporous WO_3-mesoporous carbon composites using a micelle assembly approach with a poly(styrene-*b*-vinyl pyridine-*b*-ethylene oxide) block copolymer and studied the electrochemical properties focusing on its application in supercapacitor. The uniformly distributed WO_3 nanoparticles through the carbon mesostructured are effectively utilized to enhance capacitive performances. Through a combination of both faradaic and non-faradaic processes, WO_3-mesoporous carbon exhibited a high specific supercapacitance of 381 $F.g^{-1}$ in 1 M H_2SO_4.

5:00 PM CH01.11.04
Regulating Surface Redox Activity in Li-Rich Layered Oxides via Band-Aligned Vanadium Phosphate Coatings Tristram Jenkins[1], Jose A. Alarco[1], Bruce C. Cowie[2] and Ian D. Mackinnon[1]; [1]Queensland University of Technology, Australia; [2]Australian Nuclear Science and Technology Organisation, Australia

With a specific energy density >250$mAhg^{-1}$ and average voltage of ~3.6V, Li-rich layered transition metal oxides (LLOs) are a commercially interesting high energy cathode material for the next generation of Li-ion batteries. However, LLOs critically suffer from accelerated capacity and voltage decay caused by a layered-to-spinel phase transition triggered by the involvement of O 2p states and formation of electron holes, causing lattice destabilization during redox[1]. This structural transformation is recognized as a surface-propagating phenomenon, so surface modification to improve chemical bonding stability with oxygen has become a primary approach to restrain structural transformation and its associated side effects (i.e., O_2 evolution, electrolyte side reaction, transition metal dissolution etc.) [2] . However, the behavior of the electronic structure at the interface between surface-modifier and bulk of LLOs is generally less investigated but is potentially an important aspect for oxygen redox charge transfer as well as general structural stability during cycling.

In this work, we systematically investigate the influence of redox-active vanadium phosphate (VP) coatings, $Li_3V_2(PO_4)_3$ (LVP) and $Na_3V_2(PO_4)_3$ (NVP) on the electronic structure, surface redox activity and electrochemical performance of a typical LLO ($Li_{1.2}Mn_{0.54}Ni_{0.13}Co_{0.13}O_2$) using both experimental investigation and *ab initio* DFT calculations. Experimentally, XPS, UPS, UV-Vis-NIR and ex-situ O K- and Ni, Mn, Co L-edge soft X-ray absorption spectroscopy (sXAS) were used study the redox reactions of the pristine and VP-LLOs and to map their intrinsic surface and interfacial electronic structures. Ex-situ sXAS comparison of pristine and VP coatings during both initial and long-term cycling shows significant reduction in O 2p-TM 3d hole formation at the surface (PEY, TEY) and better redox reversibility during cycling of VP-coated samples. Electronic structure investigation via DFT and spectroscopic techniques indicate evidence of electronic band alignment and a reduced surface polarization for VP-LLOs compared to pristine sample surfaces. Practically, we find VP-coated LLOs offer improved charge transfer kinetics and exhibit far better capacity and voltage retention than pristine samples with up to 90% capacity retention and -0.18eV median voltage fade after over 100 cycles. These results point to the practical utility of considering the electronic compatibility of surface modification agents at the interface in addition to current ionic transport, phase compatibility and chemical stability considerations for aiding charge transfer and alleviating structural deterioration in high energy Li-rich layered oxide battery cathodes.

5:00 PM CH01.11.07
Cu_2WO_4 Semiconductor Electrode—A Promising Photocathode for CO_2 Reduction Jessica C. Alvim[1], Nadia G. Macedo[1], Leonardo C. Soares[1], Márcio Sangali[1], Miguel T. Galante[1], Flavia Cassiola[2], Dwayne Carranza[2], Rubens Caram Jr[1] and Claudia Longo[1]; [1]Unicamp, Brazil; [2]Shell Technology Center, United States

The search for suitable materials to promote the conversion of CO_2 to value-added chemicals has been motivating researchers over the last decade. In the photoelectrochemical (PEC) approach, the CO_2 reduction reaction (CO_2RR) can be achieved under low overpotential and higher Faradaic Efficiency (FE) using a sunlight irradiated p-type semiconductor electrode as a photocathode. This work describes the investigation of photoelectrodes based on copper (I) tungstate (Cu_2WO_4) for PEC-CO_2RR. Cu_2WO_4 was synthesized by arc melting, using Cu_2O and WO_3 as precursors. After ground, the resulting reddish particles exhibited the X-ray diffraction (XRD) pattern of Cu_2WO_4; also, UV-Vis diffuse reflectance spectroscopy (DRS) revealed a broad absorption in the visible range and the band gap energy was estimated as 2.0 eV. The electrochemical properties in aqueous media were initially investigated for electrodes consisted of a porous film of Cu_2WO_4 particles deposited by drop-casting on glass-FTO. The FTO|Cu_2WO_4 behaved as a p-type semiconductor electrode, exhibiting positive photopotential and cathodic photocurrent under solar-simulated irradiation, and notable activity for PEC-CO_2RR. Also, Incident Photon-to-Current conversion Efficiency (IPCE) curve was coherent with the DRS measurements. Moreover, gas diffusion electrodes were prepared by depositing Cu_2WO_4 particles on carbon paper, that was placed between two titanium mesh (to improve the mechanical stability). The GDE|Cu_2WO_4|Ti-mesh photocathode, under CO_2 flow, was associated with a photoanode consisted of a titanium foil covered with a thin film of $BiVO_4$ modified with Ni-Fe oxyhydroxides (Ti|$BiVO_4$/FeOOH/NiOOH), in a PEC H-cell (separated compartments) containing aqueous $NaHCO_3$. Under irradiation, this PEC reactor exhibited an open circuit potential of +0.4 V;also, with no external bias, a short-circuit photocurrent of ca. 0.7 mA was observed, continuously sustained by CO_2RR and oxygen evolution reaction. After 2h-phtoelectrolysis, the main registered liquid product in this system was ethanol, with FE of (13 ± 3)%. Therefore, the p-type semiconductor Cu_2WO_4 exhibits efficient sunlight harvesting and activity for ethanol production from CO_2 reduction.

5:00 PM CH01.11.08
On The Fly Rietveld Analysis of Synchrotron Powder X-Ray Diffraction Monty R. Cosby[1,2], Adam A. Corrao[2], Gerard S. Mattei[2], Kevin Stone[1] and Peter G. Khalifah[2,3]; [1]Stanford Synchrotron Radiation Lightsource, United States; [2]Stony Brook University, The State University of New York, United States; [3]Brookhaven National Laboratory, United States

Modern synchrotrons can acquire high-resolution 1D XRD patterns containing a system's crystallographic information within seconds. With an appropriate setup, *in situ* or *operando* experiments can be performed on one or many experiments with a temporal resolution of thousands of scans per day. Unfortunately, analysis of X-ray diffraction is a tedious process that can often exceed weeks for adequate structural determination of a single pattern. This has been sped up substantially with previous software developments (such as TOPAS and GSAS-II) that have enabled refinement of many patterns sequentially. For this work, a code was developed to both perform Rietveld analysis and analyze the resulting structural information X-ray diffraction seconds after the data has been acquired enabling users to follow experiments as they develop in real-time. *In situ* and *operando* experiments have been followed with this code at SSRL, NSLS-II, and APS both on-site and with remote operations. Using on-the-fly analysis not only allows for real-time monitoring of experimental progress, but also permits experiments to be more data driven with users and can potentially enable AI making informed decisions based on the structural evolutions that occur during *in situ* synchrotron experiments.

5:00 PM CH01.11.09
Altering Solvation at the Electrolyte/Electrode Interface in a Precisely Defined Manner Feipeng Yang[1], Yang Ha[1], Kun Qian[1,2], Scott A. McClary[3], Nathan Hahn[3], Kevin R. Zavadil[3] and Jinghua Guo[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]The University of Akron, United States; [3]Sandia National Laboratories, United States

Calcium is a promising candidate in multivalent battery technologies because of its safe, economical, and nontoxic nature. It offers the promise of a more than two-fold increase in the volumetric capacity compared to monovalent lithium-ion batteries. The understanding of the solvation and charge transfer mechanism at the electrolyte/electrode interface and how different types of cations and anions will affect the calcium solvation at this interface is the key to developing novel calcium batteries since the solvation of an electrolyte near the interphase dictates the charge transfer efficiency and therefore affects the performance of a battery. However, current understanding regarding this interphase was limited due to the lack of direct interphase probing approaches under in-situ/operando conditions. In this talk, using synchrotron-based X-ray absorption spectroscopy and resonant soft X-ray scattering through a patterned e-chip, the solvation of a calcium organic electrolyte was investigated under operando conditions. The disruption of the solvation structure by a secondary anion or cation was evaluated using the methodologies developed, which will guide the designing of electrolytes for future energy storage. The strategy of these new methodologies developed will also benefit the investigation of catalysis at interphases and electrochemical microenvironments in general.

5:00 PM CH01.11.10
Visualizing Stacking Fault Formation in Shocked Diamond by Femtosecond X-Ray Radiography Kento Katagiri[1], Leora E. Dresselhaus-Marais[1], Tatiana Pikuz[2], Genki Kamimura[2], Hirotaka Nakamura[2], Gooru Masaoka[2], Ryosuke Kodama[2], Masato Ota[2], Shunsuke Egashira[2], Youichi Sakawa[2], Takayoshi Sano[2], Frank Schoofs[3], Michel Koenig[4], Bruno Albertazzi[4], Gabriel Rigon[5], Lichao Fang[1], Zoe Smith[1], Yuichi Inubushi[6], Kohei Miyanishi[7], Keiichi Sueda[7], Tadashi Togashi[6], Makina Yabashi[6], Toshinori Yabuuchi[6] and Norimasa Ozaki[2]; [1]Stanford University, United States; [2]Osaka University, Japan; [3]UK Atomic Energy, United Kingdom; [4]LULI, CNRS, CEA, Ecole Polytechnique, France; [5]Nagoya University, Japan; [6]JASRI, Japan; [7]RIKEN, Japan

Since plastic deformation of crystals is primarily driven by the motion of dislocations (line defects), it is necessary to understand how fast they can propagate in order to describe the deformation dynamics of solids compressed at highest strain rates. Although many models predict the upper bound of dislocation velocities to lie between the longitudinal and transverse acoustic velocities, experimentally capturing the ultrafast dislocation motion under high strain-rate deformation remains elusive. We present our recent experimental results of *in-situ* X-ray radiography of laser-shocked single crystal diamonds. By using the ultra-bright femtosecond-duration pulses available at the SACLA X-ray Free Electron Laser facility, we imaged inelastic shock waves in diamond that propagated with a velocity comparable to the bulk sound velocity of diamond (≥ 11 µm/ns). For these waves, we observed shock-induced stacking faults form along diamond's {111} slip planes via imaging, at velocities that indicate that the dislocations leading the stacking fault formation propagate transonically (*i.e.*, with a speed between the transverse and longitudinal wave velocities of the crystal). Our advanced characterization of transonic dislocation motion gives new insights into the fundamental behavior of the dislocation propagation in crystals.

5:00 PM CH01.11.11
Advancing Titration Mass Spectrometry to Decouple Oxygen-Redox and Manganese-Redox Voltage Hysteresis in a Li-Excess Cation-Disordered Rock Salt Cathode Tzu-Yang Huang[1,2] and Bryan McCloskey[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Voltage hysteresis can significantly drag down the round-trip energy efficiency of a Li-ion battery cathode. For Li-excess cathode materials, coexisting transition-metal and oxygen redox makes it challenging to evaluate how each redox mechanism impacts voltage hysteresis. In this work, we re-designed conventional aqueous redox titration with the aid of mass spectrometry (MS) gas analyzer to quantify two coexisting solid-phase analytes, namely oxidized oxygen and $Mn^{3+/4+}$, in a representative Li-excess cation-disordered rock salt — $Li_{1.2}Mn_{0.4}Ti_{0.4}O_2$(LMTO). Two MS-countable gas molecules evolve from two separate titrant-analyte reactions, which allows decoupling Mn and O redox capacities. As incremental redox capacities are quantitatively decoupled, each redox voltage hysteresis can be further evaluated through deconvoluted energy efficiency and overvoltage distribution, which unambiguously inform how different each redox mechanism contributes to the overall voltage hysteresis. Our results show promise of designing new analytical workflow to experimentally measure intermixed redox capacities and their round-trip energy efficiencies, even in a disordered material having complex local coordination environments.

5:00 PM CH01.11.12
Characterization of Annealing-Induced Phase Segregation in Composite Silicon Anodes for Li-ion Batteries Zoey Huey[1,2], Gerard M. Carroll[1], Patrick Walker[1], Steven C. DeCaluwe[2] and Chun-sheng Jiang[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Silicon (Si) anodes present a promising alternative to graphite anodes for lithium ion batteries (LIBs), as Si has a greater specific capacity, but issues arise as Si expands during lithiation which results in an unstable solid-electrolyte interphase (SEI).[1] One solution for this issue is the use of Si nanoparticles (NPs) that maximize the surface area to volume ratio. Here, we discuss electrodes made with Si NPs treated with polyethylene oxide (PEO) (for improving dispersion during processing), conductive carbon NPs, and P84 polyimide binder. These electrodes show significant improvements in active material utilization, first cycle efficiency, and capacity retention with extensive cycling after an annealing treatment.

We used air-free argon ion polishing to create electrode cross sections and imaged through the electrode thickness using atomic force microscopy (AFM)-based nano-electrical characterization of scanning spreading resistance microscopy (SSRM), nano-mechanical characterizations of contact resonance and force volume (CR-FV), and scanning electron microscopy-based energy dispersive x-ray spectroscopy (SEM-EDS). Results comparing unannealed and annealed electrodes show that the Si and conductive carbon segregate into phases, with the carbon-rich phase forming a distinctive banded morphology that surrounds the Si-rich phase after annealing. In pristine electrodes, the carbon- and SEI-rich bands exhibit a higher electronic conductivity and a lower elastic modulus than the Si active material phase. These banded structures, as well as distinct electronic and mechanical properties, remain after cycling. This phase separation may be a major contributor to the improvement seen in electrochemical performance after annealing, as it may provide an improvement of electrical conduction pathways and a mechanical strain buffer for active Si material expansion during cycling. Our nm-scale and multi-mode characterizations provide a novel route for understanding and improving energy storage devices, which is advantageous for imaging the highly inhomogeneous structure of composite electrodes on the nano and micro scales.

5:00 PM CH01.11.13
Intrinsic Variability in the Electrochemical Properties of Individual Battery Particles Yiyang Li; University of Michigan, United States

Advanced characterization methods including in situ microscopy have often shown substantial heterogeneity and variability upon electrochemical charge and discharge. However, while such methods can uncover qualitative differences in electrochemistry, they do not directly quantify current and voltage. In this work, we utilize the microelectrode array which enables direct measurements of electrochemical current and voltage of individual micron-sized battery particles. After cycling >20 individual NMC-532 particles, we found that, while the specific volumetric capacity of the particles has <2% variability, the exchange current density has >3x variability between the "best" and the "worst" particles. This intrinsic variability is presently not considered in electrochemical models, and can provide opportunities for uncovering structure-property relationships and engineering improved battery particles.

5:00 PM CH01.11.14
Nanocrystal Orientation Analysis of PbSe Quantum Dot 3D Superlattices Enabled By Atomic Lattice Resolved Electron Tomography Ethan M. Field[1], Xiaolei Chu[1], Alex Abelson[2], Caroline Qian[2], Oleg Igouchkine[1], Kwan Liu Ma[1], Matt Law[2,2,2] and Adam J. Moule[1]; [1]University of California, Davis, United States; [2]University of California, Irvine, United States

Colloidal quantum dot superlattices with semiconductor properties promise many exciting properties for opto-electronic devices including the delocalization of electronic bands with tunable energies. We have applied novel data analysis techniques to HAADF STEM tomographic reconstructions to measure the nanoparticle atomic lattice orientation of each of the 633 quantum dots within a 3D superlattice. Inhomogeneity in position and orientation reveal how surface layers remain more ordered after synthesis and effect interior layering. Current characterization methods like 4D-STEM and GISAXS do not probe the exact the structure of the superlattice in three dimensions. This presentation will highlight the data used and its applications in improving the superlattice structure to achieve next-generation opto-electronic properties.

5:00 PM CH01.11.15
Non-Invasive Monitoring of Lithium-Solid State Electrolyte Interface Morphology From *In Situ* Thermal Resistance Measurement Divya Chalise[1,2], Robert Jonson[2], Pallab Barai[3], Sumanjeet Kaur[2], Sean Lubner[2,4], Venkat Srinivasan[3], Michael Tucker[2] and Ravi Prasher[2,1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Argonne National Laboratory, United States; [4]Boston University, United States

Void-formation and interface morphology change at the lithium metal solid-state electrolyte interface has been identified as a significant challenge in the development of solid-state batteries. However, operando monitoring of the buried interface morphology is challenging. Several techniques that require isolating/exposing the interface for characterization inadvertently modify the interface and cannot be used for monitoring. While non-destructive methods such as Electrochemical Impedance Spectroscopy (EIS) and X-ray Tomography (XRT) have been employed to study the interface, XRT is not easy to use, whereas EIS cannot resolve other interface effects with the change in the morphology. In this work, we introduce thermal interface resistance measured using modified 3-omega sensors as a reliable method to monitor the interface morphology evolution in lithium metal-solid state cells. We first relate the thermal interface resistance at the lithium-LLZO interface with the physical morphology of the interface and then use the measured thermal interface resistance to extract morphological parameters such as the average contact radius and the number density of contacts. In this work, we study the evolution of the morphology as a function of stack pressure and the number of cell cycles in symmetric lithium-LLZO cells and verify our observations through ex-situ optical characterization.

5:00 PM CH01.11.16
***In Situ* Atomic-Scale Observation of $(Cr,Mn,Fe,Co,Ni)_3O_4$ High-Entropy Spinel Oxide Formation During Calcination Process** Yu-Tzu Yeh and Wen Wei Wu; National Yang Ming Chiao Tung University, Taiwan

High-Entropy Oxide (HEO) is a new-type of anode materials for lithium ion batteries (LIBs), owing to their stable crystal structure, superionic conductivity and high capacity. In recent years, High-Entropy Oxide (HEO) nanoparticles were synthesized via surfactant-assisted hydrothermal method [1], which exist problems of complicated synthesis procedure. In this work, we prepared the $(Cr,Mn,Fe,Co,Ni)_3O_4$ HEO by high-temperature solid state reaction [2]. In order to improve the synthesis efficiency, the formation mechanism is necessary. However, the study on the microstructure changing during calcination is still lacking. Therefore, we recorded detailed information of calcination with the temperature increasing by high-resolution transmission electron microscopy (HRTEM), and the $(Cr,Mn,Fe,Co,Ni)_3O_4$ HEO was obtained at 900°C. The entire forming process includes the aggregation of precursors at 500°C; when annealing at 600°C, MnO_2 and NiO diffused into Co_3O_4 , and the spinel-structured $(Mn,Co,Ni)_3O_4$ was formed. With the temperature increasing constantly, Fe_2O_3 and Cr_2O_3 combined with $(Mn,Co,Ni)_3O_4$ sequentially and formed $(Cr,Mn,Fe,Co,Ni)_3O_4$ spinel-structured HEO at 900°C. Furthermore, from the *in-situ* TEM observation, the particle growth direction and the structure of intermediate products were identified through the corresponding FFTs. We also unravel the valence change mechanisms and ion arrangements of $(Cr,Mn,Fe,Co,Ni)_3O_4$ via electron energy loss spectroscopy (EELS), and X-ray absorption near edge spectroscopy (XANES).
This study successfully revealed the formation and growth process of HEO at atomic scale for the first time. The results provide the roadmap on improving the manufacturing process of $(Cr,Mn,Fe,Co,Ni)_3O_4$ HEO, which are expected to play a vital part in the development of anode materials for next generation LIBs.

Selective Oxygen Reduction to Hydrogen Peroxide on Organic Mixed Ionic-Electronic Conducting Polymers Ana De La Fuente Duran, Allen Liang, Ilaria Denti, Alexander Giovannitti, William C. Chueh, Alberto Salleo and Tyler Mefford; Stanford University, United States

The oxygen reduction reaction (ORR) can involve the transfer of four electrons, resulting in the formation of H_2O, or two electrons, yielding hydrogen peroxide (H_2O_2). For either product, several reaction schemes with different intermediates are possible, complicating the identification of a detailed mechanism for a given material. Nevertheless, mechanistic studies of ORR-active materials are critical for optimizing of the use-cases for the ORR, whether it be fuel cells or electrochemical H_2O_2 synthesis. Developing a rigorous framework for the study of oxygen reduction is crucial to understanding whether the reaction proceeds via an electrocatalytic mechanism.
Using a multi-faceted approach to study oxygen reduction, our work sets out to identify the operating mechanism of hydro(gen)peroxide production on organic mixed ionic-electronic conducting polymers (OMIECs). As a model system, we primarily study p(NDI-T2 P75)—a random copolymer comprised of naphthalene diimidie (NDI) and bithiophene (T2) units, where 75% of the NDI units have polar sidechains. Through the use of rotating ring disk electrode measurements, we find that this OMIEC is capable of reducing oxygen and that it is highly selective for the two-electron reaction. Further, using operando UV-Vis and Raman spectroscopy measurements, we find the mechanisms through which this OMIEC becomes active. To gain further insights about the reaction path, we construct and test a microkinetic model. Through this model, we show that this material, as well as a number of other OMIECs, reduces oxygen through a non-electrocatalytic, outer-sphere electron transfer mechanism.

5:00 PM CH01.11.20
Selenium Nanowire Cathodes Coated with Conductive Polymers for Fast Electron Transfer and Suppression of Shuttle Effect of Conversion Cathodes Seokgyu Ryu, Jeeyoung Yoo, Juyeon Han, Harim Seo, Eunbin Jang, Wonwoo Choi, Jaeyoung Oh and Seungjin Park; Kyungpook National University, Korea (the Republic of)

For a few decades, rechargeable batteries have been widely applied in a wide range of applications, from portable electronics to electric vehicles(EVs), and the energy market in developing and continues to grow. Especially, EVs are increasingly in demand, require higher energy density than conventional lithium-ion batteries. This generation of LIBs is limited to a specific energy of around 225 Wh kg–1. To expand the use of LIBs into heavy equipment and heavy vehicle and other long-range automotive applications, there is a strong motivation to develop batteries with energies over 400 Wh kg–1. For this demand, many researchers are looking for cathode electrode with improved electrochemical properties to satisfies the requirements of high-energy lithium-ion batteries (LIBs).Therefore, it is urgently needed to pursue other new battery systems with high energy density. Of the explored candidates, conversion cathode, respresentative, Lithium-sulfur (Li-S) batteries have been widely studied as one of the most promising next-generation energy storage systems due to their high theoretical capacity (1675 mAh g-1) and fairly good energy density (2600 Wh kg-1). Furthermore, abundant reserves in nature, Nickel and Cobalt free, which are unstable in supply and demand, and low cost are the competitive advantages of Li-S battery.
Selenium is an element in group 16 of the periodic table like sulfur, and the Li-Se battery also exhibits a redox mechanism similar to Li-S battery. Li-Se batteries have a lower specific capacity than Li-S batteries, but the volumetric energy density is not significantly different from that of Li-S batteries. On the other hand, the conductivity, which is an important property of the cathode material, is Se , which is much higher than that of S .
Based on these advantages, Li-Se batteries have been researched a lot to improve their performance. Especially, carbon base materials such as CMK-3 and activated carbon are widely used for selenium anodes. Its wide porosity makes it suitable for stored large amounts of selenium, and its high conductivity can improve the poor conductivity of selenium. Additionally, many studies have been conducted to suppress the shuttle effect through surface treatment by adding functional groups to carbon. However, many processes using carbon have the disadvantage of having to manufacture the electrode through high temperature & high pressure at the high melting temperature of selenium.
To clarify these issues, We synthesized selenium nanowire through selenium dioxide(SeO2) rather than melting process to compensate for these shortcomings, to facilitate electrode manufacturing. Selenium nanowire with 1d structure has superior conductivity compared to conventional selenium, and by compounding with carbon nanotube, which was the same 1d material, selenium-carbon electrode can be manufactured without melting process. Moreover, we processd of synthesizing selenium nanowire, PEDOT:PSS coating improved the conductivity of selenium nanowire and wettability with SWCNT.
Our research team increased wettability with SWCNT through PEDOT:PSS coating on self-developed 1d wire Selenium nanowire, which is proved by numerous electrochemical data. After 100 cycles, the PEDOT:PSS coated SeNW capacity was down to under 20% to 410 mAhg-1, while the Pristine SeNW cathode was 162 mAhg-1, under half. Moreover, it appeared to have higher capacity at higher rates as well. This improved electrochemical stability is because the PEDOT:PSS coating layer not only plays an excellent electron transfer role to SeNW, but also improves the binding energy with lithium polyselenide, causing a faster conversion reaction.In order to further prove this phenomenon, DFT was applied to the VASP simulation to calculate the binding energy of the electrode surface and polyselenide according to the presence or absence of the PEDOT:PSS coating layer.

5:00 PM CH01.11.21
Effects of Ionic Liquids Confined in Carbon Nanopores with Different Geometries and Surface Charges Vladimir Pavlenko; Al-Farabi Kazakh National University, Kazakhstan

During the presentation an important role of nanopores having different geometries and various surface charges on the nanoconfinement of ionic liquids utilized to assembly the electric double-layer capacitors (EDLCs) operating at sub-zero temperatures will be discussed. Home-made carbons were prepared via different methods of templated synthesis, while a pristine imidazolium-based fluorinated ionic liquids and their binary mixture were used as a solvent-free electrolyte. It will be shown that short-range graphene layers produced with 8-nm silica nanoparticles lead to the creation of transport channels which better accommodate ions. We explain these findings per coulombic interactions among the ions and between the pore wall and the ionic species under confinement and electrochemical polarization conditions. Further, it will be shown that a microporous carbon performs better than hierarchical carbons at room temperature; however, owing to the large fraction of mesopores, the latter exhibit far higher capacitance down to −40 °C. While the ordering of ions in confinement is more critical at room temperature and dictated by the micropores, low temperature performance of supercapacitors is determined by the mesopores that provide channels for facile ion movement and keep the bulk ionic liquid–like properties.

Enabling High Performance Potassium Storage in Ceramic Structures by Dual Salt Electrolyte Shakir Bin Mujib and Gurpreet Singh; Kansas State University, United States

A dual-salt electrolyte of KPF_6/KFSI in carbonate ester solvents have been developed for long-life and high-capacity SiOC ceramic anodes in K-ion batteries. The KPF_6/KFSI in ethylene carbonate (EC)/diethyl carbonate (DEC) exhibits higher ionic conductivity than single-salt KPF_6 solution. Here, it is shown that the capacity retention and Coulombic efficiency of polymer-derived SiOC ceramics can be remarkably improved by simply using KPF_6/KFSI dual salt dissolved in EC/DEC as the electrolyte over the KPF_6 salt dissolved in EC/DEC electrolyte. By investigating different SiOC electrode structures (powder and fiber), it is discovered that the degradation of SiOC half-cells in KPF_6-containing electrolyte originates from the failure of the electrode. The SEI layer formed on SiOC during cycling was systematically investigated by using a series of characterizations.

Nanostructure and Defects Tailoring of Fe Oxide Catalysts for Nitrogen Reduction Reaction Stefania M. Privitera[1], Giuseppe Tranchida[1,2], Rachela G. Milazzo[1], Marco Leonardi[1,2], Silvia Scalese[1], Luca Pulvirenti[2], Guglielmo Guido Condorelli[2], Corrado Bongiorno[1] and Salvatore A. Lombardo[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Catania, Italy

Electrochemical ammonia synthesis under mild conditions is considered a promising strategy to produce green ammonia for renewable energy storage, taking advantage of its high hydrogen content and easy liquefaction. However, the use of electrochemical processes for ammonia synthesis has been so far challenging due to the absence of efficient catalysts, able to break the N_2 triple bond, and to the competition with the more favorable hydrogen evolution reaction in aqueous solution, preventing the nitrogen reduction to ammonia. In this work we adopt several advanced characterization techniques to optimize the efficiency of Fe oxide nanoparticles as a sustainable, earth-abundant catalyst for nitrogen reduction. SEM, XPS and TEM analyses with electron energy loss spectroscopy (EELS) have been employed to compare different deposition conditions and to optimize the morphology and composition of the nanoparticles, allowing higher catalytic activity toward electrochemical ammonia synthesis. The produced ammonia has been determined through the indophenol blue method, adopting a rigorous experimental protocol to avoid environmental contaminations. The structural characterization of the catalyst has been coupled to an electrochemical activation process, which is effective in increasing the electrochemical active area. XPS analyses performed after the electrochemical activation have shown that the increase of available active sites corresponds to an increase of oxygen vacancies and of the Fe^{+2}/Fe^{+3} ratio. After the activation process, the faradic efficiency for nitrogen reduction increases from 3.8 % to 20.4 %, giving insight on the physical mechanisms which determine the performance of FeOx catalysts for ammonia synthesis.

High Energy Density and Ecofriendly Lithium-Ion Battery with Operando Health Evaluation Avetik Harutyunyan and Oleg A. Kuznetsov; Honda Research Institute USA Inc, United States

The resolution of the energy-environment dilemma demands protection the vulnerable and limited resources of Nature while meeting the growing energy demand of the world. This makes the sustainable development of renewable energy a mission of central importance. The success of this mission depends on the advances in storage technologies such as rechargeable batteries. Therefore, the rapidly growing battery market should provide both high energy density and waste-management solutions for the anticipated global annual battery waste of about two million metric tons.
To address this dilemma, we developed self-standing composite electrodes for Li-ion batteries without electrochemically inactive metal current collectors, additives, and binders, increasing energy density by up to 40%. The resulted flexible electrodes were prepared via in situ mixing of as-grown single-wall carbon nanotubes (SWNTs) with aerosolized electrode active materials. Apparently, well dispersed pristine SWNT scaffold exhibits a piezoresistive effect. This intrinsic piezoresistance of SWNT network enables operando self-monitoring of battery structural health without implanting any new components into the battery architecture. Proposed new solution-free battery electrode fabrication technology and architecture eliminates environmentally harmful chemical compounds from the production line and enables recycling and recovery of active materials by only mechanical separation, aiming at safety and circular economy.

8:45 AM CH01.12.03
Listening to Batteries—Using Acoustic Techniques for Advanced Characterisation to Improve Battery Performance and Safety Arthur Fordham[1,2], Rhodri Owen[1,2] and Rhodri Jervis[1,2]; [1]The Faraday Institution, United Kingdom; [2]University College London, United Kingdom

The growing electrified transport and stationary storage sector continues to drive demand for more powerful and energy dense lithium-ion batteries. Therefore, it is crucial that battery monitoring systems advance at the same rate with improved diagnostics to maximise performance and safety. Acoustic methods are one of the most promising diagnostic techniques for batteries. The technique, in addition to being low-cost, non-invasive, and non-destructive, offers the potential for a real-time *operando* prediction of the State of Health (SoH), State of Charge (SoC) and State of Safety (SoS). Acoustics can complement electrochemical and crystallographic methods to better understand the phase transitions and defects occurring within cells.

The acoustic techniques can be divided into Acoustic Emission (AE) and Ultrasonic Testing (UT) methods; each slightly differs in terms of purpose and experimental setup. Both techniques can detect the physical and electrochemical changes within the cell during usage such as gas formation and cracking. Recent papers focus on SoH estimation based off the ability of acoustics to monitor these changes(1-3). However, there remain outstanding gaps in the literature which necessitate continued investigation into these techniques.
This work, based on research undertaken at UCL as part of the Faraday Institution (FI) SafeBatt project, covers three aspects of the use of acoustics in battery characterisation. The first uses a combination of AE and UT in a novel dual-sensor approach to detect how well the solid electrolyte interface (SEI) grows during the cell's formation cycle, and how this SEI layer effects long-term cell performance and degradation. This technique can characterise how successfully a cell has formed based on the acoustic signals released, offering the opportunity for optimisation of the formation process of cells, which is a critical bottleneck in industry.
The second aspect focuses on the use of acoustics to predict thermal runaway (TR). It is now required that an EV's Battery Management System provides a 5-minute advance warning to the passenger before a hazard stemming from TR occurs(4). Experiments simulated real world abuse conditions for cells to initiate TR whilst monitoring the internal structure of the cell with AE. It was found that AE can detect the damage occurring in the cell before failure by using the types of signals generated demonstrating that AE can be implemented within an EV and supply improved warning systems.
The third aspect of the work focuses on acoustics complemented with other non-destructive diagnostic techniques including X-ray computed tomography and X-ray diffraction. This work demonstrates how acoustics can be used for diagnosing aging for cells at their end of life. UT offers a rapid and non-destructive alternative to measure the degradation in each individual cell. This maximises the use of the battery and minimises the waste of raw materials.

Based on the three experimental applications outlined above, machine learning (ML) classification models are being developed to automate the signal diagnosis. ML can characterise the types of signals being produced and can be used to determine when problems are occurring within the cell. Automation is vital to reduce costs whilst simultaneously increasing accuracy of the signal classification *operando* during electrochemical cycling. The overarching aim of these investigations is to demonstrate how acoustics can be used as an advanced characteristion technique for batteries and its future use across different electrochemical technologies.

9:00 AM CH01.12.04
Discovery of Stable Sodium-Ion Battery Cathodes with Machine Learning Minseon Kim and Kyoungmin Min; Soongsil University, Korea (the Republic of)

Despite their success in commercialization, lithium-ion batteries(LIBs) have a problem of cost increase due to limited Li resources. In this respect, sodium-ion batteries(SIBs) have similar chemical properties to analogous Li-based structures and high price competitiveness, making them a strong candidate to replace LIBs. The cathode mainly determines the stability and the performance of SIBs; hence, it is important to perform research on finding the next-generation materials to develop SIBs cathode materials with high voltage, capacity, and life cycle.
Among the cathode candidates of SIBs, layered oxides, which have a high capacity and a simple structure, are mainly classified into O3 and P3, and especially, O3 has capable of improving electrochemical performance. However, an irreversible phase transition occurs from O3 to P3 during the

(de)intercalation process. Since this phenomenon causes structural and performance degradation, it is imperative to develop a thermodynamically stable material for the commercialization of SIBs. The stability can be determined by obtaining the energy difference(ED) of the O3-P3 phase. In the process of developing new materials, selecting appropriate compounds is required, but testing all materials takes excessive time and cost. Density functional theory(DFT) calculations and machine learning(ML) are efficient for the initial new material screening. Therefore, in this study, we employed DFT and ML to explore cathode candidates which potentially resist irreversible O3-P3 phase changes during electrochemical cycling.
In this study, two classification prediction models have been constructed for two states: pristine and desodiated. In the layered structure of $Na_xTM_aTM'_bO_{24}(6\leq x\leq 12)$, 27 transition metals(TM) were combined at a ratio of a:b=5:1 and 3:3 to generate a total of 2,916 candidates. A total of 392 input features were generated using chemical descriptions(CDs), atomic features, and raw chemical information used in CDs calculations. The total energy of O3-P3 materials was calculated in each state using DFT calculation. ED is a value obtained by subtracting the energy of the P3 phase from the O3 phase in each of the predefined states. If pristine and desodiated ED is negative, it is classified as stable material, and this means that the phase would not be easily transformed.
As a result of comparing several models using the Pycaret, the ExtraTrees Classifier showed the best performance and it was used as the base model. In the pristine state, unstable(194) and stable(1,257) structures were found, which is a serious data imbalance problem. However, in the desodiated state, it has a uniform distribution of unstable(697) and stable(754). To overcome such issues, data sampling algorithms(SMOTE, SMOTE+Tomek, SMOTE+ENN) and stratified sampling were conducted. As a result, in a pristine state, the model applying SMOTE+ENN to the base model performed the best, with significant performance improvement from an accuracy value of 0.878 to 0.976 and an F1 score of 0.404 to 0.979. In addition, the desodiated model also showed the highest performance with the SMOTE+ENN model and demonstrated that the accuracy and an F1 score increased from 0.650 to 0.945 and from 0.631 to 0.947, respectively.
As a result of analyzing the calculated ED of the O3-P3 phase, 1,257 stable materials in the pristine state and 754 stable materials in the desodiated state were identified. The number of intersection data in the two states was 637, and a material with high stability that did not change the phase was found. Among them, 155 materials with a voltage of more than 3V and a theoretical capacity of more than 200mAh/g were selected. New cathode candidates were presented, showing values far beyond the performance of the existing Na cathode materials. We believe that the current study provides meaningful insights into the SIB research society by providing the database of O3-P3 phase stability and the potential cathode materials.

Gas-Phase Composition as a Predictive Metric for Calendar Life Behavior of Next-Generation Silicon Anodes Kae Fink, Mel Soto, Maxwell Schulze, Gerard M. Carroll, Peter J. Weddle, Ankit Verma, Nathan R. Neale, Andrew Colclasure and Bertrand Tremolet de Villers; National Renewable Energy Laboratory, United States

The expansion of renewable technologies and electrification of the transportation sector is driving increased demand for next-generation battery materials that provide higher power and energy density with superior cycling and calendar life stability. Silicon (Si) has a theoretical capacity nearly 10x that of graphite, and is therefore a promising anode material candidate to meet these rigorous performance demands. While leading Si anode battery demonstrations are approaching target metrics for cycle life, a series of complex and interrelated modes of reactivity lead to reduced calendar life and therefore challenge practical adoption of these materials. Deconvoluting the degradation processes that impact Si calendar life is critical to informing the rational and accelerated design of improved Si materials. In the present work, we employ novel sampling techniques and GC-MS-FID characterization to measure gas-phase composition during initial Si cycling, which we tie to selective mechanisms of Si passivation. We utilize a tiered analysis approach to identify and quantify the gas-phase reaction products associated with three advanced Si material candidates under practical operating conditions. *Ex situ* analysis of Si powders (pure chemical reactivity) is coupled with nondestructive *in situ* sampling of Si electrodes in a practical pouch-cell format (coupled chemical and electrochemical reactivity). We link the observed gas-phase species evolution to electrochemical behavior and measured calendar life of the three Si materials. Further, we evaluate the voltage-resolved evolution of gas-phase species for one such Si nanomaterial, where nonmonotonic gas generation implies competition between passivating reaction pathways. The measured gas-phase compositional data serves as a critical input for our advanced electrochemical SEI models to identify favorable vs unfavorable reaction pathways to stabilize Si. In addition to bolstering a fundamental understanding of Si reactivity, the present approach informs specific and quantifiable gas-phase metrics tied to calendar life improvements in Si, which can streamline and accelerate the process of next-generation material development.

10:15 AM CH01.12.06
Evaluation of Lithium-Ion Batteries Following a Single Thermal Insult Gordon Waller, Corey T. Love and Rachel Carter; Naval Research Laboratory, United States

Lithium-ion batteries (LIB) typically have a manufacturer recommended temperature range of 0 °C to 60 °C depending on operation. Heating cells well above the recommended upper temperature limit is a common method to evaluate the safety of lithium-ion batteries. Above some critical temperature, LIB undergo a series of exothermic reactions leading to rapid self-heating, referred to as thermal runaway (1). Exothermic reactions in LIB begin with decomposition of the solid electrolyte interphase (SEI) layer on the anode at temperatures in the range of 60-80 °C, or just above the manufacturer recommended upper limit (1) (2). However, temperatures above 120 °C are typically needed before self-heating can no longer be mitigated through passive heat rejection and cell failure occurs. Observed LIB failures depend on chemistry, cell design, and state-of-charge but can range from relatively benign such as the activation of an internal safety device or venting electrolyte vapors to incredibly energetic ejections of flaming debris (3). Aging effects by cycling or storing cells near the manufacturer recommended upper temperature limit have been evaluated and generally result in a higher observed onset temperatures for thermal runaway due to growth of the SEI, however reported results vary with cathode chemistry (4)(5). Impacts of LIB exposed to temperatures in the range of 60 °C to 120 °C, or above the manufacturer recommended limits but below the onset of self-sustaining thermal runaway, have not been broadly studied. An important scenario to consider are large LIB containing many cells in which one or more cells have undergone thermal runaway. Propagating thermal runaway can occur due to the failure of a single cell, however brief exposures of adjacent cells to temperatures well above the manufacturer recommended limit without propagating failure is also a possibility. The impacts of these "thermal insults" on of cell performance and safety will be the subject of this presentation. High energy (3.4 Ah) 18650 LIB were subjected to thermal insult conditions including temperatures of 100 °C at 100% state-of-charge. After the thermal insult, galvanostatic cycling and electrochemical impedance spectroscopy were used to determine impacts on the cell capacity and impedance. Isothermal Battery Calorimetry (IBC) was used to observe changes in heat generation during cycling, while Accelerating Rate Calorimetry (ARC) was used to evaluate the thermal runaway behavior of the cells.

High Throughput Characterization Methods at the Wafer Scale for Sputtered Films Used in Micro-Supercapacitors and Li-Ion Micro-Batteries

Aiman Jrondi[1,2], Khac Huy Dinh[2,1], Bukola Jolayemi[2], Maxime Hallot[2], Clément Leviel[1,2], Christophe Lethien[2,3] and Pascal Roussel[1]; [1]UCCS - CNRS UMR8181, France; [2]IEMN - CNRS UMR 8520, France; [3]Institut Universitaire de France, France

The emergence of new miniaturized and autonomous electronic technologies leads to a request of efficient microdevices for energy storage. The development of thin film Li-ion micro-batteries or micro-supercapacitors is an interesting way to power connected sensors, as their manufacturing method is compatible with the techniques used in the microelectronics industry[1–4]. These miniaturized electrochemical energy storage devices can thus be easily integrated into embedded electronics. Most of the time, for the development of such energy microsources at the laboratory scale (and more specifically at the electrode level), studies are conducted on small pieces of substrates where the area of tested electrode material is restricted. It is however important to study the homogeneity of thin film electrodes, not only on small pieces of substrates, but at the wafer scale, in the case of an industrial transfer of more fundamental researches led at the laboratory scale (i.e the upscaling of the technology, needed for the collective fabrication of hundreds/thousands of microdevices on a single wafer). We have developed a complete mapping strategy of thin film electrodes characterization at the wafer level on different techniques, such as X-ray diffraction, X-ray fluorescence, scanning electron microscopy, Raman spectroscopy, electrical conductivity and more especially for this project, an electrochemical mapping[5,6]. By combining the information given by all these complimentary techniques, we can correlate the differences of properties observed for different zones of the wafer. For instance, in some vanadium nitrides for micro-supercapacitors applications, a strong variation of the preferred orientation (as measured by an XRD mapping of the full wafer) is evidenced, depending on the scanning area of the wafer, without any change of the chemical composition and of the electrochemical performance. It is not the case for some spinel-type compounds (i.e. sputtered $LiNi_{0.5}Mn_{1.5}O_4$ films) used as the positive electrode for Li-ion micro-batteries, that behave differently depending on the preferred orientation (i.e compounds with privileged conduction path in the structure)[7–10].

10:45 AM CH01.12.08

Ni-Rich Layered $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ with Dual Gradients on Both Primary and Secondary Particles in Lithium-Ion Batteries

Mingwei Shang, Xi Chen and Junjie Niu; University of Wisconsin--Milwaukee, United States

Abstract

As an important component in lithium-ion batteries (LIBs), cathode material is regarded as the major limiting factor for the energy density of LIBs. To meet the requirement of high energy density of LIBs, it is important to improve the capacity retention and long cycling performance. Currently the Ni-rich layered cathode materials such as NMC811 are regarded as a class of promising cathode material and attracting considerable attention due to the high capacity and the high discharge potential. However, some challenges related to the poor cycling stability and rate capability of Ni-rich oxide cathode materials still need to be addressed. The performance fading is mainly originated from the Li^+/Ni^{2+} cation mixing, Li residues, overcharging, crystal orientation of the secondary particles, etc.
Due to high surface area, controllable porous structure and periodic arrangement of metal atoms, the highly ordered 3D MOFs have been demonstrated as new pyrolytic precursors in obtaining non-precious metal oxides with homogeneous particle distribution. Here we present a novel layered NMC811 with dual Ni-gradients on both primary and secondary particles that was synthesized by applying Ni-MOF-74 during the coprecipitation (Shang, Chen, Niu. ***Cell Reports Physical Science***, 3 (2022), 100767). The introduced self-healing phase by forming a cation mixing layer on the surface of particles effectively improved the structural stability by suppressing the phase transition and internal cracks upon cycling. The battery performance with the designed D-NMC811 as cathode electrode was greatly improved. An initial specific capacity of 203.5 mAh/g at 0.1 C and a capacity retention of 88.5% after 300 cycles at 1/3 C were obtained. At the elevated temperature of 55 degree, the battery still showed a CE of 99.47% at 1/3 C after 300 cycles. Compared to the conventional NMC811, the full-cell battery with D-NMC811 exhibited an increased capacity retention of >86.7% with a CE of >99.86% at 1/3 C after 300 cycles. Moreover, the large-scale pouch cell using the D-NMC811 as cathode delivered an initial capacity of 297.62 mAh and a CE of 99.48% after activation, which contributed to an energy density of 216.41 Wh/kg. After long 500 cycles at 1.0 C, the capacity retention was still as high as 84.1%, which was much higher than the battery made by conventional NMC811. The compatible manufacturing process by incorporating with MOFs provides a new route to produce Ni-rich transition metal cathode materials at large scales with high-capacity retention and long cycling capability in next-generation batteries.

Revealing Dynamic Electrochemical Interface of $LiNi_{0.5}Mn_{1.5}O_4$ Spinel Cathode for Realizing Simultaneous Mn and Ni Redox for Cost-Effect High-Energy Rechargeable Lithium Batteries

Jihyun Hong; Korea Institute of Science and Technology, Korea (the Republic of)

The exploding electric-vehicle market requires cost-effective high-energy materials for rechargeable lithium batteries (RLBs), including Li-ion and Li-metal systems. For a decade, substituting cobalt with nickel in cathodes has been an effective strategy to reduce the materials cost for RLB production while increasing the energy density. However, the rapid spread of EVs has consumed a tremendous amount of metal resources, eventually triggering a price surge of nickel and lithium. In contrast, the price of manganese has remained incomparably low. Consequently, the use of Mn-rich chemistry has attracted

attention from researchers as a promising option to realize cathode materials with high economic sustainability and reasonable energy density.
Among the Mn-rich cathode materials, spinel-type $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO) is an attractive alternative to the Ni-rich layered oxides. LNMO is renowned for the high potential of the Ni^{2+}/Ni^{4+} redox couple, 4.7 V (vs. Li), offering a theoretical energy density of 690 Wh kg^{-1}, within a conventional voltage range of 3.5–4.9 V. A more exciting feature of LNMO is its capability to store more energy using an additional Mn^{3+}/Mn^{4+} redox reaction at 2.7 V, exhibiting a capacity greater than 200 mAh g^{-1}. The simultaneous use of Ni and Mn multi-cation redox reactions in LNMO enables an energy density exceeding 860 Wh kg^{-1}. Combining the high energy density with low materials cost, LNMO exhibits a high energy-to-cost ratio of 89.7 Wh USD^{-1}, corresponding to 547% and 279% of that of $LiCoO_2$ and $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$, respectively, when cycled over a wide voltage range.
Despite this benefit, a long-established hypothesis has restricted the use of multi-cation redox reactions in LNMO: the reduction of Mn^{4+} to Mn^{3+} inevitably results in poor capacity retention.[1] The Jahn-Teller distortion of the Mn^{3+} octahedral sites causes the phase transition from cubic (*Fdm*) to tetragonal ($I4_1/amd$) phases, inducing an extra anisotropic lattice strain. Furthermore, trivalent Mn is considered labile to the disproportionation into Mn^{4+} and Mn^{2+}, which has a high solubility in organic electrolytes. The reversible use of the Mn redox reaction, however, has been successfully demonstrated in many other cathode materials, such as Li-rich Mn-rich layered oxides and disordered Li-rich rocksalt oxides. The extended cycle life of Mn-based cathodes confirms that the formation of divalent and trivalent manganese cations does not necessarily deteriorate the battery performance. Such inconsistency requires a precise understanding of the degradation mechanism to facilitate the stable use of Mn redox chemistry in LNMO in addition to the conventional Ni redox.
Herein, for the first time, we demonstrate the excellent reversibility of Mn^{3+}/Mn^{4+} redox within 2.3–4.3 V, leading us to revisit the conventional theory of LNMO degradation. LNMO loses capacity only when cycled within a wide voltage range of 2.3–4.9 V, simultaneously employing Mn^{3+}/Mn^{4+} and Ni^{2+}/Ni^{4+} redox. Using surface-sensitive structural and chemical probes, we reveal that a dynamic evolution of the electrochemical interface, e.g., potential-driven rocksalt phase formation and decomposition, repeatedly occurs during cycling. The interfacial evolution induces electrolyte degradation and surface passivation, impeding the charge-transfer reactions. We further demonstrate that stabilizing the interface by electrolyte modification (e.g., EC exclusion) enables LNMO to possess a capacity retention of 91.0% after 100 cycles, an energy density of 715 Wh kg^{-1}, and a power density of 588 W kg^{-1} within the voltage range of 2.3–4.9 V. Our discovery of the prominent role of electrochemical interfaces on the cycling of LNMO proposes modulating the CEI stability as a promising strategy to develop high-energy and long-cycle-life RLB cathode materials of Mn-rich chemistries.

Understanding Electrochemical Growth of Carbon Nanotubes from CO_2 Andrew B. Wong; National University of Singapore, Singapore

The development of new carbon-negative electrochemical processes are of paramount importance to the future sustainability of human civilization. This presentation will focus on the electrochemical growth of carbon nanostructures from CO_2. Previous works have pioneered the observation of carbon nanotube growth in molten $LiCO_3$ electrolytes from CO_2. However, in many past works, several CO_2-derived cathodic carbon morphologies were observed, which included carbon particles/spheres, graphite flakes, carbon nanofibers, CNTs, and graphene-like ultrathin carbon sheets. Moreover, these morphologies are often mixed, resulting in a low selectivity and difficult separation towards one single carbon morphology, and the factors leading to various morphologies are not currently well understood. In this talk, we will explore the fundamental growth mechanism to inform the broader long-term goal of improving the selectivity towards carbon nanotubes from CO_2. This present work studied the cathodic growth of carbon nanotubes by utilizing a simple three-electrode configuration consisting of pure Li_2CO_3 electrolyte, pure transition metal foil cathodes, Pt anode, and homemade Ag/Ag_2SO_4 reference electrode to determine the impact of tunable parameters on the resulting electroreduction products. These products are studied via potential-dependent studies as well as via ex-situ techniques such as TEM, XPS, XRD, and Raman spectroscopy to gain insights into the growth of these materials.

Building 3D-organaized Nanocrystallites to Harness Grain-boundary Defects Myoung Hwan Oh[1,2,3]; [1]Korea Institute of Energy Technology, Korea (the Republic of); [2]UC Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

Topological defects (i.e. dislocation, grain-boundaries) play an essential role in the properties of crystalline materials. When the size of the crystallite or functional domain of the materials decreases to the nanometer scale, the defects predominantly determine those properties. To date, however, neither bottom-up nor top-down methods for synthesizing nanocrystalline materials have been able to find a reliable way of controlling these defects. Herein, we demonstrate the delicate control of 3D heteroepitaxy using a lipid membrane-like synthetic system to grow various nanocrystallites, 3D organized with uniform grain-boundaries and related defects. In the resulting structures, the 3D-patterned strain field, which exists in the form of disclinations and dislocations, can be determined with atomic precision and even tailored. Through nano-to-macro crystallography and spectroscopy, we have also confirmed that the uniformity and dicreteness of the defects allow us to find a reliable correlation between the local strains/defects and collective electrochemical properties (i.e. catalytic activities for oxygen reduction reactions). These middle-entropy nanomaterials give us an opportunity to conduct nano-mechanics of 3D organizations of interconnected and symmetry-related functional domains and explore novel electronic states emerging from 3D coherent lattice and topological defects. Lastly, the current research focus to build next-generation functional nanomaterials for energy nanotechnology using 3D nano-mechanics will be discussed.

Chemical Crossover Accelerates Degradation of Lithium Electrode in High Energy Density Rechargeable Lithium-Oxygen Batteries Shoichi Matsuda and Manai Ono; National Institute for Materials Science, Japan

There has been considerable interest in developing rechargeable lithium oxygen batteries (LOBs) that have the potential to significantly exceed the energy density limit of a Li ion battery (approximately 300 Wh/kg). Although 500 Wh/kg LOB has been demonstrated and exhibited stable discharge/charge cycle at room temperature condition[1], their cyclability remains less than 10 cycle. For realizing the LOB with practically high energy density and long cycle life, the deep understanding of complicated reaction in LOBs has been highly demanded. Especially, the problems specifically associated with the limited electrolyte (“lean-electrolyte”) conditions need to be taken into account in LOBs.

Although the importance of investigating negative lithium electrodes in lean-electrolyte systems has been recognised in recent years[2], specific problems associated with the negative lithium electrode in a LOB has not been investigated so far. In particular, chemical crossover from the positive electrode to the negative electrode is a crucial factor that needs to be taken into consideration. Actually, recent studies have shown that LiOH is formed on the surface of a lithium-metal electrode through reaction with H_2O in the electrolyte[3,4]. This H_2O is generated by the decomposition of the tetraethylene glycol dimethyl ether (TEGDME) solvent at the positive oxygen electrode, which then migrates to the negative electrode side to react with the lithium-metal electrode. Consequently, problems related to chemical crossover are prominent in lean-electrolyte LOBs, where the effective water concentration in the electrolyte is much higher than that in an excess electrolyte system.

Despite the importance of investigating the reaction of negative lithium electrodes in LOB with appropriate technological parameters, mechanistic details remains unclear due to the technical difficulty for applying non-destructive analytical methods. In the present study, we investigated the reaction of a negative lithium electrode in a lean-electrolyte LOB operating under high areal capacity conditions. The use of advanced non-destructive analytical methods, including three-electrode electrochemical techniques and an in-situ analytical setup revealed that the reaction efficiency of the lithium electrode mostly decreases through chemical crossover from the positive oxygen electrode. In particular, the H_2O generated as a side-product at the positive oxygen electrode crosses over to the negative electrode side and reacts with the lithium-metal electrode to form a porous $LiOH/Li_2CO_3$ layer on the electrode surface. LiOH and Li_2CO_3 accumulates, and the porous layer thickens through repeated discharge/charge cycling, which supresses efficient Li-ion transport through the layer. In addition, the solvent decomposes rather than lithium peroxide during the final stage of charging at the positive oxygen electrode, and the generated CO_2 crosses over to the negative electrode side where it is further electrochemically reduced. This complicated LOB chemistry results in a significant decrease in reaction efficiency at the negative electrode. Importantly, the degradation behaviour observed for the lithium-metal electrode, which is due to chemical crossover from the positive electrode, is a common problem for next-generation rechargeable battery systems that use lithium electrodes. Hence, the methodology demonstrated in the present study, which combines non-destructive analytical techniques, effectively clarified the complicated hidden reaction mechanism associated with lithium-metal-based rechargeable batteries that operate under lean electrolyte conditions.

Understanding the Effect of Low Temperature Degradation on Lithium-Ion Battery Performance and Safety Charlie R. Kirchner-Burles[1], Paul Shearing[1], Dan Brett[1] and Gareth Hinds[2]; [1]University College London, United Kingdom; [2]National Physical Laboratory, United Kingdom

As efforts to decarbonise the world economy ramp up, lithium-ion batteries have become a crucial component in facilitating the transition of key industries to clean energy. Successfully tackling this challenge requires continuous improvements in energy-density, longer cell lifetimes and better assurances in safe cell operation. In recent years, numerous high-profile failures of Li-ion batteries have been reported[1], contributing to wider concerns about the safety of high energy density cells. Inadequate management of such systems, in applications such as electric vehicles, aerospace, and portable commercial devices, can be costly in both human health and financial damages. Therefore, it is important to study battery safety in order to provide a reliable alternative to fossil fuels. Apprehensions in cell safety can mainly be attributed to a cell's ability to enter thermal runaway, a process that is most often caused by an internal short circuit (ISC). Such an event can be triggered by three different modes of abuse: thermal, mechanical, and electrical.

Conditions of thermal and mechanical abuse are mostly because of a cells external environment and can be controlled more easily; however, electrical abuse often originates from internal conditions that accelerate the growth of lithium dendrites that can pierce the separator – a mechanism that is more difficult to monitor or predict. At the anode, metallic lithium can precipitate onto the surface via three main conditions: overcharge, high charging currents, and low charging temperatures. Each of which create a saturation of intercalated lithium ions in the crystallographic active sites near the anode surface. This lowers the anodes surface potential until it is sufficiently low enough for lithium plating to occur. To better understand this process and how it affects battery safety, our work investigates the degradation of commercial cylindrical cells (with NCA cathodes) at low temperatures and how it changes their response to abusive conditions. Here we show that as the temperature is lowered, plating becomes more aggressive and pseudo-homogenous due to the reduced rate of lithium-ion diffusion into the bulk graphite.

By utilizing various *in-situ* lithium detection techniques, such as post-charge voltage relaxation, Electrochemical Impedance Spectroscopy, and Differential Capacity Analysis, the extent of a cell's degradation and its state of safety can be estimated by monitoring real-time electrochemical data. Further optimization of these techniques to generate quantitative measurements on the aforementioned parameters would greatly improve battery management systems and their predictive capabilities of cell failure. Moreover, subsequent Accelerated Rate Calorimetry (ARC) studies highlight that a cells thermal stability diminishes as degradation becomes more advanced. These findings demonstrate how lithium plating has an impact on battery safety and why more work is needed on developing real-time assessments of a battery's state of degradation. Insights into the mechanisms at play in such failures have been achieved through post-mortem X-ray computed tomography (CT) and *operando* ultra-high-speed tomography and radiography. Together, these techniques act as a valuable tool in elucidating failure behaviours.

MALDI-TOF-MS as a Powerful Tool for Elucidating Nanocrystal Synthesis Mechanism Artur Feld[1,1], Agnes Weimer[1,1], Andreas Kornowski[1], Naomi Winckelmans[2], Jan-Philip Merkl[1], Hauke Kloust[1], Robert Zierold[1], Christian Schmidtke[1], Theo Schotten[3], Maria Riedner[1], Sara Bals[2] and Horst Weller[1,1,3]; [1]University of Hamburg, Germany; [2]University of Antwerp, Belgium; [3]Fraunhofer-CAN, Germany

The synthesis and development of colloidal nanocrystals still proceed by trial and error.[1] High-quality semiconductor quantum dots and iron oxide nanocrystals are synthesized in organic solvents using universally applicable ligands such as oleic acid. Thereby, starting from a few compounds, a highly complex reaction pathway is rapidly developing, whose essential aspects are still unknown. Insufficient knowledge of fundamental reaction mechanisms, especially the role of reaction intermediates during the formation of colloidal nanocrystals, prevents the expansion of the application potential of many nanoparticle systems.

Therefore, an essential goal of advanced nanocrystal synthesis is a comprehensive understanding of the reaction mechanisms in order to tailor and simultaneously control the triad of size, shape, and crystal structure. Since targeting this triad is hampered by numerous intertwined variables and severely limits the scope of synthetic results, unraveling the essential reaction mechanisms is of paramount importance.

We show exemplarily on the system - iron oxide - that significant aspects of the fundamental reaction mechanism can be elucidated by using matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-ToF-MS). The combination of highly pure iron oleate and advanced mass spectrometry enabled us to gain a deep insight into the composition of iron oleate and elucidate a new cascade of redox reactions responsible for converting the individual complexes into each other already at low temperatures and early synthesis stages. Furthermore, we obtained evidence for the catalytic activity of iron in iron oleate by identifying many new complexes, thus essentially contributing to a more profound knowledge of the reaction conditions.[2]

This study serves as a template for the investigation of related systems[3,4] and reveals fundamental commonalities that will be exploited to unlock the missing tailored and simultaneous control of the triad of shape, size, and crystal structure.

Mapping Distribution of Modern Binders in Graphitic Li-Ion Electrodes Enables Optimization of Electrodes Structure Stanislaw Zankowski[1,2] and Patrick Grant[1,2]; [1]University of Oxford, United Kingdom; [2]Faraday Institution, United Kingdom

Despite their low fraction (<5 % volume) in Li-ion electrodes, polymeric binders are a critical component of Li-ion batteries. Binders provide cohesion and adhesion of electrode particles to one another and to current collectors, and stabilize active particles against volume changes upon cycling. But binders also impede transport of Li^+ in the electrode pore space and, therefore, co-determine overall battery rate performance and lifetime. During high rate drying of cast electrodes, re-precipitated binder is prone to migrate from the current collector (where needed most) towards the electrode free surface (adding to ionic resistance). Consequently, slow electrode drying to maintain optimal binder distribution can become the bottleneck to high throughput, low-cost electrode fabrication. Up to now, however, practical binder optimization studies in negative Li-ion electrodes have been hindered by the lack of a convenient method to map the aqueous-processable binder used in most modern graphite electrodes that comprises a mixture of sodium-carboxymethyl cellulose (CMC) and styrene butadiene rubber (SBR).

We have developed two methods of independently labelling CMC and SBR using aqueous Cu^{2+} ions and gaseous Br_2 vapour, respectively, and tracing their distribution in electrodes using energy dispersive X-ray spectroscopy (EDX). Immersing electrodes in aqueous Cu^{2+} solution results in instant formation of an insoluble Cu-CMC complex, while exposing the electrodes to Br_2 vapour results in rapid bromination of SBR C=C bonds. Owing to the specificity of reactions, both binder components can be precisely mapped using EDX for copper and bromine. Additionally, bromination allows rapid (few seconds) detection of binder using backscattered electron imaging for quick assessment and feedback of binder distribution. Enabled by these new labelling techniques, we present two exemplary studies on binder agglomeration from sub-optimally mixed slurries, and on mitigating binder migration during fast electrode drying using a novel phase inversion approach. We show how improved CMC/SBR binder control can enhance the electrochemical performance of negative Li-ion electrodes.

Quantifying Speciation and Degradation of Tin Anodes in Aqueous Batteries Sofia Catalina, Jianbo Wang, William C. Chueh and Tyler Mefford; Stanford University, United States

Aqueous batteries based on metal anodes (Zn, Al, Mg, Sn, etc.) present an attractive alternative to lithium-ion for long-duration energy storage due to their low-cost, high-safety, and theoretically high energy density. Still, despite many efforts towards development and commercialization, metal anode systems remain hampered by irreversible hydrogen evolution (HER), detrimental shape change, and passivation during cycling. Direct characterization of charge/discharge products and efficiency losses to parasitic side reactions are thus crucial to mitigate the degradation processes that limit the performance and applications of aqueous batteries.

Our work focuses on tin (Sn) as a largely unexplored alternative metal anode for aqueous systems. In alkaline electrolytes, Sn is reversibly electrodeposited from and anodically stripped to an aqueous $Sn(OH)_6^{2-}$ complex through an overall 4-electron process. This process is complicated by the generation of a soluble $Sn(OH)_3^-$ intermediate which limits the coulombic efficiency of the cell through crossover to the cathode. At high utilization, the limited solubility of $Sn(OH)_6^{2-}$ drives precipitation of an insulating SnO_2 product with limited reversibility. Additionally, while Sn has a high overpotential for HER, hydrogen generation during charge is still present at higher rates.

In this talk, we will describe our efforts to quantify these processes to understand the partitioning of charge/discharge current during cycling. Speciation between Sn(II) and Sn (IV) in the liquid phase is quantified using ^{117}Sn nuclear magnetic resonance (NMR). To investigate the solid plating behavior and reversibility of SnO_2 reduction, we perform *operando* XRD of Sn anode pouch cells. Lastly, we will describe the development of an *operando* gas detection method to quantify parasitic hydrogen and oxygen production using Clark type electrodes. The combination of these techniques may have wide applicability in aqueous battery development and help to explain commonalities in degradation processes that generate irreversible solid, liquid, and gaseous products.

New Diagnostic Technique to Characterize Electro-Kinetics in Redox Flow Battery Chao Zeng, Soowhan Kim, Yucheng Fu, Yunxiang Chen, Jie Bao and Zhijie Xu; Pacific Northwest National Lab, United States

As the fraction of electricity generated from intermittent renewable sources (such as solar and wind) grows, developing reliable energy storage technologies to store electrical energy in large scale is of increasing importance. Redox flow batteries (RFB) are regarded as a leading technology in providing a well-balanced solution for current daunting challenges of grid-scale energy storage. Cell-level resistive losses reduce RFB power density and originates from ohmic, kinetic, or mass transfer limitations. existing studies on electron and mass transfer rates are mostly performed in ex-situ conditions based on planar electrodes, so the obtained key parameters are difficult to make specific interference about the performance of a practical electrode in a battery. To address this limitation, an in-situ electroanalytical technique for RFB is proposed for the first time by a symmetrical cell design. For both cathodic and anodic reactions, the polarization curves at condition of a serious of flow rate are obtained on the symmetrical flow cell. The high frequency resistance is also obtained by electrochemical impedance spectroscopy (EIS) at open circuit condition. The ohmic, kinetic and mass transfer resistance can be decomposed from total polarization. Then, the corresponding key parameters, i.e., membrane conductivity, reaction rates, transfer coefficients and mass transfer rates, can be obtained by using a theoretical calculation of specific surface area. The extracted key parameters are validated on both vanadium redox flow battery and aqueous organic redox flow battery.

Magnifying Rate Capability and Efficiency of Li-Ion Storage Mechanism via Next-Generation Standalone Electrodes Enabled by $MoSe_2$ Nanosheets in SiOC High Aspect Ratio Structures Sonjoy Dey and Gurpreet Singh; Kansas State University, United States

Transition metal dichalcogenides (TMDs) such as $MoSe_2$ have continued to generate interest in the engineering community because of their unique layered morphology—the strong in-plane chemical bonding between transition metal atoms sandwiched between two chalcogen atoms and the weak physical attraction between adjacent TMD layers provides them with not only chemical versatility but also a range of electronic, optical, and chemical properties that can be unlocked upon exfoliation into individual TMD layers. Such a layered morphology is particularly suitable for ion intercalation as well as for conversion chemistry with alkali metal ions for electrochemical energy storage applications. Nonetheless, host of issues including fast capacity decay arising due to volume changes and from TMD's degradation reaction with electrolyte at low discharge potentials have restricted use in commercial batteries. One approach to overcome barriers associated with TMDs' chemical stability functionalization of TMD surfaces by chemically robust precursor-derived ceramics or PDC materials, such as silicon oxycarbide (SiOC). SiOC-functionalized TMDs have shown to curb capacity degradation in TMD and improve long term cycling as Li-ion battery (LIBs) electrodes. Herein, we report synthesis of such a composite in which MoSe2 nanosheets are in SiOC matrix in a self-standing fiber mat configuration. This was achieved via electrospinning of TMD nanosheets suspended in pre-ceramic polymer followed by high temperature pyrolysis. Morphology and chemical composition of synthesized material was established by use of electron microscopy and spectroscopic technique. When tested as LIB electrode, the SiOC/MoSe2 fiber mats showed improved cycling stability over neat $MoSe_2$ and neat SiOC electrodes. The freestanding composite electrode delivered a high charge capacity of 586 mAh g−1electrode with an initial coulombic efficiency of 58%. The composite electrode also showed good cycling stability over SiOC fiber mat electrode for over 100 cycles.

Correlative Multi-Microscopies Study of Electrodeposited Pt Nano-Assemblies as Precipitation Platforms for $Ni(OH)_2$ Nathaly Ortiz Peña[1], Louis Godeffroy[2], Jean-François Lemineur[2], Frédéric Kanoufi[2], Damien Alloyeau[1] and Jean-Marc Noël[2]; [1]Université Paris Cité, CNRS, Laboratoire Matériaux et Phénomènes Quantiques, France; [2]Université de Paris Cité, ITODYS, CNRS UMR 7086, France

Nanoscience involving nanoparticles (NPs) is a key element in the development of the next generation of efficient and safe systems enabling the conversion or storage of renewable energy. NPs being intrinsically heterogeneous in size, shape or composition, it is of prime importance to develop strategies able to investigate chemical processes at the single entity level or even at the sub-entity level. This will allow identifying structure-activity relationships that is fundamental to predict and control the activity of the NPs. Herein, we have harnessed the controlled monitoring of individual NPs electrodeposited on micrometric conductive surfaces to visualize operando by electrochemical transmission electron microscopy (EC-TEM) and post-mortem high-resolution TEM (HR-TEM) their electrocatalytic activity. It is exemplified herein by tracking the electrodeposition of platinum nano-assemblies (Pt-NA) and their modification by $Ni(OH)_2$. This electrochemical decoration of Pt nanostructures with metal hydroxides like $Ni(OH)_2$ is of great interest for the enhancement of hydrogen evolution reaction efficiency in alkaline media.[1] In this sense, we have been able to analyze the morphologies of the electrodeposited Pt-NA *post-mortem* by HR-TEM depending on the electrodeposition strategy, whereas the precipitation of $Ni(OH)_2$ was followed *operando* by EC-TEM. Complementary post-mortem analysis of the nano-assemblies by energy dispersive spectroscopy (EDS) and HR-TEM allowed determining the structure of the bifunctional material. Finally, the reactivity of the $Ni(OH)_2$/Pt for the hydrogen evolution reaction was investigated by EC-TEM.

Advances in the Characterisation of Honeycomb Layered Oxides Titus Masese[1], Yoshinobu Miyazaki[2], Godwill M. Kanyolo[3], Shintaro Tachibana[4], Yuki Orikasa[4], Hiroshi Senoh[1] and Tomohiro Saito[2]; [1]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [2]Sumika Chemical Analysis Service (SCAS), Ltd., Japan; [3]The University of Electro-Communications, Japan; [4]Ritsumeikan University, Japan

Honeycomb layered oxides constitute a burgeoning class of materials with vast compositional and crystal structural versatility,[1] and with prospects in diverse fields spanning from electrochemistry, materials science, condensed matter physics and cosmology.[2-8] Despite the prospects envisioned in this class of materials, their augmentation is still encumbered by knowledge gaps that obscure the current understanding of their atomistic properties and behaviours. In this context, characterisation techniques are considered an efficient approach for accelerating the pace of discovery and optimisation of these materials through the elucidation of the atomic-level origins of material functionality and performance. In this talk, we introduce analytical techniques based on diffraction, microscopy and spectroscopy that have been applied to unravel various structural and electronic aspects of honeycomb layered oxides, particularly those that entail pnictogen or chalcogen atoms.[9-12]

8:30 AM *CH01.14.02
High Spatial and Temporal Resolution Imaging for Advancing Fuel Cells and Electrolyzers Aimy Bazylak; University of Toronto, Canada

The transportation sector is responsible for 15% of global greenhouse gas emissions. In Canada, it is even more significant, i.e. 30% of country-wide emissions originate in the transportation sector, of which heavy-duty vehicles are an increasing contributor. Clean electrochemical energy conversion technologies, such as fuel cells and electrolyzers, are critical for reaching global net-zero 2050 decarbonization targets. However, cost and durability are key barriers to the widespread commercial adoption of fuel cells and electrolyzers, where these issues stem from inefficient transport of reactants and charge through materials and interfaces. Polymer electrolyte membrane (PEM) fuel cells and electrolyzers are composed of porous materials, including the catalyst layer, microporous layer, and substrate, and both material characteristics and associated multiphase flow behaviour have a significant impact on electrochemical performance. Commercial materials typically exhibit highly heterogeneous material and chemical properties, both of which are not fully resolved in the current literature. To reach cost targets for widespread commercial adoption, we must realize materials that enable more effective multiphase flow phenomena than what currently exists. Mass transport losses in PEM fuel cells and electrolyzers are both prohibitively significant, yet designing these materials requires the a priori knowledge of how the heterogeneous properties of the porous materials and their interfacial contacts influence electrochemical performance. In this talk, I will discuss our numerical and experimental methods of elucidating the complex multiphase flow behaviour in the porous materials of PEM fuel cells and electrolyzers and the critical impacts of material design.

9:00 AM *CH01.14.03
Visualization of Electrochemical Reactions in All-Solid-State Li-Ion Batteries by *Operando* Transmission Electron Microscopy Kazuo Yamamoto and Yuki Nomura; Japan Fine Ceramics Center, Japan

All-solid-state Li-ion batteries (ASS-LIBs) having incombustible solid-electrolytes are expected to be promising energy-storage devices because they have advantages of safety, long life-time, low cost and high energy density, compared with common liquid-based LIBs. However, there is a serious issue that needs to be solved for practical use, namely, large resistance of Li-ion transfer at the electrode/solid-electrolyte interfaces and/or in the electrodes. The high resistance of Li-ions drastically reduces the power density of the batteries. To overcome this issue, it is necessary to understand how Li-ions are transferred across the solid-solid interfaces during battery operation. We have so far developed a technique to operate ASS-LIBs in a transmission electron microscope (TEM) and succeeded in visualizing the electric potential distribution using electron holography [1, 2]. Moreover, to directly visualize the Li distribution, we have used electron energy-loss spectroscopy (EELS) in a scanning/transmission electron microscope (S/TEM) [3, 4]. Here, we report recent results of *operando* observation using S/TEM techniques.
We prepared a thin-film-type ASS-LIB having $LiCoO_2$-cathode/Al-, Si-, Ge-doped $LiTi_2(PO_4)_3$-solid-electrolyte (LATP)/*in-situ*-formed-anode structures. We used *operando* STEM-EELS to visualize the 2-dimensional Li maps in $LiCoO_2$ region [4, 5]. In a pristine state, the Li concentration was not uniform and the low concentration layers (20 nm) were observed near the interface. We found that mixture of Co_3O_4 and $LiCoO_2$ was formed, which is the origin of the large interfacial resistance of Li-ion transfer. In charge/discharge states, the Li concentration was changed in the $LiCoO_2$ as expected. To improve the time-resolution of *operando* STEM-EELS, we applied machine learning technique to obtain Li signals from EELS data set by reducing random noises. We succeeded in observing that Li-ions moved in not only perpendicular direction but also parallel direction to the interface [5]. If presentation time is permitted, we will show another result of Li observation in a bulk-type ASS-LIB having sulfide-based solid-electrolyte [6].
We would like to thank Dr. M. Fujii, Dr. T. Hirayama, Ms. E. Igaki, Prof./Dr. K. Saitoh and Prof./Dr. Y. Iriyama for valuable discussion in this study. This work was partially supported by JSPS KAKENHI (JP17H02792, JP19H05814).

9:30 AM CH01.14.04
Proton-Conducting Composite Membranes with Graphene Oxide and (3-mercaptopropyl) Trimethoxysilanefor Hydrogen Fuel Cells Shahjahan K. Chowdury[1], Young Jin Cho[1], Sung Bum Park[2] and Yong-il Park[1]; [1]Kumoh National Institute of Technology, Korea (the Republic of); [2]Dongguk University Gyeongju, Korea (the Republic of)

Graphene oxide membrane (GOM) has outstanding electrolyte properties in electrochemical devices, such as fuel cells, electrolyzers, and batteries. In proton exchange membrane fuel cells (PEMFCs), perfluorinatedsulfonic acid (PFSA) membrane, i.e., Nafion®, is used as an electrolyte, which has disadvantages in the fuel cells application, such as fuel crossover, expensive, difficult manufacturing process, and many more. However, GOM has a much lower proton conductivity in through plane (σ_{th}) compared to Nafion® due to anisotropic properties of GOM, and the loss of surface functional groups due to reduction by hydrogen is accompanied by an increase in electron conductivity when in contact with hydrogen gas in a fuel cell. Therefore, in this study, an MPTS-modified GO composite (MGC) was synthesized using a high-viscosity GO solution (5 mg/ml) and a dilute (3-mercaptopropyl)trimethoxysilane(MPTS, $HS(CH_2)_3Si(OCH_3)_3$) (0.790 g/mL) (MPTS) and this was followed by impregnation of excess MPTS as a binding agent for MGC.The thiol group of the MPTS monomer is oxidized by hydrogen peroxide (H_2O_2) to a sulfonic acid group ($-HSO_3$), providing a fast proton conduction path with negative oxygen functional groups on the GO particle surface.The optimum weight of incorporation was analyzed by examining the amount of MPTS from 1 to 70 wt% in the GOM matrix. The physicochemical properties, gas crossover, chemical and thermal stability and proton conductivity of composite membranes were studied and compared with pristine GOM and Nafion®. In addition, hydrogen-permeable Pd was deposited on the surface of the MGC membrane to improve gas tightness and maintain high mechanical stability to prevent membrane degradation and reported the performance of hydrogen fuel cells using synthesized MGC membranes.

Addressing the Stability Challenges of Gas Diffusion Electrodes in the Presence of ILs-Based Solutions for the Continuous Electrochemical Reduction of CO_2 Federica Zammillo[1], Hilmar Guzmán[1], Danilo Candela[1], Stéphanie Narbey[2], Boyan Iliev[3] and Simelys Hernandez[1]; [1]Polytechnic University of Turin, Italy; [2]Solaronix SA, Switzerland; [3]IOLITEC, Germany

Nowadays, it has become clear that the ever-increasing concentration of carbon dioxide (CO_2) in the atmosphere is a threat to global security[1]. Therefore, the adverse climate events remind us that a transition towards a carbon neutral economy is more necessary than ever. Several approaches have been proposed to convert CO_2 to valuable products and, among these, the electrochemical reduction of CO_2 (ECR-CO_2) represents one of the most promising alternatives. Herein, the ECR-CO_2 has been carried out for the first-time employing silver based-gas diffusion electrodes (GDEs) within a continuous flow cell and in the presence of ionic liquids (ILs)-based solutions, which have been known to boost CO_2-derived products[2]. As reported in the literature, the instability of GDEs is initiated by the high overpotentials needed during the CO_2 reduction reactions and usually culminates in flooding[3]. This eventually has a negative impact on the product selectivity as well as limits the perspectives of scalability. In particular, in this work, different stability issues have been faced and visualized, for example, in the blackening of typical carbon-based gas diffusion layers (GDLs) and in the degradation/colour changes of ILs-electrolyte. Interestingly, by switching to non-carbon based GDLs it has been possible to reach and maintain a steady-state production of carbon monoxide (CO) both at -10 mA cm^{-2} and at -20 mA cm^{-2} for at least 40 minutes, with a H_2/CO ratio slightly above 2 in the former case. Field Emission Scanning Electron Microscopy (FESEM) and Electrochemical Impedance Spectroscopy (EIS) techniques have been employed to carry out the physicochemical characterization of the electrodes and to assess the electrochemical interfaces within the system, respectively. The observed findings definitely encourage us to proceeding with our study on GDL-supported catalyst for the continuous ECR-CO_2 in the presence of ILs solutions and offers openings for a large-scale deployment.

The financial support of the SUNCOCHEM project (Grant Agreement No 862192) of the European Union's Horizon 2020 Research and Innovation Action programme is acknowledged.

Stabilizing Cobalt-free Li-rich Layered Oxide Cathodes through Oxygen Lattice Regulation by Two-phase Ru Doping Yameng Fan[1,2]; [1]University of Surrey, United Kingdom; [2]University of Wollongong, Australia

The limited theoretical capacity of traditional cathode materials solely based on transition metal (TM) redox has been a primary factor for the ceiling placed on the energy density of LIBs. In this regard, Li-rich layered oxides (LLOs) have received a great deal of attention, due to their high reversible capacity (> 250 mAh g^{-1}) and high energy density (900 Wh kg^{-1}), courtesy of the TM redox and the additional high-voltage O^{2-} redox.[1] Developing Co-free cathodes is inevitably a holy grail to overcome the limitations faced by conventional Co-containing LIB cathode materials (e.g., $LiCoO_2$, NMC) due to the high-cost, toxicity, and limited geological distribution of cobalt. Therefore, studies on Co-free LLOs are necessary for creating long-term benefits for the cathode industry. Like typical LLOs, Co-free LLOs suffer from dramatic voltage decay on cycling, which hinders their applications in commercial LIBs. It is well accepted that this voltage decay is primarily attributed to the irreversible anionic redox and structural degradation in LLOs. The doping strategy has been widely used to address the voltage decay of LLOs.[2] While the dopant is typically introduced to the layered Rm component, the lithium-rich component (C2/c) in the LLOs, which is the source of anionic redox, has always been ignored.

In this work, a small quantity (3%) of the electrochemically active 4*d* metal, Ruthenium (Ru), is successfully doped into TM octahedral sites in both hexagonal and monoclinic phases in the typical Co-free Li-rich LNMO cathode.[3] The effects of Ru doping on the structure and redox activities of the LNMO are investigated using various morphological, local structure, and crystallographic techniques. Neutron-based pair distribution function (PDF) analysis, neutron powder diffraction (NPD), and *in operando* synchrotron-based X-ray powder diffraction (XRPD) is employed to characterize the short- and long-range cation arrangement, the chemical environment of lattice oxygen, and the structural evolution on cycling. Post-mortem synchrotron-based near-edge X-ray absorption fine structure (NEXAFS) and X-ray absorption characterizations (XAS) are utilized to investigate the cationic/anionic redox process. The correlation between voltage decay with structural changes is reported in detail. Owing to enhanced structural stability, Ru-doped LNMO exhibits an extraordinarily low voltage decay (< 0.45 mV per cycle) and meanwhile retains a high reversible capacity (215 mAh g^{-1} at 1 C) contributed by both cationic and O^{2-} redox. This work unravels the role of heavier ions in modifying the structural evolution and suppressing the voltage decay and sheds light on improving the performance of cathodes for practical applications in LIBs.

Material Development Strategy Guided by Degradation Analysis Under Dynamic Load in Proton Exchange Membrane Water Electrolysis

Anastasiia Voronova[1,2], Jong Hyun Jang[1,2], Hee-Young Park[1] and Bora Seo[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]University of Science and Technology, Korea (the Republic of)

To realize the hydrogen economy and achieve net-zero carbon emission, practical implementation of water electrolysis (WE) technique is of prime importance. Among the WE techniques, proton exchange membrane water electrolysis (PEMWE) has attracted much attention due to its high performance, compact design, and fast response. However, the lack of an appropriate evaluation protocol for durability, and the lack of understanding on degradation behavior of each component in PEMWE hinder its widespread application. In this presentation, degradation behavior under dynamic load-based accelerated stress test (AST) protocols will be discussed to guide material development strategy. Load ranges were varied by changing the low voltage limit (LVL) between 1.4 V and 1.9 V while fixing the high voltage limit at 2.2 V. The used AST protocols can simply mimic solar profiles characterized by high ramp rates and loads fluctuations. The AST protocols with LVL 1.4 V and LVL 1.5 V resulted in contrast degradation behaviors, showing an increase and decrease in performance after the test, respectively. The performance decrease, observed for the LVL 1.4, was ascribed to the fuel cell-like operation mode with reversal current occurrence, considered as additional stress factor for the cathode catalyst degradation. For the LVL 1.5, the slight performance increase is ascribed to the membrane thinning and/or catalyst dissolution at the anode/catalyst interface, which temporarily increases roughness, thereby exposing more active sites to the electrolyte. The AST protocols with LVL 1.7 and LVL 1.9 resulted in the substantial increases in mass transport overpotential. Given the cross-sectional SEM analyses, the results is presumably attributed to the bubble nucleation and subsequent degradation on membrane/catalyst and/or diffuse layer/catalyst interfaces together with decrease in catalyst layer porosity. Meanwhile, a comparative AST protocol with steady-state load (2.2 V) resulted in the performance decay, mostly attributed to the increase in ohmic overpotential due to the Ti porous layer passivation. The degradation study can suggest a practical guidance for understanding degradation behavior of each component, and for material development strategies in designing durable PEMWE system.

SESSION CH01.15: Virtual Session II

8:00 AM *CH01.15.01
Towards a Realistic Modelling of Electrified Interfaces the Nanoscale Clotilde Cucinotta; Imperial College London, United Kingdom

In this talk I will introduce some issues connected with the simulation of electrified interfaces at the nanoscale focusing on simulating the effect of an applied potential to an electrochemical (EC) cell, using realistic models for the charged electrode electrolyte interface. I will present some recent progress in the simulation of the double layer of the fundamental Pt-water interface and its response to changes of potential applied to the cell [1]; this is obtained applying a general ab initio electrode-charging approach we developed. If time allows, I will illustrate how combining knowledge from molecular electronics and DFT based methodologies to simulate atomic dynamics could lead to a more sophisticated description of EC phenomena.

8:30 AM *CH01.15.02
Development of Lab-on-a-Chip Platform for Electrocatalyst Screening, Electrochemical Testing, *In Situ* Probing of Product Chemical Composition and Morphology Evolution in Li-CO_2 Batteries Yunlong Zhao, Manman Wang and Kai Yang; University of Surrey, United Kingdom

Li-CO_2 batteries (LCBs) have received extensive attention as a promising alternative to solve both energy crises and CO_2 emission issues. However, the development of LCBs is still in its infancy, lacking efficient electrocatalysts, with unclear mechanisms and uncontrollable reaction pathways. Here, we developed a versatile on-chip electrochemical testing platform to simultaneously achieve efficient catalyst screening and in-situ probing of product chemical composition and morphology evolution. Among selected nine typical metal catalysts, the on-chip LCBs with screen-out optimal catalyst exhibited the smallest ultra-low overpotential (~0.55 V). Their high reversibility and reaction pathways were verified by the integrated functions of in-situ electrochemical Raman and atomic force microscopy and supported by the ab initio calculations. Following the on-chip platform guidance, LCB coin cells and pouch cells were fabricated, exhibiting large capacity with a superior energy efficiency of up to 90% and stability. These results demonstrate the practical competitive advantages of LCBs, and more generally, the demonstrated multimodal platform can be broadly applied to other systems (such as metal-air batteries, electrocatalysis, fuel cells and photoelectrochemical), opening new avenues for rapid catalyst screening, mechanism investigation and guiding macroscopic applications.

9:00 AM *CH01.15.03
New X-Ray Spectroscopy Techniques for Energy Materials Research Sofia Diaz-Moreno[1], Oliver Blackman[1,2], Armando Ibraliu[1,3,4], Andrea Russell[2], Daniel Bowron[3] and Christopher Hardacre[4]; [1]Diamond Light Source, United Kingdom; [2]University of Southampton, United Kingdom; [3]ISIS Pulsed Neutron and Muon Source, United Kingdom; [4]The University of Manchester, United Kingdom

X-ray Absorption Spectroscopy (XAS) is an established experimental technique that is used for the study of the electronic and local atomic structure of materials. The high sensitivity of the method together with its element selectivity make it very suitable for the study of energy materials. The technique is also frequently used for the study of processes in situ and under operando conditions.

In recent years, advanced spectroscopy techniques and analysis methods have been used to circunvent some of the shortcomings of traditional XAS. For example, X-ray Emission Spectroscopy at the Kb emission line can be used to perform spin-selective spectroscopy. In addition, the use of Modulation Excitation assisted by phase-sensitive detection (ME-PSD) analysis methods can significantly enhance the sensitivity of XAS by filtering out contributions of spectator species that are unaltered by the external stimulation.

In this contribution I will present two recent examples ilustrating the application of these new methodologies to the study of electrochochemical systems and energy materials. The changes in the structure of the iron metal centre in prussian blue and prussian blue analogues have been studied as a function of the applied potential, and the changes have been assigned to the iron in low and high spin. ME-PSD analysis has been applied to the study of the reversible ferrocyanide/ferricyanide couple using XAS.

9:30 AM *CH01.15.05
***In Situ* Spectroscopy-Guided Design of Synthesis and Processing—Bridging the Gap from Battery Innovation to Manufacturing** Feng Wang; Argonne National Laboratory, United States

Rechargeable batteries are among the key technologies for decarbonization with increasingly expanded applications in transportation and power grids. The demand for safer, longer-lasting, durable energy storage continues to fuel the need for battery innovation. This need, in turn, requires designing new materials, understanding how they function and developing scalable processes to manufacture them. Technical advances in characterization and computation have greatly facilitated materials design and discovery in the past decade. However, making battery materials to meet multifaceted performance needs (capacity, power, lifespan, and safety) has been nontrivial, often hindered by the practical engineering challenges encountered when optimizing the multiple intercorrelated steps – synthesis, processing, benchmarking, and upscaling.
We will present our effort to develop *in situ* spectroscopies applied to studying the synthesis/processing of battery materials, thereby gaining insights into the process design for addressing engineering challenges in battery materials manufacturing. Specifically, synchrotron X-ray based in situ spectroscopies are developed for real-time probing of the intermediate phases and their structural evolution as the materials are being synthesized and processed. The technique allows access to the details of the processes, elucidating how the processing parameters affect the kinetic reaction pathways and, consequently, the target material phases and their properties. Insights gained from such studies provide a basis for materials synthesis/processing by design – rationally selecting synthesis/processing parameters to improve performance and reduce cost. Specific examples will be provided to demonstrate the in situ spectroscopy-guided design of calcination and other scalable processes for processing nickel-based cathode active materials. We will conclude by discussing emerging opportunities in automated experimentation and digitalized process design, bridging the gap from battery innovation to manufacturing.

CryoTEM as a Tool for Investigating Crystallization in Aqueous Systems Jingshan S. Du[1], Jennifer A. Soltis[1], Elias Nakouzi[1], Guomin Zhu[2,1] and James J. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

Solution based synthesis is a common method for production of energy-related materials and a pervasive process in environmental settings tied to energy technology through the impact on carbon emissions and climate. The realization that crystallization in aqueous systems occurs along diverse structural pathways has motivated extensive TEM-based investigations to understand the nature of those pathways, the associated dynamics, and the underlying thermodynamic and kinetic factors. Ex situ TEM studies of such systems suffer from the unknown impact of drying, as well as an inability to directly relate structures seen at one time point with those present at another, rendering an understanding of pathways nearly impossible. For systems amenable to in situ liquid phase TEM, these two problems can be readily circumvented, but the effect of the electron beam through the creation of radiolysis products that alter the solution chemistry and, in the case of organic compounds, the breakdown of the solutes themselves often cast doubt on the applicability of the results to synthetic processes outside the microscope. CryoTEM offers a middle ground that gives a true picture of crystallization at any given time point and allows for the construction of likely pathways per the ergodic principle by analyzing structures present over large areas as a substitute for following individual structures over time. Here we present two examples of crystallization processes for which cryoTEM provides critical information concerning the structural state. The first involves the process of crystal growth through repeated oriented attachment (OA) events, i.e., the growth of single crystals by repeated fusion of nanocrystals that adopt crystallographic coalignment prior to attachment. Using data from minerals aluminum and iron oxide growing by OA, we show that cryogenic high-resolution TEM (HRTEM) can provide definitive information on the temporal evolution of the growing crystals and the structural relationship of the primary particles. The second example involves the crystallization of the water itself. Visualizing the crystalline network of ice with atomic resolution in real space is challenging due to the weak directional hydrogen bonds between water molecules and the resulting instability of ice under an electron beam in vacuo. However, we find that crystallizing water encapsulated between amorphous carbon membranes and freezing it in liquid nitrogen to form hexagonal ice (Ih ice) enables successful HRTEM of the resulting ice sections. Even though the sections show overall single-crystallinity by diffraction standards, the crystal may exhibit structural variation and contain sub-domains ~ 10 nm in size. Quantitative strain and tilt mapping reveals the sub-surface flexibility of ice and is used to demonstrate the correlation between defect structures and strain accumulation. Both sharp low-angle grain boundaries and gradual lattice bending are associated with sub-domains with different crystal orientations. Taken together, this work shows promise in elucidating the molecular and defect structures of ice and may shed light on the physics of ice surfaces and their interfaces with substrates that promote ice nucleation.

8:45 AM *CH02.01.02

Cryo-Enabled Imaging of Interactions Between Airborne Pollution Particles and Human Cells Alexandra Porter[1], Victoria Garcia[1], Sharon Mumby[1], Gloria young[1], Prashant Kumar[2], Gopinath Kalaiarasan[2], Hisham Abubakar-Waziri[1], Iain M. Adcock[1], Kian Chung[1] and Maria Harkiolaki[3]; [1]Imperial College London, United Kingdom; [2]University of Surrey, United Kingdom; [3]Diamond Light Source, United Kingdom

Air pollution is becoming one of the most pressing issues because of the increasing levels of pollution around the world. Airborne particulate matter (PM) can trigger cellular oxidative stress and inflammation, which are the basis for respiratory diseases associated with pollution. Understanding the effects of PM pollution on respiratory system cells is key to develop strategies to reduce personal exposure, especially in congested areas. Currently, there is no correlated cell-level information about the effects of PM on primary human epithelial cells metabolism, the structural damage of cellular organelles and the size and chemistry fractions of PM that cause this cellular damage. In a collaboration with the National Heart and Lung Institute, we have been focusing on the impacts of pollution PM collected from a London Underground platform on the health of cell organelles and cellular metabolism. We have shown that the PM collected from the London Underground is composed of trace quantities of ultrafine particles composed of redox-active transition metals, including Cu, Cr, Fe and Mo that could damage respiratory cells by generating damaging free radicals[1]. We have exposed human nasal epithelial cells from healthy and asthmatic volunteers to this pollution PM. We have chemically fixed and stained the cells, embedded them in a resin and cut ultrathin sections for transmission electron microscopy and analysed the chemistry of intracellular nanoparticles of pollution using high resolution electron microscopy. In parallel, cryo soft X-ray tomography (cryo SXT) with structured illumination microscopy (cryo-SIM) (B24 Beamline, DLS, UK) was employed to generate whole-cell structural and metabolically relevant information about the cells (cell lines and human cells) exposed to PM in their near-native state. I will discuss the changes observed to ultrastructure and metabolism of cell organelles in cells exposed to London Underground pollution particles and the challenges of preparing and imaging human cells for correlative cryoSXT, cryo-SIM and cryo electron microscopy. I will also discuss how optimisation of cryo-focussed ion beam milling scanning electron microscopy (FIB-SEM) techniques could be used subsequently in specific areas for higher resolution imaging and complementary compositional analysis, as well as for lamella preparation for high-resolution cryo-TEM, where oxidation states and composition of damaging PM can be attained. In future, the development of this multidimensional workflow using human derived cells will bring together imaging of whole-cell structure and metabolism with chemical analysis of the PM to identify which chemistries are most damaging to intracellular cell organelles and their mechanisms of toxicity. This novel approach will offer new insights into how to mitigate the health effects of pollution PM.

Local Chain Orientation and Alignment in All-Polymer Solar Cell Christina Cheng, Camila Cendra, Yilei Wu, Zhenan Bao and Alberto Salleo; Stanford University, United States

In recent years, all-polymer solar cell performance has accelerated, in part due to significant improvements in controlling microstructure by optimizing processing parameters. However, quantitative relationships between processing, microstructure, and performance remain weak. While charge generation in all-polymer blends is highly dependent on local chain orientation and local stacking structure, common microstructural characterization techniques only provide bulk average characteristics of film morphology. On the other hand, cryogenic High Resolution Transmission Electron Microscopy (cryo-HRTEM) has emerged as a promising method to image and quantify local polymer structure at sub-nanoscale resolutions.

In this study, we use cryo-HRTEM to analyze the structural organization of the fluorinated all-polymer blend PBDB-T-2F:F-N2200, and we show that donor microstructure can be selectively tuned with processing additives. By applying Fourier analysis and statistical methods, we map the local orientation of lamellar stacking, characterize donor/acceptor domains and interfaces, and quantify inter- and intra-species chain alignment. The results demonstrate how advances in quantitative analysis of cryo-HRTEM images can reveal new structural characteristics in polymer blends.

9:30 AM CH02.01.04

Structural Study of Hydrated Organic Mixed Ionic Electronic Conductors Using Cryogenic 4D-STEM Yael Tsarfati[1,2,3], Karen Bustillo[1], Benjamin Savitzky[1], Colin Ophus[1], Alberto Salleo[2] and Andrew M. Minor[1,3]; [1]National Center for Electron Microscopy, Molecular Foundry, Lawrence Berkeley National Laboratory, United States; [2]Stanford University, United States; [3]University of California, Berkeley, United States

Organic mixed ionic–electronic conductors (OMIECs) are soft organic materials that are advantageous for varied bioelectronic devices, ranging from organic electrochemical transistors (OECTs) and biosensors to batteries and supercapacitors.[1] Their ability to operate in aqueous environments is an important virtue that qualifies them for these applications. One widely used successful strategy for obtaining OMIECs with enhanced water and ion uptake and hence increased capacitance, is placing ethylene glycol side chains on the polymer backbone.[2] However, the structural understanding of these glycolated OMIECs is still limited, particularly in operational states such as being hydrated in water, or used in aqueous electrolytes, or when electrochemically doped. One significant challenge in filling this gap is the challenge in characterizing hydrated or solvent swollen OMIECs, that is incompatible with many standard relevant techniques that involve high vacuum conditions.[3] Here we describe experiments where we used cryogenic vitrified solid-state samples and advanced scanning nanobeam diffraction (4D-STEM). We have previously applied 4D-STEM to study these materials in the dry solid-state, mining structural information from the molecular to the mesoscale level, providing a baseline and analysis pipeline for the more complex states. Applying this hybrid approach, we demonstrate the structural changes induced in glycolated OMIECs by hydration. The most prominent change is the lamellar expansion. Noteworthy, this is not an obviously predicted structural change, and theoretical simulation even predicted a lamellar contraction.[4] We believe this methodology can bring us one step closer to a deeper understanding of the structures of these materials in their operational modes. Our results show how cryogenic 4D-STEM can provide true structure-function relationships that can help improve our rational design of OMIECs thin films for more efficient devices.

9:45 AM BREAK

10:15 AM *CH02.01.05

Development of a Stable Cryogenic *In Situ* Biasing System for Atomic Resolution (S)TEM Yevheniy Pivak[1], Hongyu Sun[1], Tijn Omme[1], Eva Bladt[1], Shelly Michele Conroy[2] and Leopoldo Molina-Luna[3]; [1]DENSsolutions, Netherlands; [2]Imperial College London, United Kingdom; [3]TU Darmstadt, Germany

The development of cryogenic electron microscopy started in the 1970s in order to study the structure of proteins and other biological material. However, only recent advances in detector technology and software algorithms have allowed the determination of biomolecular structure at atomic resolution [1]. The application of cryogenic transmission electron microscopy (cryo-TEM) methods to materials science and energy-related fields has been mainly limited to the study of beam sensitive materials such as lithium-ion batteries, organic semiconductors, perovskite-based solar cells, polymers and metal organic frameworks (MOFs). Most low-temperature in situ TEM experiments are carried out using cryogenic holders based on liquid nitrogen cooling and using 3-mm-sized TEM support grids. Despite their widespread use, grid-based cryogenic systems suffer from poor stability, making it challenging and time-consuming to obtain adequate atomic-resolution imaging [2]. Additionally, these systems often have the inability to set intermediate temperatures, which limits the experiments to be performed at either liquid nitrogen temperature or room temperature. Furthermore, such systems are limited in applications when understanding the structure, electronic and transport properties of materials under an applied electrical stimuli at low temperatures is of interest. For such applications, a system with low sample drift that combines liquid nitrogen cooling with an external voltage bias is needed. Such a development can enable a vast range of applications in the field of quantum materials [2], magnetic materials and nanostructures, ferroelectrics [3], topological insulators, metal-to-insulator transitions, superconductors.

In this talk, we will share our latest developments with respect to a combined in situ cooling and biasing system. The system includes a novel double-tilt cryogenic holder which is based on micro-electro-mechanical-systems (MEMS) technology, and uses liquid nitrogen for cooling. It has multiple electrical contacts and is compatible with the DENSsolutions heating and biasing Lightning Nano-Chips, enabling the setting of any intermediate temperature between LN2 and room temperature. Without the presence of the cooling agent, it is also possible to perform in situ heating experiments up to 1000oC. By exploiting the high stability of this system and its double tilt capability, we will demonstrate how atomic resolution imaging can be achieved while applying a bias to the sample and present a number of application examples, including ferroelectric focused ion beam (FIB) lamellas.

10:45 AM CH02.01.06
Compressive Sensing for 4D-STEM Imaging Jacob Smith[1,2], Hoang Tran[2], Zhaiming Shen[3], Guannan Zhang[2] and Miaofang Chi[2]; [1]North Carolina State University, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Georgia, United States

Quantum materials experience novel phenomena at low temperatures, either developing new structural or ferroelectric phases or new properties such as superconductivity and spin liquids. Because of its ability to simultaneously derive complex information about a material's electric field, charge density, and magnetic structures, four-dimensional scanning transmission electron microscopy (4D-STEM) has gained favor in cryogenic experiments to investigate a material's temperature dependent properties and phase transitions. However, 4D-STEM detectors usually require a per-pixel acquisition time in the region of a millisecond, resulting in a relatively lengthy acquisition time and potential sample damage due to excessive electron dose. One possible strategy is to only capture the probe positions required to recover the desired information. If a proper sampling method is taken and the data at redundant sites can be reconstructed using an algorithm, the total acquisition time and electron dose could be substantially reduced.

In this work, we developed a machine learning (ML) based compressive sensing algorithm to reconstruct 4D-STEM datasets from a limited subset of the available data. Our ML model consists of an autoencoder that extracts a low-dimensional feature space from the limited subset of the diffraction patterns, and a fully connected neural network to map from the integrated images, e.g., bright field, center of mass, to the extracted feature space. Once the neural networks are trained, for each missing pixel, i.e., the pixel that is not scanned during the acquisition, we can use compressive sensing to interpolate the pixel values in the integrated images, map the interpolated values to the feature space via the fully connected network, and then push the feature sample through the decoder to construct the missing diffraction pattern. [1]

Our 4D-STEM compressive sensing algorithm has been successfully implemented on a pair of datasets including different features in real space, including periodical atomic structural imaging as well as samples including interfaces and defects. Using this algorithm, we demonstrate significantly reduced sampling points (down to 25%) is sufficient to reconstruct STEM images retaining atomic-scale structural information.

Elucidating Phase Transition of Metal Trihalides using Cryogenic Scanning Transmission Electron Microscopy Hsin-Yun Chao and Miaofang Chi; Oak Ridge National Laboratory, United States

Transition metal trihalides are two-dimensional van der Waals interlayer-bonded quantum materials with complex phase transitions and intrinsic magnetic orderings at lower temperatures. For instance, $RuCl_3$ stirred up considerable interest due to its potential as a spin-1/2 honeycomb-lattice magnet, which is predicted to have characteristics of a spin liquid [1]. For these 2D materials, shifts in interlayer stacking can cause distinct transitions in magnetic properties [2]. However, atomic scale understanding of variations in layer-by-layer stacking arrangements of metal trihalides at relevant temperatures have yet to be empirically explored. Scanning transmission electron microscopy (STEM) is an exemplary technique to visualize changes in stacking structures. We select $CrCl_3$ as a model material as it is a relatively stable metal trihalide with an observed bulk phase transition at 240 K and ferromagnetic characteristics between 14 K and 17 K [3]. Cryogenic-STEM techniques are employed to examine low-dimensional $CrCl_3$ samples at varying thicknesses and temperatures from room temperature to 103 K. Unexpected stacking shifts deviating from expected phase transitions in the bulk are directly observed through high annular dark field (HAADF) imaging. Implications for these structural changes will be further discussed. [4]

Cryogenic EM Across Length Scales for Li Metal Anode Batteries Katherine L. Jungjohann[1], Laura C. Merrill[2], Renae N. Gannon[3], Steven J. Randolph[4] and Katharine Harrison[2]; [1]National Renewable Energy Laboratory, United States; [2]Sandia National Laboratories, United States; [3]Thermo Fisher Scientific, United States; [4]Oak Ridge National Laboratory, United States

An interfacial understanding is necessary for developing strategies to commercialize high-energy density rechargeable lithium metal anode batteries, as currently, the lithium anode/electrolyte interface is unstable with prolonged cycling. We have used several strategies to improve the cycling performance of lithium metal anodes, including reducing the parasitic reactions between lithium metal and the electrolyte, and improving the electrodeposited lithium metal morphology. These strategies have generated unconclusive electrochemical data, that has required the need for nanoscale interfacial characterization of these solid-liquid interfaces. Our team has used the cryogenic transfer workflow developed by Leica in collaboration with cryo-SEM/FIB tools by Thermo Fisher Scientific to cross-section lithium metal anodes and intact coin cell batteries to observe the interfacial structures, lithium morphology, and failure mechanisms relative to changes in electrode contract pressure, electrode coatings, and electrolyte chemistry. Cross-sectional SEM images and EDS maps of the lithium metal anodes have provided a better understanding of the electrodeposited lithium morphology, quantity of ‘dead’ lithium metal, and quantity of solid electrolyte interphase material that has formed alongside the lithium metal. In understanding lithium metal battery failure at the system level, we used a cryogenic stage in a laser plasma FIB to cross-section through the coin cell’s cap for imaging/mapping the entire battery stack under cryogenic conditions. The tools, methods, and results of these studies will be detailed in this presentation.

11:45 AM CH02.01.09
Event-based direct detection for transmission electron microscopy Barnaby D. Levin, Michael Spilman and Benjamin Bammes; Direct Electron LP, United States

The great majority of detectors currently used in electron microscopy are frame-based. Each time data is read from the sensor, a "frame" is generated by reading out all of the pixels on the sensor, or in a region of the sensor. In applications involving sparse signals, such as electron counting for imaging in cryogenic transmission electron microscopy, frame-based detectors are inefficient, as sparsity means that the majority of each frame does not contain signal, and therefore reading out frames of pixels involves large volumes of redundant data. In contrast, event-based detectors are an alternative technolgy in which pixels are read out asynchronously when they register a significant change in intensity. When event-based readout is employed on a direct detector with a very high single-electron signal to noise ratio, the detector can be designed such that pixels are only read out when they are excited by an incident electron. This strategy avoids the redundancy of reading out large numbers of pixels that contain no signal, and as a result, event-based direct detectors promise higher electron counting performance at a lower cost than frame-based detectors. In this presentation, we will review the development of event-based direct detectors, and their current and potential applications in transmission electron microscopy.

Cryo-TEM for Rechargeable Battery—Does Cooling Solve the Beam Sensitive Problem We Face? Chongmin N. Wang; Pacific Northwest National Laboratory, United States

An imaging process can exert an inadvertent effect on the object being observed. Consequently, what we observe does not necessarily represent what had been present before the observation. Normally, this effect can be ignored if the consequence of such a change is believed not to be significant. Electron beam based imaging and spectroscopic techniques appear to be one of the indispensable approaches for probing the characteristics of rechargeable batteries. Modification of battery materials by the electron beam during their imaging has been widely noticed, which, for some cases, appears to be not amendable for capturing any useful information. This is especially true for the case of dynamically formed entity during battery cycling, such as solid electrolyte interphase (SEI) layer, a thin layer formed on the electrode surface that is essential for electrochemical reactions in batteries and critically governs the battery stability. Recently, it has been demonstrated that, cooling of the battery sample, as termed as cryo-microscopy for materials science, can effectively mitigate the imaging electron induced modification effect, therefore to allow the capturing of structural features of beam sensitive battery materials at multi-scale down to atomic resolution. In this presentation, we will check into the latest advances of cryo-TEM and its application for probing into the structural and chemical evolution of rechargeable batteries, typically in the system of Si and Li anode and their SEI layers. In general, the pros and cons of cryo-TEM for material science will also be discussed.

2:00 PM *CH02.02.02
Cryogenic Electron Microscopy Imaging of Synthetic Soft Materials at the Atomic Level Xi Jiang[1], Tianyi Yu[1], Morgan E. Seidler[1,2], Xubo Luo[1], David Prendergast[1], Ronald Zuckermann[1] and Nitash Balsara[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Atomic resolution imaging of soft materials using electron microscopy is challenging because of the radiation damage under the electron beam. By leveraging low-dose cryogenic transmission electron microscopy (cryo-TEM) and the sophisticated image processing approaches developed by the structural biology community, atomic-scale structural information can be obtained from the nanostructures formed by synthetic soft materials. Our experiments were conducted on crystalline nanosheets and nanofibrils formed by self-assembly of amphiphilic polypeptoid molecules. Low-dose cryo-TEM micrographs were obtained from vitrified nanosheets and nanofibrils. A combination of electron crystallographic and single particle analysis was used to obtain two-dimensional (2D) and three-dimensional (3D) high resolution images of crystal motifs and single molecules. 2D atomic-scale imaging reveals the importance of halogen bonds in the design of crystal motifs in self-assembled nanostructures. Moreover, the hidden lattice symmetry in halogenated nanosheets is clearly illustrated in 3D density map. In addition, 3D reconstruction of nanofibrils shows the direct view of chain conformation, the unique internal structures comprising two opposite layers and the effect of capping group interactions on the design of nanostructures. These discoveries thus allow us to explore the effect on inter/intra interactions on the self-assembled nanostructures at the atomic level.

2:30 PM *CH02.02.03
Development of Cryogenic Techniques for Characterizing Energy Storage Materials in Electrochemical Process Minghao Zhang[1] and Y. Shirley Meng[2]; [1]University of California, San Diego, United States; [2]The University of Chicago, United States

Lithium-ion batteries (LIBs) commercially dominate portable energy storage and have been extended to hybrid/electric vehicles by utilizing electrode materials with enhanced energy density. The energy density and cycling life of LIBs must extend beyond the current reach of commercial electrodes to meet the performance requirements for transportation applications. Recently, researchers proposed to use Li metal as the anode to achieve higher energy density. However, the dendritic growth of Li metal during cycling will result in low coulombic efficiency as well as safety issue which is detrimental for practical applications. It is proposed solid state electrolytes (SSE) are compatible with lithium metal because of lithium penetration resistance, which can be the ultimate choice to achieve the energy density of 500 Wh/kg. The performance of existing all-solid-state batteries is still not optimal, which is mainly attributed to the poor interfacial stability. Further improvements and developments of these energy storage materials rely on a fundamental understanding of their electrochemical cycling mechanisms at atomic level. Characterization of Li anodes and SSE/Li-metal interfaces remains difficult due to their sensitivity to beam damage, the nano-scale of interfacial decomposition products, and their buried nature. Our group has demonstrated the importance of cryogenic techniques for preparation (cryogenic focused ion beam, cryo-FIB) and characterization (cryogenic transmission electron microscopy, cryo-TEM), to preserve the morphology and structure of lithium metal. These breakthroughs enabled unprecedented characterization of plated Li metal and are currently being extended to all-solid-state batteries.

The first demonstration of the functionality of the cryo-TEM will focus on characterizing the morphology and crystallinity of electrochemically cycled lithium metal with different electrolytes. This work will also cover recent advances on cryo-EM development for Li/LiPON/LNMO interfaces. The combination of cryo-FIB and cryo-EM is necessary for quantitative structural and chemical analysis due to extreme susceptibility of both lithium metal and LiPON to air and beam damage. The obtained results provide new insights of decomposition, diffusion of chemical species, and chemical evolution along the interface, which leads to a better understanding of the cycling stability for Li metal batteries.

Atomic-Scale Imaging of Exciton and Phonon Dynamics in Quantum Materials Sandhya Susarla; Arizona State University, United States

Accessing the atomic scale structural and electronic properties is crucial to understand fundamental correlated properties in quantum materials. In recent times, analytical electron microscopy techniques such as scanning transmission electron microscopy (STEM)-electron energy loss spectroscopy (EELS) under cryogenic conditions have been applied to image local bosonic states such as excitons and phonons. My talk will be focused on probing these bosonic states at low temperatures. I would start my talk with moiré two-dimensional transition metal dichalcogenides which have correlated electronic states resulting from atomically varying strains associated with the stacking configuration. I will talk about the recent progress that we have made in cryogenic imaging excitons in moiré two-dimensional transition metal dichalcogenide heterostructures at the atomic scale from barely detecting the moiré exciton signal in EELS [1] to imaging these excitonic states at the atomic scale [2] to recognizing the fine structure of the moiré excitons [3]. I would also elaborate on the future cryogenic experiments that could be performed on these systems. In the second part, I will take the example of a thin film $PbTiO_3$ layer grown on $DyScO_3$ substrate [4] and explain how the phonon properties vary near the domain walls. I hope to end my talk by provinding insights about future for cryogenic electron spectroscopy to be successful in accessing fundamental structural and electronic states in quantum materials with some of the pathways that our group is adopting to solve this problem.

5:00 PM CH02.04.01
Imaging Gas Adsorption in MOFs via 4D-STEM Sarah Karstens[1], Karen Bustillo[2], Jeffrey Long[1,1] and Andrew M. Minor[2,1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Metal–organic frameworks (MOFs) are crystalline coordination networks composed of metal ions connected by organic linkers. One of the most prominent advantages of MOFs originates from interactions of the framework with small molecules; these are referred to as host-guest interactions. Visualizing interactions between host MOFs and guest molecules with cryoTEM enables us to explore their structure under different conditions. For example, it is possible to compare partial loading and visualize the nanostructural morphology of individual crystals, and ultimately optimize loading of MOFs.[1] Currently, host-guest interactions in MOFs are either understood via theoretical simulations or bulk characterizations using x-ray/neutron diffraction, in situ diffuse reflectance infrared spectroscopy, or nuclear magnetic resonance.[2] These experimental techniques average out information such as heterogeneity among adsorption sites.

MOFs are inherently electron beam-sensitive and typical electron irradiation causes collapse of the structure within seconds.[1] Since gas adsorption in a MOF is usually optimized to be reversible (so that the MOF can be cycled and reused), the host-guest interaction is ideally somewhat weak. At atmospheric pressure, small gas molecules and any other volatile solvent easily desorbs from the material. The high vacuum in the TEM further promotes desorption.[2]

For this project, a novel, air-free workflow to activate and gas dose metal-organic frameworks on a TEM grid has been devised. This is followed by cryogenic transfers that ensure that the gas molecules remain adsorbed in the pores of the material for imaging in the TEM.

This workflow was used on Co(bdp) (bdp^{2-} = 1,4-benzenedipyrazolate), a MOF in which adsorption induces a structural phase transition. Scanning nanodiffraction or “4D-STEM”[3] was employed to map the change in lattice parameters upon desorption. First, 4D-STEM at cryogenic temperature was used to image several crystals of CO2-dosed Co(bdp). To induce a phase transition, the sample was then heated to room temperature, and 4D-STEM was carried out on the same crystals. A change in lattice spacing was observed after warming, indicating the release of CO2 from the framework. Measured lattice spacings around 13 Angstroms suggest the framework itself, rather than dry ice, is being imaged. In the future, larger ensembles of crystals will be scanned to investigate the heterogeneity of adsorption, and the methodology will be used on an air-stable, industrially relevant framework that is isostructural to Co(bdp).

5:00 PM CH02.04.02
Effect of Lithium Ion in Block Copolymer Electrolytes Phase Separation Process by using 4D-STEM Min Chen[1,2], Xi Jiang[2], Vivaan Patel[1], Karen Bustillo[2], Lorena Grundy[1], Nitash Balsara[1,2], Benjamin Savitzky[2], Steven Zeltmann[1,2], Ronald Zuckermann[2,2] and Andrew M. Minor[2,1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Polymers that dissolve lithium ions are promising electrolyte materials for the next generation of rechargeable batteries. Both high mechanical stability and high ionic conductivity can be achieved through microphase separated block copolymer electrolytes by using one phase to conduct ions while the other provides rigidity[1]. The ion transport properties of such composite materials are not easily predicted solely from ion transport properties of the conducting domain alone [2], as the microphase and morphology play an important role in electrochemical performance [3, 4]. In previous research, heavy element staining bright field imaging and Energy-filtered transmission electron microscopy spectrum-imaging (EFTEM-SI) have been used to study PS-*b*-PEO [1, 2, 5]. Here, we utilize cryo-4D-STEM (four-dimensional scanning transmission electron microscopy) to investigate both the polymer morphology as well as the crystallinity as a function of Li concentration. 4D-STEM is a technique by which a nearly parallel electron nanoprobe is rastered across a sample (two dimensions in real space), recording the diffraction pattern (two dimensions in reciprocal space) at each scan point.[6] The diffraction patterns acquired form a 4D dataset provide real space information about the phase distribution and orientation of the polymer materials. It is a powerful tool to unveil the microphase of PS-*b*-PEO and provide further information about how the structure effects electrochemical performance.[2, 3]

Adding lithium salt into PS-*b*-PEO is a crucial step for real applications. Here we used mixtures of poly (styrene-block-ethylene oxide) copolymers (SEO) and bis(trifluoromethane)sulfonimide lithium salt (LiTFSI). By utilizing an air-free glove box and a cryo-transfer holder, we have established a workflow that avoids air exposure to these air-sensitive samples. 4D-STEM was later applied to show how the phase and DPs change when lithium concentrations change from r = 0 to 0.1. We calculated and carefully controlled the beam damage and successfully produced 4D-STEM results in cryo-condition. Compared with traditional RuO_4 staining 4D-STEM bright field imaging, 4D-STEM is shown to produce similar phase information without using toxic chemicals. Furthermore, 4D-STEM can provide additional phase distribution and orientation information inside the crystalline phase. The relation between the electrochemical performance and phase distribution, in relation to the crystallinity with and without the Li salt will also discussed.

Carbon-Silica Hybrid Microporous Membranes for Gas Separations Jong Suk Lee, Hyun Jung Yu and Ju Ho Shin; Sogang University, Korea (the Republic of)

Membrane-based gas separation requires highly delicate engineering of molecular structures for the desired separation performance. For instance, natural gas processing including CO_2/CH_4 and N_2/CH_4 separations or olefin/paraffin separation involves a minimal molecular size difference of less than 0.5 Å. However, the extent of improvement in separation performance via engineering the chemical structure of polymeric membranes is very limited due to the trade-off relationship between permeability and selectivity. Moreover, most polymeric membranes are susceptible to condensable gas-induced plasticization at high pressures, suffering from significant selectivity loss. Carbon molecular sieve (CMS) membranes are promising molecular sieving candidates to overcome the intrinsic drawbacks of polymeric membranes including the limited separation performance and weak plasticization resistance. Recently, our group proposed a new approach to engineering the selective micropore structure of CMS membranes for various gas separations, including CO_2/CH_4, N_2/CH_4, or C_3H_6/C_3H_8 separation by pyrolyzing homogeneous blends of polyimide and ladder-structured polysilsesquioxanes. In particular, the SiOx phases in a carbonaceous matrix contributed to enhancing the molecular sieving ability of the resultant carbon-silica hybrid microporous membranes for various gas separations. In addition, our newly proposed approach enabled the formation of asymmetric CMS hollow fiber membranes with an excellent separation performance owing to the enhanced thermal stress resistance.

Recent Developments in S/TEM Technology Enabling Low-Dose, Low-Temperature, and Low-kV Observation of Beam-Sensitive Energy Materials Anahita Pakzad, Cory Czarnik and Ray Twesten; Gatan Incorporated, United States

Observing materials at atomic resolution gives us insight into how these systems operate and their failure mechanisms. This understanding is required to develop clean energy technology for a sustainable future on earth. In most cases, the key materials of the system under study (e.g., lithium batteries, perovskite solar cells, and MOFs/COFs) are sensitive to moisture, air, and electron beam irradiation, thus making it quite challenging, and in some cases, even impossible to succeed if conventional S/TEM methods are applied.
Using results from various materials, we will review some of these challenges. We will highlight how recent developments at Gatan in specimen holder (cryo-transfer vacuum holder), detection technology (high-speed electron counting direct detectors for imaging, diffraction, and EELS), and software (*in-situ* and multi-modal data acquisition and processing) enable the observation of such beam-sensitive materials at low dose, low temperature, and low accelerating voltage.

9:00 AM *CH02.05.02
Accessing the Solid-Liquid Interface of Materials at the Nanoscale Using Cryogenic Electron Microscopy and Spectroscopy Patricia Abellan[1], Helene Roberge[1,2], Aekta Upadhyay[1], Laura Samperisi[1], Eric Gautron[1], Baptiste Charbonnier[3], Angelique Galvani[3], Philippe Moreau[1], Jean Le Bideau[1], Pierre Weiss[3], Valérie Geoffroy[3], Estelle Couallier[2] and Jay LaVerne[4]; [1]Institute of Materials of Nantes (IMN) Jean Rouxel, Nantes University - CNRS, France; [2]Nantes Université-CNRS, France; [3]Nantes University, INSERM U1229, France; [4]University of Notre Dame, United States

Cryogenic transmission electron microscopy allows for the observation of samples in near native conditions and for higher electron beam tolerances than room temperature observations. Crucially, it provides the opportunity of obtaining quantified information from solid-liquid interfaces. In practice, accessing the solid-liquid interface at high-resolution represents specific challenges that are sample dependent and that must be addressed. Typically, sample preparation for cryo-(S)TEM is central and as a matter of fact, a significant bottleneck in many experiments. For the case of hard-soft interfaces in hydrated systems there are additional challenges which arise by the mismatch between the bio(chemical), mechanical and physical properties of both sides of the interface. Imaging conditions that are suitable for the different electron scattering produced by the different materials must be found and there can be limitations by the fact that a specific site within the sample (with a specific orientation) must be accessed. In this presentation, I will show our latest experimental results and discuss the specific challenges met on the application of 3D Cryo-FIB/SEM to the study of hard-soft tissue interfaces, to probe biomolecules fouled in polymeric filtration membranes and for the analysis of biomaterials interfaces. One specific challenge that is common to all experiments in hydrated samples is to understand the effect of the electron beam in our observations to disregard possible artefacts. Despite the more limited diffusion of secondary species at cryogenic temperatures, the high-energy electron beam used to probe the sample will unavoidably induces chemical processes due to radiolysis. Methods to directly probe the effects of radiation chemistry inside the EM have not been developed yet. In this talk, I will also present our investigations combining scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS) on ice and discuss the effects of high-dose rate electron irradiation on water and on water-solid interfaces in the EM.

9:30 AM CH02.05.03
Dedicated Cryogenic Workflows for Atomic STEM Based Analysis on Lithium Based Battery Materials Paolo Longo[1], Zhao Liu[1], Maarten Wirix[1], Eric Van Cappellen[1], Minghao Zhang[2], David Foord[1] and Y. Shirley Meng[3]; [1]Thermo Fisher Scientific, United States; [2]University of California, San Diego, United States; [3]The University of Chicago, United States

In the past decade, the rapid growth of electric vehicles and consumer electronics market leads Li-ion batteries to attract significant attention. In order to further advance their performance for higher energy and better safety, fundamental understanding of battery materials structures and chemistry is essential. Nowadays, in order to pursue higher battery performance, more and more materials used in battery are beam sensitive and inherently air sensitive. This brings challenges to preserve their native structure and property via routine electron microscope practice.
Low-dose EELS STEM analysis carried out at cryogenic temperature on a Krios (S)TEM under cryogenic conditions has proven to be a very successful approach to study the solid electrolyte interface (SEI) in the Li metal anode region. The main challenges that until recently has limited the accurate investigation of SEI samples are the extreme sensitivity to air and probing sources such as the electron beam. However, by combining the cryo transfer approaches developed for life science tools and the extra stability of the dedicated cryo-stage in the Krios, it was possible to successfully carry out, morphological, chemical and tomography studies of the solid electrolyte interface region in Li-anodes [1].
Motivated by cryogenic electron microscope (Cryo-EM) technology in structural biology, the application and challenges of cryo-EM in battery research is discussed here.

Cryogenic Analytical Transmission Electron Microscopy for Multivalent Ion Based Energy Storage Kevin R. Zavadil, Scott A. McClary, Kathryn Anderson Small and Paul Kotula; Sandia National Laboratories, United States

Limited knowledge of the chemistry and time dependent formation of Ca or Mg solid electrolyte interphases exists as current tools do not combine surface sensitivity, high spatial resolution, chemical specificity and preservation of the electrolyte environment. In response to this challenge, we have developed and demonstrated cryogenic transmission electron microscopy (cryo-TEM) combining the above attributes to determine the identity and properties of anode interphases that enable long cycle lifetimes in emergent Mg and Ca metal batteries. We find that a nanometric, heterogeneous oxide, not a hydride as previously thought, is the interphase responsible for reversible Ca cycling in a calcium borohydride - tetrahydrofuran electrolyte. Ca^{2+} conductivity in such a ubiquitous material, specifically along oxide, borate, and carbonate phase boundaries, raise the possibility of controlling SEI formation to support working cation conductivity in a broader class of chemistries. We demonstrate a strong dependence of SEI composition and properties on Ca and Mg cation solvation structure, highlighting the possibility of directing reactivity by controlling speciation within the electrolyte. In this presentation, we explore this concept of directing reactivity and correlate outcomes with SEI performance.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

10:00 AM BREAK

10:30 AM *CH02.05.05

Gas Injection System Free Cryogenic Focused Ion Beam Sample Preparation for Complementary Cryogenic Scanning Transmission Electron Microscopy and Atom Probe Tomography James O. Douglas[1], Shelly Michele Conroy[1], Finn Giuliani[1] and Baptiste Gault[1,2]; [1]Imperial College London, United Kingdom; [2]Max-Planck-Institut für Eisenforschung GmbH, Germany

The Imperial Centre for Cryo Microscopy of Materials (I(CM)^2) is a new facility at Imperial College London for the development and application of cryo microscopy to environmentally sensitive materials. The facility consists of the three state of the art microscopes (Cameca Local Electrode Atom Probe 5000 XR, FEI-Thermofisher Scientific Helios Hydra DualBeam with cryo-stage and FEI-Thermofisher Scientific Spectra 300 with cryo-holders) connected via an inert gas glovebox with cryo-vacuum transfer capability. By combining the complementary capabilities of these instruments, nanoscale compositional and structural analysis on environmentally sensitive materials of interest to a wide range of fields can be achieved.

Cryogenic focused ion beam (cryo-FIB) sample preparation for site specific liftout has significant challenges compared to the standard room temperature process flow. A number of applications that require cryo-FIB have successfully bypassed the requirement for liftout such as on-grid thinning for cryo electron microscopy (cryo-EM) [1] or “satellite dish” samples for Atom Probe Tomography (APT) [2]. However, there are many number of situations in life sciences and materials science where the cryo-FIB liftout stage is essential and so reliable and reproducible processes to enable this to become routine are required. Complementary Scanning Transmission Electron Microscopy (STEM) and APT analysis on the same sample [3] is increasingly commonplace and the application of this to materials requiring cryo-FIB is an emerging field of interest. This requires samples to be fabricated and mounted in a manner that is appropriate for the specific requirements for high yield and data quality from both techniques.

Room temperature FIB liftout generally uses site specific decomposition of an organometallic precursor gas supplied by a Gas Injection System (GIS) to provide protective layers and to attach liftout lamella to micromanipulators and support structures such as grids. If this gas is released into a FIB chamber with a cryogenically cooled stage then the gas immediately condenses. The thickness of this condensate is hard to control, it requires “curing” via an electron or ion beam to become conductive and using it significantly increases the difficulty of the liftout process [4]. GIS-free cryo-FIB liftout of TEM lamelle using redeposition methods has been shown to be viable [5] [6] and a cryo-FIB approach using a combined controlled cryogenic GIS deposition and redeposition has been demonstrated for APT samples [7] but has not been optimised for the extreme conditions experienced during APT analysis.

In this presentation, we demonstrate a reproducible, GIS-free, process flow for cryo-FIB liftout and mounting of APT samples using selective resputtering [8] of an in-situ tungsten micro-manipulator. APT samples made using cryo-FIB liftout from single crystal silicon using this method have been successfully analysed and the data collected was found to be comparable in quality to that collected from commercial pre-sharpened silicon calibration specimens (Cameca) [9]. Progress of this approach and applications of this process to facilitate cryo-FIB sample preparation for complementary cryo-STEM and APT on the same sample will be discussed along with the numerous challenges of cryo and vacuum transfer between instruments involved in this process.

Imaging the Solid-Electrolyte Interphase in Lithium Metal Batteries with Cryogenic Electron and Ion Microscopy Hyeong-Jun Koh, Eric Detsi and Eric A. Stach; University of Pennsylvania, United States

The solid-electrolyte interphase (SEI) controls the transport of ions and electrons during battery operation. Thus, understanding its structure and chemistry is necessary to understand battery function. However, there are significant challenges in characterizing the SEI: it is nanoscale in dimension, heterogeneous in composition, and comprised of organic and inorganics species. The first two points suggest that electron and ion microscopy methods are needed, as they have the appropriate spatial resolution. However, organic materials present significant challenges to these approaches, as these materials are usually susceptible to irradiation damage.

Cryogenic transmission electron microscopy (cryo-TEM) has recently been used to observe lithium metals and their SEIs without electron beam damage. Most cryo-TEM research has probed lithium by electrochemically growing lithium on copper grids or extracting it from current collectors. These approaches necessitate removing liquid electrolytes from active materials by drying and washing before being characterized. However, it is unclear whether the structure and chemistry of the SEIs remain intact during such processes.

Vitrification is one way to observe the SEI: this is done by rapidly freezing liquid electrolyte media. However, as the vitreous liquid electrolytes that cover the active materials are often too thick, it is difficult to probe nanoscale assemblies of SEIs at high resolution through subsequent cryo-(S)TEM imaging. It is, therefore, crucial to develop a strategy to control the thickness of vitrified samples to obtain the desired electron transparency.

Cryogenic focused ion beam microscopy methods (cryo-FIB) allow thickness control through the cryogenic lift-out process; samples can be lifted out from specific sample areas and subsequently attached to TEM support grids for further thinning. Using the cryogenic lift-out process to characterize SEIs in energy storage materials has two advantages: (i) the thickness of the sample of interest can be carefully controlled through FIB milling and (ii) the configuration of battery structures can be preserved and selectively extracted without losing spatial information surrounding the region of interest.

In this work, we have used lithium and its SEI as a model material to identify how ion and electron beam damage can occur and how cryo-FIB can mitigate them. We also demonstrate the potential of cryo-TEM analysis for beam-sensitive battery materials using cryo-FIB.

In this talk, we will answer the following three critical questions:
1. We will answer how lithium gets damaged by ion beam milling at cryogenic temperatures.
2. We will discuss ion beam damage to SEIs.
3. We will finally show the structural alteration of SEIs before and after liquid electrolytes are removed, demonstrating the possibility of high-resolution imaging of nanoscale features in SEIs with vitrified electrolytes.

11:15 AM CH02.05.08
The True Role of Ethanol in Lithium-Mediated Ammonia Synthesis as revealed by Cryo-Electron Microscopy Olivia Westhead[1], Shelly Michele Conroy[1], Baptiste Gault[1,2], James O. Douglas[1] and Ifan E. Stephens[1]; [1]Imperial College London, United Kingdom; [2]Max-Planck-Institut für Eisenforschung GmbH, Germany

Ammonia is one of the highest value industrial chemicals, with 50% of global agriculture using industrially produced ammonia in fertiliser. However, the industrial method to make ammonia, the Haber-Bosch process, is extremely environmentally damaging. The requirement for extreme operating conditions and reliance on methane derived hydrogen results in an enormous energy and CO_2 penalty[1]. A better method of ammonia production would be distributed, powered by renewable energy, and carbon free. Electrochemical ammonia synthesis via the Nitrogen Reduction Reaction (NRR) could provide a solution. The only rigorously verified method of electrochemical ammonia synthesis is the lithium-mediated nitrogen reduction system[1,2]. This system utilises a lithium salt and organic electrolyte to catalyse the reaction between dinitrogen gas and a non-aqueous proton donor, which is often ostensibly sacrificial ethanol. While great strides have been made in terms of Faradaic efficiency, stability and activity[1,3], there are still numerous unanswered questions about exactly why this system is the sole example of efficient electrochemical ammonia synthesis.

One aspect of the lithium-mediated paradigm that could make it unique is the formation of the Solid Electrolyte Interphase (SEI) on the surface of the working electrode[1]. This electronically resistive but ionically conductive SEI is formed from the decomposition of the organic electrolyte and lithium salt on the application of the highly reductive lithium plating potential, analogous to that formed in lithium-ion batteries[1]. Recent work[4] reveals that the chemical makeup of the SEI is critical for system stability and controlling the access of reactants (Li^+, N_2 and protons) to the electrode surface. The role of ethanol as a proton donor has been recently disputed and it is proposed that it may in fact play a greater role in NRR-SEI formation[5,6]. It would be beneficial to be able to study NRR-SEI morphology changes with ethanol concentration via electron microscopy. However, the NRR-SEI is highly beam and air sensitive, making both analysis in and transport to the microscope complex. Therefore, a specialised air-free transfer system and cryogenic analysis is required.

While previous cryo-microscopy investigations suggest changes in NRR-SEI makeup with and without ethanol[6], we present a systematic study of the effect of changing ethanol concentration on NRR-SEI morphology via cryo-Scanning Electron Microscopy and cryo-Focussed Ion Beam milling, and propose how NRR-SEI morphology may affect Faradaic selectivity. Such work also paves the way for the future investigation of the SEI via cryo-Transmission Electron Microscopy. In addition, we present a novel method of cryogenic specimen preparation for Atom Probe Tomography (APT)[7]. APT will allow us to examine low atomic number elements, such as Li[8], as well as the effect of ethanol concentration on reactant transport through the SEI.

Vacuum Transfer System for EM Application Combined with a Cryogenic Technique Hiroya Miyazaki; Mel-Build Inc., Japan

Low-carbon efforts to realize a sustainable society are being vigorously pursued around the world. Rechargeable batteries, which are recognized as one of the most important nextgeneration energy technologies, are urgently needed not only for mobile applications such as cell phones and notebook PCs, but also for applications in transportation technology such as electric vehicles to promote low-carbon society.

Among these, lithium-ion battery materials, which are attracting attention because of their high energy density, react with water in the atmosphere when exposed to air, resulting in deterioration. In most cases, however, the sample is exposed to the atmosphere when it is transported to the electron microscope after preparation, making the observation itself difficult. Even if the sample can be transported to the electron microscope without being exposed to the atmosphere, it must be observed under cooled conditions because the crystal structure of the material tends to change due to electron irradiation during observation.

In order to conduct research on such samples, it is essential to develop a multifunctional system that can perform the entire transport process from sample preparation to electron microscopic observation under non-atmospheric conditions, as well as observation under cooled conditions. Against this background, Melville has been working on the development of non-atmospheric exposure and sample cooling techniques to meet the technical requirements of electron microscopy applications.

In this presentation, we will introduce our new TEM holder with non-exposure cooling and Peltier-cooled stage for FIB-SEM, which were developed based on the technologies we have developed so far.

Cryogenic STEM Visualizations of Correlated Electronic Order Ismail El Baggari; Harvard University, United States

Scanning transmission electron microscopy (STEM) is highly sensitive to lattice degrees of freedom and enables tracking of lattice displacements with sub-Angstrom resolution and picometer precision. This has ushered novel visualizations and discoveries of functional atomic displacements in ferroelectric materials, magnetoelectric oxides, and 2D materials. Due to stringent stability requirements, the overwhelming majority of high-resolution STEM measurements are limited to room temperature or above. In many classes of correlated electronic materials, however, subtle and exotic ground states emerge exclusively below room temperature. Achieving cryogenic capabilities in STEM is therefore paramount to accessing and probing low temperature phases including high-temperature superconductivity, charge order, metal-insulator transitions, and more.

I will illustrate recent, successful applications of high-resolution cryogenic STEM for discovering and understanding novel correlated phases at low temperature (~90 K) [1,2,3]. I will focus on charge order, a state in which the electrons and the lattice form superstructures that break the translational symmetry of the atomic lattice. In an overdoped manganite, we directly visualize intrinsic topological defects and show how these local fluctuations alter the periodicity and long-range order of incommensurate charge order stripes [1]. In a half-doped manganite, we address the long-standing question of whether charge order resides on the sites or bonds, discover an exotic intermediate state which breaks inversion symmetry, and find that non-linear couplings between distinct lattice distortion modes locally determine phase competition [3]. These cryogenic STEM results pave a clear path to imaging low temperature electronic phases with high resolution and precision.

2:30 PM BREAK

3:30 PM CH02.06.03

Observation of Charge Ordering in $EuAl_4$ via Cryogenic Scanning Transmission Electron Microscopy Haoyang Ni[1,2], Jian-Min Zuo[1] and Miaofang Chi[2]; [1]University of Illinois, Urbana-Champaignaign, United States; [2]Oak Ridge National Laboratory, United States

$EuAl_4$ is one of charge density wave materials where the lowering of the crystal symmetry at a phase transition give rise to incommensurate modulation[1–4]. CDW transition occurs below 145.1 K and exhibits four successive magnetic transitions below 16 K[2]. Very recently, a chiral spin skyrmion structure was reported, making it a rare case where one could observe the co-exitance of exotic magnetic order and charge order[5,6]. CDW phase transition is accompanied by symmetry-breaking atomic displacement in general. Knowledge of the atomic structure, especially which and how atoms are displaced and how CDW gives rise to these exotic physical properties, is thus of utmost importance for understanding nontrivial quantum properties.

Here, we combine atomic resolution Scanning Transmission Electron Microscopy (STEM) combined with scanning convergent beam electron diffraction (SCBED) at cryogenic temperature, enabled by the development of a new liquid nitrogen holder. We show this combination allows for the visualization and determination of the atomic structure in $EuAl_4$. SCBED is achieved by acquiring electron diffraction patterns formed by a highly coherent nanometer-size electron probe at different specimen locations. With the high-speed direct electron detector, diffraction patterns from a field-of-view of 200 nm with sub-nanometer sampling can be achieved, this powerful technique allows the mapping of interatomic distances in real space. This talk will show that the atomic displacement changes the intensity of Bragg reflection, and CDW can be visualized by diffraction contrast. Analysis of CBED patterns shows a reduction of inversion symmetry, and dominant displacement modes can be identified. Imperfections of CDW, such as dislocations and phase boundaries, can be revealed by interatomic distance mapping. Further, whether a relatively higher temperature CDW phase could be a precursor of the lower magnetic phases remains an open question.

Taking Low Energy Excitations at High Spatial Resolution to Low Temperatures Jordan A. Hachtel; Oak Ridge National Laboratory, United States

Over the last decade, modern monochromated electron energy loss spectroscopy (EELS) in a scanning transmission electron microscope (STEM) has achieved the ability to combine ultrahigh energy and spatial resolution simultaneously. As a result, a new wave of experiments on ultralow energy excitations, such as phonons, phonon-polaritons, molecular vibrations, shallow electronic structure, and infrared optical excitations have achieved exciting results in the STEM.

The emergence of monochromators that can reach the mid-infrared has largely coincided with the development of stable cryogenic TEM holders that can reach ultralow temperatures. However, due to the relative recency of both techniques achieving consistency and accessibility only limited opportunities have been available to combine them on the same materials systems. Here, I will show recent work at ORNL on the combining cryo-STEM and monochromated EELS. Focusing on cryogenic phase changes, emergent behavior at cryo-temperatures, and the effect of low-temperatures on beam-sensitive materials.

4:15 PM *CH02.06.05
Electron Spectroscopy at Cryogenic Temperatures for Nano-Optics Luiz H. Galvao Tizei; Centre National de la Recherche Scientifique, France

Fast electrons spectroscopies have had huge success for nano-optics [1]. For phase-locked excitations (e. g. surface plasmons) electron energy loss spectroscopy (EELS) is an optical extinction analogue and cathodoluminescence (CL) that of optical scattering [2]. For "incoherent" excitations, EELS also measures optical extinction for atomically thin materials [3,4,5], while CL measures spectra similar to off-resonance CL [3]. For many technologically and fundamentally interesting materials, including semiconductors, experiments at cyrogenic temperatures is a requirement. For example, many quasi-particles (such as excitons and trions) are only stable at low temperatures, due to their low binding energy. This will be discussed in this contribution, including variable temperature measurements down to about 100 K. This will be used as a motivation for still colder experiments (to be realized).

Despite clear benefits (link to structural and chemical information, atomic-scale spatial resolution and broadband excitation), electron spectroscopies have some penalties which limit applications to nano-optics: lack of resonant excitation and polarization degrees of freedom and still limited spectral resolution (EELS). In this seminar, we will discuss how temporally resolved spectroscopies can mitigate some of these issues.

The lack of excitation energy control can be circumvented by measuring the energy lost by each electron in time coincidence EELS-CL experiments. This has been achieved using a nanosecond-resolved direct electron detector (Timepix3) [6], correlation electronics and a PMT. The information retrieved here is analogous to that of photoluminescence excitation spectroscopy (PLE), hence we name it cathodoluminescence excitation spectroscopy (CLE) [7]. With it, we explored the relative quantum efficiency of different excitation energies and decay pathways towards 4.1 eV defect photon emission in h-BN flakes [7].

The current impressive energy resolution achieved with electron beams (~meV range) is still orders of magnitude away from the necessary one to access the physics of lifetime-limited high quality factor optical modes, such as cavity modes in dielectric spheres [8]. As proposed more than a decade ago [9], electron energy gain spectroscopy (EEGS) should easily overcome this limitation. Here, we will discuss EEGS experiments using fast electron blankers (~ns) in a continuous-gun electron microscope, allowing energy resolution delivered by laser beams compatible with a state-of-the-art electron microscope performance. As an example, we will show measurements of whispering gallery modes in dielectric spheres separated by a few hundreds μeV with energy sampling in the μeV scale [10].

8:30 AM *CH02.07.01
Probing Properties and Dynamic Behaviors of Topological Polar States by 4D STEM Xiaoqing Pan; University of California, United States

Topological polar solitions such as domain walls, polar voritices, skyrmions, etc, in ferroelectrics have attracted much attention owing to their unique functionalities and potential applications in electronic devices. Recent advances in transmission electron microscopy (TEM) and electron energy-loss spectroscopy (EELS) provides powerful tools to study the structure, properties, and dynamic behaviors of nanostructures with atomic resolution. In this talk, I will show how ferroelectric domains nucleate and evolve under applied electric field in TEM. Using quantitative TEM, we can measure and map the electric polarization of nanodomains, vortices and other polar solitons with the atomic resolution. Recently, we have developed a novel four-dimensional STEM (4D STEM) method that can directly map the local electric field and charge density of crystalline materials in real space with sub-angstrom resolution.[1]. I will also show that skyrmion-like polar nanodomains can be created in lead titanate/strontium titanate bilayers transferred onto silicon and can be switched from one type to another by an applied electric field, which substantially modifies their resistive behaviours.[2] The polar-configuration-modulated resistance is ascribed to the distinct band bending and charge carrier distribution in the core of the two types of polar texture. The integration of high-density (more than 200 gigabits per square inch) switchable skyrmion-like polar nanodomains on silicon may enable non-volatile memory applications using topological polar structures in oxides.

9:00 AM *CH02.07.02
Phase Contrast Imaging of Non-Collinear Spin Textures with Lorentz Microscopy Robert Streubel; University of Nebraska-Lincoln, United States

Transmission electron microscopy is a critical asset to basic and applied sciences research as it enables the characterization of, e.g., structural order on the atomic scale. This includes not only crystalline structures and orientation, but also their temporal evolution, behavior at and across interfaces, and disordered, amorphous materials leveraging tomographic imaging. To date, the vast majority of electron microscopy harnesses the superior spatial resolution owing to a de Broglie wavelength of a few picometers. Taking advantage of the wave properties of coherent electrons and their interaction with electromagnetic fields, e.g., matter, allows for enhancing sensitivity and resolution and visualizing the spin degrees of freedom in the form of the in-plane magnetic induction. These experiments are based on the detection of the electron phase using off-axis or in-line holography. The former requires a biprism, the latter works in Fresnel mode/Lorentz mode with post processing involving a phase retrieval algorithm, such as transport-of-intensity or Gerchberg-Saxton. I will discuss the fundamentals, including pros and cons, of phase contrast imaging and review recent applications to visualize non-collinear spin textures in magnetic films in the presence of magnetic bias fields and cryogenic temperatures triggering magnetic phase transitions and spin fluctuations. One focus will be on chiral spin textures in amorphous materials where exit wave reconstruction allows to disentangle electrostatic, magnetization, and magnetic field contributions to the phase shift [1,2].

9:30 AM *CH02.07.03
Cryogenic Lorentz Transmission Electron Microscopy of van der Waals Ferromagnetic Heterostructures Charudatta Phatak[1], Arthur McCray[1,2], Yue Li[1], Rabindra Basnet[3], Krishna Pandey[3], Jin Hu[3], Daniel Phelan[1], Wei Wang[1], Xuedan Ma[1] and Amanda Petford-Long[1,2]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States; [3]University of Arkansas, Fayetteville, United States

Magnetic skyrmions are topologically protected magnetic spin textures that can exist both as individuals and in dense quasiparticle lattices. Manipulation of skyrmions then requires a detailed understanding of their stability. While individual skyrmions have been studied extensively, their collective behavior in skyrmion lattices is poorly understood, both on the micron-scale where lattice ordering is observed and the nanoscale where inter-skyrmion interactions occur. In this work, we will present the observation of Néel skyrmion lattice ordering in the van der Waals (vdW) ferromagnet Fe3GeTe2 (FGT) using cryo-Lorentz transmission electron microscopy (LTEM). We will discuss the magnetic domains formed in FGT under various conditions of applied field and as a function of temperature. We will discuss the stability of skyrmions under applied fields and formation of domains with higher topological charge. In order to understand the collective behavior of these Néel skyrmions, when imaged with LTEM, we performed imaging of skyrmion lattices over a large field of view and employed a machine learning algorithm which applies a convolutional neural network (CNN) to identify skyrmion centers. We will discuss the local and global lattice order, and the observed thermal hysteresis in the order. Based on an analytical model, we can elucidate the collective behavior of skyrmion lattices to be dependent on the competition between the Zeeman energy and the domain energy.

10:30 AM *CH02.07.04
Cryogenic Electron Holography and Differential Phase Contrast Imaging of Quantum Materials and Electron-Beam-Sensitive Materials Rafal E. Dunin-Borkowski, Penghan Lu, Fengshan Zheng, Lei Jin, András Kovács, Thibaud Denneulin, Qianqian Lan, Luyan Yang, Michael Feuerbacher, Joseph Vas, Michael Faley and Amir H. Tavabi; Forschungszentrum Juelich, Germany

Cryogenic transmission electron microscopy offers new prospects for studying quantum materials and electron-beam-sensitive materials. Here, we describe recent progress in the use of phase contrast techniques in the (scanning) transmission electron microscope, in combination with liquid nitrogen and liquid helium cooling, to obtain quantitative information about electromagnetic fields in nanoscale materials and to generate improved contrast at low electron dose from materials that are affected by irradiation damage.

The first examples involve the use of off-axis electron holography and Lorentz imaging at low temperature to study magnetic skyrmions in crystallographically chiral materials such as FeGe and magnetic flux vortices in superconducting materials such as NbN in focused ion beam milled samples that provide geometrical lateral confinement. The influence on the measurements of sample preparation damage, the direction and strength of an applied magnetic field and electrical current, as well as the presence of electron-beam-induced specimen charging, will be discussed.

The second examples involve the use of (integrated) differential phase contrast imaging in the scanning transmission electron microscope at low temperature to record atomic-resolution images of electron-beam-sensitive materials, including metal-organic frameworks, organic materials and minerals. The use of event-driven detectors, automation of experimental workflows and non-standard electron beam scanning protocols will be discussed.

Finally, new concepts for improved instrumentation for such experiments, including liquid-helium-cooled specimen stages, advanced magnetizing units, specimen holders for high frequency experiments, sample transfer cartridges and capabilities for in situ laser irradiation of the sample in the electron microscope, will be presented.

11:00 AM *CH02.07.05
Cryogenic Electron Microscopy for Quantum Materials Yimei Zhu; Brookhaven National Laboratory, United States

Quantum materials refers to a class of materials with exotic properties that arise from the quantum mechanical nature of their constituent electrons, exhibiting, for example, high-temperature superconductivity, colossal magnetoresistivity, multiferroicity, and topological characteristics. Quantum materials often have incompletely filled d- or f-electron shells with narrow energy bands and the behavior of their electrons is strongly correlated. One distinct characteristic of the materials is that their electronic states are often spatially inhomogeneous, thus is well suited for study using spatially resolved electron beams with its great scattering power and sensitivity to atomic ionicity. Furthermore, most of these exotic properties only manifest at very low temperatures, posing a challenge to modern electron microscopy. It requires extraordinary instrument stabilities at cryogenic temperatures with critical spatial, temporal, and energy resolutions in both static and dynamic manner to probe these materials. On the other hand, the ability to directly visualize the atomic, electronic and spin structures and inhomogeneities of quantum materials and correlate them to their functionalities creates enormous opportunities. At the most elementary levels of condensed matter physics, understanding the competing orders of electron, spin, orbital, and lattice and their degrees of freedom, the impacts of defects and interfaces, and the site-specific quantum phenomena and phase transitions that give rise to the emergent behaviors allows us to discover and control novel materials for quantum information science and technologies [1].

In this presentation, several of our research examples are selected to highlight the use of Cryo-EM to study strongly correlated quantum materials. We focus on the critical roles of heterogeneity, interfaces, and disorder in crystal structure, electronic structure, and spin structure to understand the physical properties of the materials. We show how electron diffraction and diffuse scattering analysis at low temperatures empowers us to reveal the nature of structural disorder and phonons under thermal equilibrium and far-from equilibrium [1]; how atomically resolved imaging and electron energy-loss spectroscopy at 10K can be used to understand the interface-enhanced superconductivity (Fig.1); and how to use Lorentz phase microscopy to explore the intriguing transformations among various topological chiral spin states under applied magnetic field at various cryogenic temperatures (Fig.2). Finally, we review our recent unprecedented development of a closed-cycle cryocooler for Cryo-EM without the need of refilling liquid He. The system is designed to reach a temperature as low as 4k with temperature stability and control better than a few mK.

The Quest for New Frontiers in Cryo Electron Microscopy for Materials Sciences Juan C. Idrobo; University of Washington, United States

Modern scanning and transmission electron microscopes (S/TEM) are now almost ubiquitous in materials and biological sciences laboratories. They have radically enhanced our understanding matter at the atomic level, bringing unique information of structure, chemical composition, and electronic properties of materials. Moreover, the recent development of stable cryogenic TEM holders at temperatures ranging from liquid N_2 (100 K) to 300 K with electrical contacts, combined with aberration-corrected and monochromated electron optics has allowed S/TEM to study magnetic, structural and electronic phase transitions with unprecedented spatial and energy resolutions.

In this talk, I will present two examples of cryogenic STEM measurements done in a set of two-dimensional (2D) transition metal dichalcogenides (TMDs) samples. In the first example I will address excitonic dephasing in MoS_2. I will present experimental results that show how monochromated electron-energy-loss spectroscopy (EELS) can reveal the exciton-phonon coupling of a few layers of MoS_2 encapsulated in hexagonal boron nitride (hBN). The measurements are spatial localized beyond the diffraction limit of the associated optical excitation, indicated how STEM can be complementary to conventional optical probes. In the second example I will present measurements that show a spatial dependence of a moiré-exitonic coupling in a hBN/WSe_2/WS_2 heterostructure at LN_2 cryogenic temperatures. I will also present a geometrical phase analysis of the moiré structure that allows to reveal the strain on the lattice at large field of views (>30 x 30 nm^2) while still maintaining atomic resolution. Prospects and limitations of future experiment will be discussed in the detail during the talk.

Structure & Dynamics in Sustainable Energy Materials: The Crucial Role of Large-Scale Facilities Martin Mansson; KTH Royal Institute of

Technology, Sweden

Establishing a sustainable society is our century's grand challenge. Here, one of the main obstacles is how to efficiently harvest, store and utilize green energy. To facilitate such transition new generations of advanced functional energy and quantum materials needs to be developed. This includes understanding and controlling material properties on an atomic, or even subatomic, length-scale. Only recently, technological advancement in materials synthesis and characterization techniques have opened new possibilities for studying both structural and dynamic material properties on the length- and time-scales necessary for advancing the field. Here a new generation of large-scale research infrastructures with more powerful neutron, x-ray and muon sources have played an important role. This state-of-the-art research landscape is the main platform for the SMaRT research group at the KTH Royal Institute of Technology. We run a comprehensive scientific program for advanced development of sustainable energy materials as well as novel quantum materials, studied mainly by large-scale techniques **[1]**.

In this talk I will give the general background as well as a few examples that show that neutron scattering, and complementary techniques are both crucial and optimal techniques for advancing this important field. I will show our recent work on Li-/Na-/K-ion battery materials that reveal new possibilities to improve battery performance using strain/pressure as well as surface coating **[2-6]**. I will further show how *in-operando* measurements of porous carbon reveal novel insight into the synergy effect between structure and dynamics in H-storage materials **[7-10]**. Finally, I will showcase our more fundamental efforts into organic quantum materials that could be a key development towards future energy efficient information and communication technologies **[11]**.

In summary, I aim to show that our current research program has established an innovative and detailed insight into the atomic structure and ion-diffusion mechanisms, as well as their synergy. This now allow us to actively consider tuning of future energy related materials with improved functional properties. In our quest, the use of neutron scattering has clearly been a crucial component. To support continuous breakthroughs for science and technology, Sweden and Europe are currently making unprecedented investments with the development and construction of the European Spallation Source (ESS) **[12]**. We are in parallel also building the next generation of neutron users/experts within the Swedish national graduate school in neutron scattering (SwedNess) **[13]**.

11:00 AM *CH03.01.03
Direct Observation of Dynamic Lithium Diffusion Behaviour in Nickel-Rich Cathodes Using *Operando* Muon Spectroscopy Serena Cussen[1], Innes McClelland[1] and Peter Baker[2]; [1]University of Sheffield, United Kingdom; [2]ISIS Pulsed Neutron and Muon Source, United Kingdom

Efficient and sustainable energy storage technologies will form a core element in decarbonising our energy system and batteries are one of those technologies which will enable that transition. Central to this is the development of new materials and methods which, for example, enable stable interfaces to improve power densities or mitigate degradation processes to improve energy densities. This talk details the use of muon spin relaxation spectroscopy as a local probe of diffusion dynamics in battery materials.
In this talk, I will discuss a new *operando* muon spectroscopy (μSR) method which can be applied to investigate how local Å-length scale diffusion and internal field properties change in the high nickel content cathode NMC811 during cycling. Our design of a new Battery Analysis by Muon (BAM) cell allows monitoring of diffusional properties with highly correlated structural changes in the unit cell during operating conditions.
The nature of μSR as a local probe means it reflects the diffusion rates at specific sites and from a site-to-site basis, in contrast with bulk measurements such as electrochemical impedance spectroscopy (EIS) which provides information on resistive interfaces and long-range charge transfer. In the case of the high nickel content cathode NMC811, we find that Li^+ dynamics increase most rapidly at the beginning of charge, before decreasing above 75% state of charge (SOC). We also interestingly observe a sensitivity of the static field distribution width parameter Δ, obtainable by μSR, to the TM redox activity and resultant TM-O bond length changes, with a correlation between the trends observed in dQ/dV, cyclic voltammetry and Δ. This observed sensitivity to changes in TM-O bond length is particularly intriguing for investigating anion redox in next-generation cathodes, where μSR can provide additional insights into ongoing challenges in stabilising anion redox behaviour.

SESSION CH03.02: Materials for Energy Conversion and Storage

Session Chairs: Alexander O'Malley and Valeska Ting
Tuesday Afternoon, April 11, 2023
InterContinental, Fifth Floor, Fremont

1:30 PM *CH03.02.01
Inelastic Neutron Scattering, A Unique Tool to Study Hydrogen In Materials Anibal J. Ramirez-Cuesta, Rafael Balderas and Yongqiang Cheng; Oak Ridge National Laboratory, United States

Inelastic neutron scattering can measure the vibrational spectra of materials on the whole range of vibrational motions (0-4400 cm−1) and effectively open up the field of neutron spectroscopy [1]. INS is a technique mainly used to study hydrogen-containing materials due to the high cross-section of hydrogen

[2].
The VISION spectrometer at the SNS in Oak Ridge, Tennessee, has increased overall flux at low energy transfers up to 40 times over its competitors and has unprecedented sensitivity.
In this paper, the author will present examples of the technique's unique capabilities for studying metal hydrides and molecular hydrogen in confinement.
In $ZrVH_2$, the inelastic neutron scattering spectra analysis reveals that these structures originate from hydrogen vibrations confined by neighboring hydrogens, partially at distances as short as 1.6 Å. This is an experimental demonstration of the violation of Switendick's criterion, which predicts the minimal possible hydrogen-hydrogen distance in a metal hydride is around 2.1Å.[3]
Inelastic neutron scattering (INS) and neutron diffraction (ND) experiments were performed at the VISION beamline, demonstrating the existence of rapid and efficient hydrogen clathrate hydrate formation in a confined nanospace. It shows that specially designed activated carbon materials can surpass these obstacles of hydrogen clathrate formation by acting as nanoreactors promoting the nucleation and growth of H2 hydrates. The confinement effects in the inner cavities promote massive growth of hydrogen hydrates at moderate temperatures, using pure water, with high-speed kinetics, and at lower pressures than the bulk system. [4]
Adsorption on various adsorbents of hydrogen and helium at temperatures close to their boiling points shows, in some cases, unusually high monolayer capacities. Theoretical and INS studies of molecular hydrogen on mesoporous silica demonstrate the formation of such a super-dense phase. [5]

2:00 PM *CH03.02.02
Adsorption and Separations Processes Within Metal-Organic Frameworks Through Neutron Scattering Craig Brown[1], Hayden A. Evans[1] and Ryan A. Klein[2,1]; [1]National Institute of Standards and Technology, United States; [2]NREL, United States

Metal organic frameworks (MOFs) are crystalline materials that contain metal-ions or metal-ion clusters as nodes and organic ligands as linkers to form 1-, 2-, and 3-D structures. Their structural versatility and multifunctional properties have sparked much interest in advanced materials synthesis. Due to their modular nature, many of these materials can be constructed by design. Over the last decade there are several MOFs that reportedly have high surface areas allowing them to physically adsorb significant amounts of gas and/or exhibit significant separations performance. Adsorption of molecules in functionalized and high surface area microporous materials is of technological importance in a multitude of areas ranging from catalysis, drug delivery, chemical separations, and energy storage to personal care products. Through careful selection of the ligand and metal, which control pore size/shape and MOF-adsorbate interactions, their uptake properties can be tuned. Over the past several years we have focused our research efforts on understanding the properties of gas interactions within a variety of microporous materials with the goal of improving new optimal storage and separation materials.

Probing the Hydrogen Interaction with Supported Pt and Pd Catalysts by Inelastic Neutron Scattering Andrea Piovano[1], Eleonora Vottero[2], Riccardo Pellegrini[3] and Elena Groppo[2]; [1]Institut Laue-Langevin, France; [2]University of Torino, Italy; [3]Chimet SpA, Italy

Pt and Pd nanoparticles on carbonaceous supports are widely employed as heterogeneous catalysts for hydrogenation reactions, and find application in fundamental industrial sectors such as fine chemistry or as fuel cell electrocatalysts. Carbonaceous materials are also largely investigated as hydrogen storage materials, and the introduction of metal nanoparticles was demonstrated to be able to increase the hydrogen uptake of the material. Albeit their routine use, many details about their interaction with H_2, and hence on their hydrogenation catalytic activity, are still not completely understood.
In this presentation, I will make a journey into the recent advances we made on the understanding of several key aspects of these catalysts: the influence of the carbon activation method and possible post-treatment on the catalytic activity [1,2]; the morphology of the H-terminated graphenic domains [3]; identification and quantification of functional groups [4]; the active hydrogen species in the catalytic process [5]; the dynamical nature of the active species [6,7,8]; the catalysts support interaction including spillover effects [5,8]; the differences in behavior between gas and liquid phase [7,9]. All such effects are those that together finally shape catalytic activity and selectivity.
In this respect, Inelastic Neutron Scattering played a major role thanks to its high sensitivity to hydrogen. INS spectra display an unprecedented quality, allowing the detection of extremely small changes on real catalysts. The data obtained for this same set of carbons and catalysts from other laboratory techniques, offered us the possibility to critically compare the results without the issue of sample reproducibility. When necessary, measurements were made on the same catalysts supported on alumina, to be able separate effects due to active phase or support.
Overall, our findings provide important insights for better understanding the complex nature of the support-catalysts system and the interaction between hydrogen and Pt and Pd-loaded catalysts.

***In Situ* Small-Angle Neutron Scattering Study of Hydrogen Physisorption in Nanoporous Carbons** Sebastian Stock[1,2], Malina Seyffertitz[1], Bruno Demé[2], Viviana Cristiglio[2], Nikolaous Kostoglou[3] and Oskar Paris[1]; [1]Montanuniversität Leoben, Chair of Physics, Austria; [2]Institute Laue Langevin, France; [3]Montanuniversität Leoben, Chair of functional materials and materials systems, Austria

When produced with renewable energy, molecular hydrogen (H_2) is considered an environmentally beneficial alternative to carbon-rich fossil fuels. However, one of the major challenges to the widespread use of H_2 as a fuel is its efficient and secure storage. Physisorption of molecular H_2 in high-surface area nanoporous materials is regarded as an alternative volume-efficient solution as compared to high-pressure tanks [1]. Due to the low binding energy between the gas molecules and solid surfaces, it is associated with quick adsorption/desorption kinetics and complete reversibility. H_2 adsorbs preferentially within very small, sub-nanometer-sized pores due to their overlapping potentials from opposing pore walls [2,3]. Experimental observations of the underlying mechanisms during physisorption can be facilitated by neutron scattering techniques, as neutrons strongly interact with the hydrogen nucleus. In this study, we employed in-situ small angle neutron scattering (SANS) during gas sorption to investigate the physisorption of H_2 and D_2 in a micro-/mesoporous activated carbon material at cryogenic temperatures. The SANS measurements were carried out with the high resolution diffractometer D16 at the Institute Laue-Langevin, which allowed covering a wide range of the scattering vector. The SANS data indicate that H_2 fills the small micropores at very low pressures, and with increasing pressure a densification of the adsorbed gas in the micropores, as well as a filling of the larger mesopores takes place. Using established models for the scattering from nanoporous carbons [4], with strong emphasis towards different contrast scenarios to analyze the scattering data [5,6], allowed to quantify the density evolution as a function of pressure within the two distinct pore size regimes [7]. The strong interaction of neutrons with the hydrogen nucleus and the different interaction with D_2 enabled us to probe the density of gas molecules in their confined spatial arrangement, as well as to evaluate isotope effects .Our results suggest that the isotope substitution of H_2 with D_2 has a significant effect on the adsorption behaviour in nanoporous carbons, with the capacity of D_2 being higher than the one of H_2 due to a preferred adsorption of D_2 in even smaller pores.

Poster Spotlight: Designing Next Generation Compositionally Complex Oxide Emissions Abatement Catalysts Using *In Situ* Neutron Total Scattering Sreya Paladugu[1], Palani Jothi[2], Cheng Li[3], Stephen Purdy[3] and Katharine Page[1]; [1]University of Tennessee, Knoxville, United States; [2]JTEC Energy, United States; [3]Oak Ridge National Laboratory, United States

Integration of renewable feedstocks into the current energy infrastructure will require the development of catalysts and sorbents that can maintain high surface area and catalytic activity under challenging thermal/hydrothermal environments and acid gas exposure Studying the time-resolved structural evolution of materials under gas flow conditions is key to understanding catalytic performance under real-world operating conditions with the end goal of extracting design strategies for industrially relevant catalysts. Total scattering, including both Bragg and diffuse scattering signals, enables the study of structural evolution in catalysts and can provide key insights into how long-range, nanoscale, and local atomic structure motifs differ and deliver unique properties. We have designed a new high temperature sample environment capable of hazardous gas flow (HGHS) at the Nanoscale Ordered Materials Diffractometer (NOMAD) at Oak Ridge National Lab, that will result in the capability to study acid gas interactions with sorbents and catalysts *in-situ* by neutron total scattering. The HGHS will deliver *in-situ* exposure to industrially relevant acid gas at NOMAD, enabling investigations of acid gas interactions with sorbents and catalysts, which will be a unique capability among neutron sources in the world and will aid in the design of new materials and processes with higher energy efficiency and a smaller emissions footprint. We have developed compositionally complex oxide (CCO) cerate/zirconate-based fluorite catalysts hypothesized to have high sinter resistance and improved low temperature activity compared to the single component oxide analogue. We will discuss the design, commissioning, and proof-of-concept demonstration of the capabilities of the HGHS using cerate/zirconate fluorite catalysts. Overall, this study will offer crucial structural insights into the suitability of CCO catalysts for industrial applications in comparison with traditional single component oxides, thus informing design strategies for next generation emissions abatement catalysts.

SESSION CH03.03: Characterization of Energy Materials

Understanding Molecular Behaviour in Industrial Microporous Catalysts Alexander O'Malley[1,2]; [1]University of Bath, United Kingdom; [2]UK Catalysis Hub, United Kingdom

The contributions of neutron spectroscopy techniques (INS and QENS) to the study of active species behaviour in microporous catalysts relevant to established industrial chemical processes have become more and more significant in recent years. Vibrational spectra obtained using INS can give great insight into the interactions between the active species and the catalyst active sites, while QENS may allow for the probing of a range of timescales of molecular behaviour. These include short timescale motions local to the active site, on the scale of ~10-100 ps such as rotations and confined translations, all the way through to long range diffusion processes throughout the framework structure.

Recent studies have included the uncovering of primary steps in the ZSM-5 catalysed Methanol to Hydrocarbons (MTH) process thanks to access to low energy vibrational modes (showing surface methoxylation at room temperature)[1] while accurately measuring rotation/diffusion dynamics of methanol and dimethylether using the QENS obtained elastic incoherent structure factor, showing a switch from isotropic methanol rotation to confined diffusion at higher temperatures, even alluding to the preferred channel siting in the catalyst micropores[2], and how this may change as a function of catalyst usage and the associated pore blockage and framework destruction.

QENS has also been used to show how the uniaxial rotation, and intramolecular methyl rotations of common fluid catalytic cracking species (n-octane and dimethyl hexane) in industrial zeolite catalysts are hindered when more acidic sites in the catalyst are present.[3] More emerging fuel/chemical production processes employing lignicellulosic biomass as a feedstock have also been probed with QENS, showing how the isotropic rotation of phenol[4] in potential zeolite catalysts is of a similar rate compared to catechol, but a significantly higher proportion of catechol is static on the instrumental timescale due to the presence of the extra hydroxyl group on catechol.[5]

The work presented highlights the unique insight that neutron spectroscopy techniques bring to microporous catalyst design, particularly when combined with molecular simulations, either for the direct reproduction of neutron scattering observables, or as complementary simulations taking place over different timescales to build a detailed picture of molecular behaviour in these industrially important catalytic systems.

Cooperative Water Dynamics Investigated by Joint Approach of TOF Polarization Spectroscopy and Polarization Analysis Using Neutron Spin Echo Margarita Russina[1], Gerrit Gunther[1], Bela Farago[2], Earl Babkock[3], Zahir Salhi[3], Alexander Ioffe[3] and Ferenc Mezei[4]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Institut Laue-Langevin, France; [3]Forschungszentrum Julich GmbH, Germany; [4]Institute for Solid State Physics and Optics, Hungary

Water is the most abundant liquid on Earth and is chemically a very active substance. Liquid water can act as a solvent and as a solute, as reactant and as catalyst and has therefore a broad importance for energy relevant technologies. The presence of hydrogen bonds, which control the local water structure and water tetrahedrality, leads to many unique and anomalous water properties setting it aside from other molecular liquids. Therefore, the understanding of hydrogen bonds formation and criteria governing the molecular mobility at nanoscale is of high importance for a broad range of applications. In general, the formation of hydrogen-bonded networks and / or rearrangements of molecular ensembles is a highly cooperative process. However, due to the absence of pronounced long-range order the elucidation of the local structure in water is non-trivial and investigations of cooperative phenomena have been extremely difficult and limited to very few studies.
Here we report the results of our investigation of the cooperative nanoscale dynamics in bulk water using polarized neutron spectroscopy. Polarization spectroscopy can be used in non-magnetic systems for the separation of coherent from incoherent scattering signals, which are associated with cooperative and self-particle dynamics respectively. For our study we have used a polarization spectroscopy option implemented on TOF spectrometer NEAT in Berlin [1]-[3]. Furthermore, to broaden the experimental time scale we have developed a new approach for polarization analysis using neutron spin echo spectrometer WASP at ILL, Grenoble [4]. Using a combination of these two experimental methods we observed a dynamic process on the picosecond time scale in addition to the previously observed relaxation processes which are usually associated with a long-range self-diffusion and molecular rotational diffusion. The process is visible in coherent signal and must be of cooperative nature. We also observe some fine differences in H_2O and D_2O which will be also discussed here.

9:45 AM CH03.03.03

Crystal Growth, Thermal Transport Properties and Neutron Scattering Study of Single Crystal Garnet Electrolyte $Li_{6.5}La_3Zr_{1.5}Ta_{0.5}O_{12}$ Yitian Wang[1], Yaokun Su[1], Youming Xu[1], Qingan Cai[1], Travis Williams[2], Chen Li[1,1] and Xi Chen[1,1]; [1]University of California, Riverside, United States; [2]Oak Ridge National Laboratory, United States

Li-ion batteries with solid-state electrolytes (SSEs), known as all-solid-state batteries, have gained great interest due to their improved safety with high energy density. One of the promising SSEs is the garnet-type lithium ionic conductor $Li_{6.5}La_3Zr_{1.5}Ta_{0.5}O_{12}$ (LLZTO), which exhibits excellent chemical stability against lithium metal and high ionic conductivity. Although there have been many studies on its ionic properties, the thermal properties and phonon dynamic of LLZTO are not fully understood. Here we synthesize millimeter-size LLZTO single crystals using the infrared-heating floating zone method. The crystal quality and chemical composition are checked by Laue X-ray diffraction, electron microscopy and Raman scattering. The thermal and mechanical properties are also measured on the single crystal samples. Furthermore, we investigate the phonon dispersion of LLZTO using inelastic neutron scattering. In addition, quasielastic neutron scattering is used to reveal the important information about the Li ion diffusion behavior. These results provide useful insights into the thermal transport and phonon dynamics in solid ionic conductors.

Cation Short Range Ordering of $MgAl_2O_4$ and $NiAl_2O_4$ Spinel Oxides Studied via *In Situ* Neutron Total Scattering John M. Hirtz[1], Eric O'Quinn[1], Igor Gussev[1], Joerg C. Neuefeind[2] and Maik K. Lang[1]; [1]University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Complex oxides that adopt the isometric spinel structure (AB_2O_4) are regularly used in energy storage technologies. Their performance in these applications can be drastically different depending on the defect structure present in the material. Using total neutron scattering experiments at the Spallation Neutron Source (Oak Ridge National Laboratory), we elucidated both the long-range repeating structure and the short-range local atomic arrangements of disordered and defective spinels. We have performed this technique on $MgAl_2O_4$ and $NiAl_2O_4$ disordered through chemical substitution ($Mg_{1-x}Ni_xAl_2O_4$), external heating (up to 1000°C), and dense electronic excitation through swift heavy ion irradiation (2.2-GeV Au ions). In the case of chemical substitution and external heating, the induced anti-site defects and associate inversion create a heterogeneous structure where the long-range structure is different from the short-range order. Locally, the isometric [endif]-->*m* spinel structure re-arranges to a tetragonal $P4_122$ atomic arrangement in order to maintain local charge balance, which can be rationalized by Pauling's rules. The local phase fraction is directly linked to the amount of inversion, whether it is intrinsic (chemical substitution) or external (heating). Interestingly, this behavior is modified for spinels that are disordered through far-from-equilibrium swift heavy ion irradiation. In addition to the local phase changes, the resulting defect structure includes cations trapped at vacant sites that are unoccupied when the structure is ordered or disordered by less extreme conditions. These results demonstrate that disordering in spinel oxides is highly heterogeneous across length scales and strongly dependent on the processing method; neutron total scattering with pair distribution function analysis and sensitivity to the anion sublattice provides an ideal approach to experimentally interrogate this complex behavior.

Using Neutron Scattering to Reveal Complex Dynamics of Ions in Energy Materials Olivier Delaire; Duke University, United States

A better understanding of atomic motions in solids is critical to design improved materials for a wide range of energy applications. Neutron scattering provides us with key insights into a wide range of atomic dynamics in solids, from fast ionic diffusion in solid-state electrolytes to phonon propagation and thermal transport in thermoelectrics, or electron-phonon coupling and phase transitions in metal-halide perovskites for photovoltaics and optoelectronics. Our group combines state-of-the-art neutron and x-ray scattering techniques together with atomistic materials modeling to probe and rationalize atomic dynamics. This presentation will highlight results from our investigations of atomic dynamics in several classes of materials impacted by strong anharmonicity and a proximity to lattice instabilities, such as halide perovskite photovoltaics, thermoelectrics, and superionic conductors [1-6]. In these materials, we have found that one needs to properly account for the effect of strong anharmonicity, which disrupts the quasiharmonic phonon gas model through large phonon-phonon coupling terms. Large phonon amplitudes can also amplify the electron-phonon interaction and lead to renormalization of a material's electronic structure. Similarly, phonons of the host framework couple with hopping of mobile ions in superionic conductors, and significantly impact the bulk diffusivity. Such interactions, often neglected in textbooks, remain insufficiently understood but could open the door to new and improved material functionalities. By mapping spatio-temporal correlations throughout reciprocal space, complex atomic dynamics can be studied in detail. Our first-principles simulations enable the quantitative rationalization of these effects, for example with ab-initio molecular dynamics simulations and machine-learning accelerated simulations.

1:30 PM *CH03.04.01
Elucidating the Mechanism of the Magnetocaloric Effect in Compounds of the Series $Mn_{5-x}Fe_xSi_3$ Karen Friese[1,2], Karin Schmalzl[1], Jörg Voigt[1], Nikolaos Biniskos[1], Stephane Raymond[3], Andrzej Grzechnik[1,2], Flaviano Jose dos Santos[4,1] and Thomas Brückel[1]; [1]Forschungszentrum Jülich GmbH, Germany; [2]RWTH Aachen University, Germany; [3]Université Grenoble Alpes, France; [4]École Polytechnique Fédérale de Lausanne, Switzerland

Domestic and industrial refrigeration applications contribute a substantial part to mankind's energy consumption. New technologies based on solid state caloric effects promise considerable efficiency gains as compared to today's vapor compression technology. In caloric materials, applied fields (e.g. magnetic, electric, pressure, strain) lead to changes in entropy and in the adiabatic temperature. The observed caloric effects form the basis of the caloric refrigeration cycles. Within our research we aim at a better understanding of the relation between the structure and the dynamics of the materials to guide a sustainable material design.

We focused our research on the magnetocaloric effect in the family of compounds $Mn_{5-x}Fe_xSi_3$. Within the series the magnetocaloric behavior changes from an inverse MCE below 100 K for the end member Mn_5Si_3 (x=0) to a moderately high direct MCE close to room temperature for $MnFe_4Si_3$ (x=4) [1,2]. We performed macroscopic magnetization measurements in static and pulsed fields which provide a basis to quantify and explain phenomenologically the MCE and to elucidate its anisotropy [3,4]. Crystal structures were investigated using powder and single crystal x-ray and neutron diffraction studies under varying temperatures and pressures [5].

Neutron diffraction experiments were of particular importance here as - on one hand - they allow to unambiguously characterize the preferred ordering of Mn and Fe on the two symmetry independent sites available for the paramagnetic ions and thus help elucidating the site dependence of the magnetocaloric effect [6]. On the other hand, they are mandatory for the determination of the magnetic structures in the system [2,6].

The underlying spin dynamics of the system was studied by a combination of inelastic neutron scattering and density functional theory calculations [7,8]. The parent compound Mn_5Si_3 (x=0), undergoes two first order phase transitions to a collinear AFM2 phase (60K<T<100K) and a non-collinear AFM1 phase (T<60K) with the transition from AFM1-AFM2 being related to an inverse MCE. The spin excitation spectrum of the AFM1 phase consists only of propagating spin waves, in contrast to the AFM2 phase where propagative spin waves coexist with diffuse spin fluctuations [9].

For the ferromagnetic compound $MnFe_4Si_3$ (x=4), which exhibits a direct MCE, we observed a strong anisotropy between in- and out-of-plane magnetic exchange interactions in the magnon spectrum which is also reflected in the *q*-dependent line-widths in the paramagnetic state. The obtained correlation lengths of this system indicate a short-range order and the in- and out-of-plane spin-fluctuations around T_c are found to be isotropic [10].

Furthermore, we performed inelastic neutron scattering investigations under external magnetic field on Mn_5Si_3 (x=0) and $MnFe_4Si_3$ (x=4). We could show that the inverse MCE which is observed in Mn_5Si_3 is related to field-induced spin fluctuations [9], while on the contrary the direct MCE observed in $MnFe_4Si_3$ is associated to the usual suppression of fluctuations by magnetic field [10].

2:00 PM *CH03.04.02
Caloric Materials for Decarbonisation of Heating and Cooling Xavier Moya; University of Cambridge, United Kingdom

Half of the world's CO_2 emissions can be attributed to heating and cooling [1]. This is primarily due to heating with natural gas and cooling with compression of greenhouse gases, which are neither environmentally friendly nor energy efficient. Therefore there is great interest in developing energy-efficient solid-state heat pumps that can replace these environmentally damaging technologies. Caloric materials are at the core of novel solid-state heat-pump technologies, and neutron scattering provides a unique tool for their in-operando study of structure and dynamics. During this talk I will describe our work on field-driven phase transitions in caloric materials, by combining calorimetric and neutron scattering techniques.

3:00 PM *CH03.04.03
Dynamics in the Metal Halide Perovskites $FAPbI_3$ and $CsPbI_3$ Investigated Using Neutron Scattering Techniques Maths Karlsson[1], Rasmus Lavén[1], Lorenzo Malavasi[2], Adrien Perrichon[3], Michael M. Koza[4], Fanni Juranyi[5], Markus Appel[4] and Garrett Granroth[6]; [1]Chalmers Univ of Technology, Sweden; [2]University of Pavia, Italy; [3]ISIS Pulsed Neutron and Muon Source, United Kingdom; [4]Institut Laue-Langevin, France; [5]Paul Scherrer Institute, Switzerland; [6]Oak Ridge National Laboratory, United States

Metal halide perovskites are currently attracting considerable attention because of their photovoltaic and photoluminescent properties and concomitant promise for use both in solar cells and in light emitting diodes. Understanding the local structure and dynamics in these materials is critical to future breakthroughs in the optimization of their performance in such devices, however, the impact of local structure and dynamics on the performance of metal halide perovskite is, in general, insufficiently understood. In this contribution I will report on new insight into the dynamics of metal halide perovskites, as obtained from recent quasielastic and inelastic neutron scattering experiments on the prototypical hybrid organic-inorganic perovskite formamidinium lead iodide $HC[NH_2]_2PbI_3$($FAPbI_3$), its methylammonium (MA, CH_3NH_3) substituted variant $FA_{0.6}MA_{0.4}PbI_3$, and the all-inorganic counterpart $CsPbI_3$.

The study on $FAPbI_3$ focused on the dynamical nature of the organic FA cation and how it changes with temperature, using quasielastic neutron scattering by the time-of-flight and backscattering techniques. The phase diagram of $FAPbI_3$ is relatively well understood, and the analysis of the quasielastic neutron scattering data established that the FA cation dynamics evolve from nearly isotropic rotations in the high-temperature (T > 280 K) cubic phase, to reorientational motions with preferred orientations related to the symmetry of the distorted tetragonal phase at intermediate temperatures (140 K < T < 280 K), to even more complex dynamics in the lower-temperature (T < 140 K) tetragonal phase. The study on $FA_{0.6}MA_{0.4}PbI_3$, a composition which was selected due to its excellent performance when used in a solar cell device, reveals strikingly different organic cation dynamics with respect to the single-organic-cation systems $FAPbI_3$ and $MAPbI_3$. It follows that tuning of the MA/FA concentration ratio represents a promising gateway to tune the dynamical properties of the mixed-cation system $FA_{1-x}MA_xPbI_3$ and hence, possibly, its performance in devices.

The study on $CsPbI_3$ focused on the nature of vibrational dynamics and how it changes with temperature, using inelastic neutron scattering. The results unraveled a quasi-harmonic and almost temperature-independent lattice dynamics from 10 K all the way up to the orthorhombic-to-cubic phase transition around 600 K. In the cubic perovskite phase (T > 600 K) of $CsPbI_3$, the dynamics are, conversely, highly anharmonic and overdamped, which are due to anharmonic rattling motions of the Cs^+ ions with the "perovskite cage" and spatially coherent, yet overdamped dynamics of Pb-I perovskite sub-lattice. Since the overdamping of vibrational dynamics in metal halide perovskites have been suggested to reduce the interaction with charge carriers and hence lead to an increase of the charge carrier lifetime and diffusion lengths, which are critical factors affecting the performance of metal halide perovskites in actual devices, this new insight can be expected to help in the rational design of new metal halide perovskites towards specific applications.

3:30 PM *CH03.04.04
Local Order and Dynamics in Hybrid Metal Halide Perovskites Nicholas J. Weadock; University of Colorado at Boulder, United States

Hybrid metal halide perovskites (MHPs) are a rediscovered class of semiconductor with remarkable optoelectronic performance in applications such as solar absorbers, radiation detectors, spintronics, and light emitting diodes. Recent computational results have demonstrated that the optoelectronic properties of MHPs are not explained by classic semiconductor models, instead it is the large structural fluctuations, driven by strong anharmonicities, which govern the behavior [1,2]. Despite recent progress in understanding the fundamental physics underlying thermal and charge carrier transport in these

materials, there still exist detrimental issues like lead toxicity and halide migration which hinder widespread deployment of MHP-based devices [2].
In this talk I will present two studies which highlight the uniqueness of neutron scattering to investigate (i) the lattice dynamics contributions to thermal conductivity in lead-free MHPs, and (ii) the two-dimensional dynamic local order in the prototypical MHPs, $CH_3NH_3PbI_3$ and $CH_3NH_3PbBr_3$. In the first study, we use triple-axis neutron spectroscopy to measure the acoustic phonon lifetimes in $Cs_2AgBiBr_6$ and find that the acoustic mode contributions to the lattice thermal conductivity are larger than in other MHPs. In the second study, we utilize neutron and X-ray single crystal total scattering to reveal that the simple cubic structure of $CH_3NH_3PbI_3$ and $CH_3NH_3PbBr_3$ is in fact and assembly of two-dimensional tilted regions of PbX_6 octahedra which induce further correlations on the $CH_3NH_3^+$ sublattice. I will connect this dynamic local structure to unresolved questions surrounding the optoelectronic properties and halide migration in these materials.

4:00 PM CH03.04.05
Tunable Phase Transitions in a Two-Dimensional Superionic Conductor Alex Rettie; University College London, United Kingdom

Superionic conductors (SICs) possess liquid-like ionic diffusivity in the solid state, finding wide applicability from electrolytes in energy storage to materials for thermoelectric energy conversion. Type I SICs, where high ionic diffusivity is linked to the crystal structure *via* a first-order transition and is therefore either on or off, are attractive for energy storage and conversion applications providing the transition temperature can be controlled. However, such SICs (e.g., AgI, Ag_2Se, etc.) have been found exclusively in 3D crystal structures so far, limiting existing approaches to applied pressure and nanoscale size effects – which affect the transition temperature in one direction – while the effects of chemical substitution cannot be easily decoupled from 3D ion-conducting pathways. Layered materials have spatially separated mobile and immobile sublattices, potentially facilitating wide tunability and functioning as platforms to study two-dimensional superionic conduction.

We previously identified a first-order, order-disorder phase transition in 2D KAg_3Se_2 – a dimensionally-reduced derivative of 3D Ag_2Se – at ~695 K using in-situ XRD and DSC [1]. Here, we use quasi-elastic neutron scattering and AIMD simulations reveal that a-KAg_3Se_2 is a type I SIC with a highly disordered Ag sublattice restricted to 4 Å thick layers [2]. The superionic local structure was probed by in-situ XPDF analysis, confirming the defect dynamics from AIMD simulations (Fig. 1b). Thermal analyses of cation-substituted AAg_3Se_2 (A = Li-Cs) compounds indicate that the superionic transition temperature can be tuned by the composition of the immobile charge-balancing layers (Fig. 1c). Our work extends the known classes of superionic conductors and points the way to the design of new materials, in bulk, single-/few-layer and thin film forms, with tailored ionic conductivities and phase transitions.

Moscone West, Level 1, Exhibit Hall

5:00 PM CH03.05.02
Poster Spotlight: Designing Next Generation Compositionally Complex Oxide Emissions Abatement Catalysts Using *In Situ* Neutron Total Scattering Sreya Paladugu[1], Palani Jothi[2], Cheng Li[3], Stephen Purdy[3] and Katharine Page[1]; [1]University of Tennessee, Knoxville, United States; [2]JTEC Energy, United States; [3]Oak Ridge National Laboratory, United States

Integration of renewable feedstocks into the current energy infrastructure will require the development of catalysts and sorbents that can maintain high surface area and catalytic activity under challenging thermal/hydrothermal environments and acid gas exposure Studying the time-resolved structural evolution of materials under gas flow conditions is key to understanding catalytic performance under real-world operating conditions with the end goal of extracting design strategies for industrially relevant catalysts. Total scattering, including both Bragg and diffuse scattering signals, enables the study of structural evolution in catalysts and can provide key insights into how long-range, nanoscale, and local atomic structure motifs differ and deliver unique properties. We have designed a new high temperature sample environment capable of hazardous gas flow (HGHS) at the Nanoscale Ordered Materials Diffractometer (NOMAD) at Oak Ridge National Lab, that will result in the capability to study acid gas interactions with sorbents and catalysts *in-situ* by neutron total scattering. The HGHS will deliver *in-situ* exposure to industrially relevant acid gas at NOMAD, enabling investigations of acid gas interactions with sorbents and catalysts, which will be a unique capability among neutron sources in the world and will aid in the design of new materials and processes with higher energy efficiency and a smaller emissions footprint. We have developed compositionally complex oxide (CCO) cerate/zirconate-based fluorite catalysts hypothesized to have high sinter resistance and improved low temperature activity compared to the single component oxide analogue. We will discuss the design, commissioning, and proof-of-concept demonstration of the capabilities of the HGHS using cerate/zirconate fluorite catalysts. Overall, this study will offer crucial structural insights into the suitability of CCO catalysts for industrial applications in comparison with traditional single component oxides, thus informing design strategies for next generation emissions abatement catalysts.

SESSION CH03.06: Neutron Techniques for Energy Materials
Session Chairs: Ke An and Margarita Russina
Thursday Morning, April 13, 2023
InterContinental, Fifth Floor, Fremont

8:30 AM *CH03.06.01
Probing Defect Fluorite Catalysts and their Interfaces with Operando Total Scattering Studies Katharine Page[1,2]; [1]The University of Tennessee,

Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Integration of renewable feedstocks into the current energy infrastructure will require the development of heterogenous catalysts that can maintain high surface areas and selective catalytic activities under a variety of challenging chemical and environmental conditions. Recently, a number of compositionally complex oxides have been reported with intriguing and tunable thermal stabilities and catalytic properties. As with traditional catalysts, the all-important atomic structure details of their gas-solid and liquid-solid interfaces, which are aperiodic and transient nature, remain almost entirely out of reach by traditional structural probes. The ability to capture chemically reactive catalyst surfaces, including correlated defects and chemical short-range order, in real time and at elevated temperatures, represents a modern frontier in the field of crystallography. We will demonstrate how neutron total scattering methods, including both Bragg and diffuse scattering signals, can provide information on local atomic structure motifs and the unique properties they provide to nanomaterial platforms with significant surface to volume ratios. Neutrons offer advantages of light atom sensitivity, distinguishing neighboring atoms in the periodic table, and superior penetration of sample environments for *operando* studies. We present studies following multiple length-scales of interest in two cerate-based catalytic material systems with these probes: (1) the oxidation and reduction behaviors of ceria and Pt-decorated ceria nanorods at elevated temperatures, specifically following the evolution of oxygen vacancy correlations; and (2) the unique compositional complexity and nanoscale heterogeneities leading to increased stability and selectivity in novel, compositionally complex Rare Earth cerate and cerate zirconate emissions abatement catalysts. These examples highlight the importance but also the current limitations of studying nanocatalyst candidates and their structure-property characteristics under real-world reaction conditions. Emerging opportunities for *operando* investigations of industrially relevant catalytic and chemical separations processes with a hazardous gas handling system currently under construction at the Nanoscale Ordered Materials Diffractometer (NOMAD) and planned capabilities at the proposed DISCOVER beamline at the Spallation Neutron Source at Oak Ridge National Laboratory will be presented.

9:00 AM *CH03.06.02
Evaluating Structural Anisotropy from Neutron Pair Distribution Function Analysis of Uniaxially-Loaded Sustainable Cement Undergoing Viscoelastic Relaxation Nishant Garg[1], Brendan Kehoe[2], Daniel Olds[3], Joseph Vocaturo[2], Michelle Everett[4], Katharine Page[5], Joerg C. Neuefeind[4] and Claire White[2]; [1]University of Illinois Urbana-Champaign, United States; [2]Princeton University, United States; [3]Brookhaven National Laboratory, United States; [4]Oak Ridge National Laboratory, United States; [5]The University of Tennessee, Knoxville, United States

Pair distribution function analysis (PDF) is well-suited for determining time-dependent local atomic structure changes occurring in amorphous and disordered systems. Sustainable cements, with reduced CO_2 emissions compared with Portland cement, fall into this category due to multiple amorphous phases that are known to evolve concurrently during initial formation and over the service life of the material. Viscoelastic relaxation of cement-based systems is known to control macroscopic creep, but the underlying mechanisms responsible for this viscoelastic behavior are still to be fully reconciled. Due to the high penetrating power of neutrons and their sensitivity to hydrated materials, neutron PDF analysis is ideal for uncovering these mechanisms. However, typically PDF analysis assumes isotropic scattering which may not be applicable to cement systems subjected to uniaxial loads.

In this talk we will discuss a unique sample environment setup and data reduction approach that were used on the NOMAD instrument at the Spallation Neutron Source, Oak Ridge National Laboratory, to obtain directional-dependent total scattering patterns and associated PDFs. Alkali-activated slag and hydrated tricalcium silicate cement cylinders were subjected to 40% of their ultimate strength while data were collected in situ for the initial 24 hours, and then at 1, 2, 4, 8, 16 and ~32 weeks. As part of this talk uniaxial structural anisotropy will be assessed from neutron PDFs parallel and perpendicular to the loading direction, and mechanistic insights on cement viscoelasticity will be discussed. Key challenges that were faced as part of the investigation will also be outlined.

9:30 AM BREAK

10:00 AM CH03.06.03
Designing CENTAUR for Understanding *In Situ/Operando* Structure Evolution from Atomic to Meso Scale Shuo Qian and Cristina Boone; Oak Ridge National Laboratory, United States

CENTAUR is one of the first eight instruments to be first built for the Second Target Station of Spallation Neutron Source at Oak Ridge National Laboratory. As a work-horse SANS instrument, its capabilities are extended to cover wide-angle scattering and diffraction, therefore provide a simultaneous measurement for structures from atomic scale to hundreds of nanometers. This will fill a gap in the US neutron scattering capability. The large dynamic range coupled with high flux provides an ideal tool for *in-situ/operando* energy materials research, especially for kinetic and/or out-of-equilibrium studies of phenomena with time-resolution down to seconds.
In this presentation, I will go through the progress and the current design of CENTAUR. Highlighted features will be presented to seek feedbacks from a broader materials research community. For example, CENTAUR will have a broad wavelength band and 4 arrays of large detector coverage to enable wide Q coverage simultaneously. The optimized yet fixed-position detector arrangement maximizes the output with high data rate. A flexible optics system provides different collimation lengths for adjustable instrument resolution. We also emphasis the design on an open, spacious, and easy to access sample area with modular sample environment setups. Additionally, the spectrometer mode extends the momentum transfer and energy transfer to a lower Q than those typically covered by other spectrometers and provides a unique capability for inelastic SANS experiment. Also beam polarization will enable detailed structural and dynamical investigations of magnetic materials and quantum materials. We hope those features will enable better future materials research. With this presentation, we invite the energy materials research community to engage with us during the design phase so any additional important requirement especially the *in-situ/operando* sample environment can be captured and reflected in the next iteration of the design process.

10:15 AM CH03.06.04
Neutron Scattering Aiding to Understand Material Processing for Energy Storage Applications Yan Chen and Ke An; Oak Ridge National Laboratory, United States

Clean energy innovation is seeing drastic increase in demand, and a key step is to develop advanced renewable energy materials with high efficiency, reliability and safety. Given the right selection of compositions, the crystal structures plus various defects such as atom disordering, vacancies and incoherent boundaries usually act as determinative factors of materials performance. The understanding and controls of those factors in multiple length scales in the structure are highly desired in the design of material synthesis and manufacturing. However, the dynamic and sometimes reversible structure evolution during material processing makes the trial-and-error paradigm less effective to reveal the full mechanisms. Neutron scattering is a powerful characterization tool for the studies of energy storage materials. It possesses unique capabilities of detecting vacancies of light-weight elements and ordered arrangement of transition-metal-elements in lattice. Neutrons' high penetration in materials facilitates equipping various sample environments that mimic material processing. Over the structure evolution, the neutron scattering reveals the processing mechanisms towards superior performance. This presentation takes an example of high-energy ball milling on the high-voltage $LiNi_{0.5}Mn_{1.5}O_4$ spinel cathode of Li-ion battery. Neutron scattering reveals the ball-milling effects on structure breakdown, defect generation and atom disordering. By employing in-situ neutron diffraction, the kinetics of the structure recovery during the subsequent annealing are visualized and resolved in multiple length scales. The ball milling is also found to influence Mn^{3+} formation, Mn/Ni ordering, and the rock-salt phase transition during annealing. In addition, another example of the synthesis mechanism study on the garnet-type solid-state electrolyte is given. The in-situ neutron diffraction reveals how the element doping and the synthesis control manipulate the Li vacancy quantity and distribution to facilitate the fast-ion transport network in the solid $Li_7La_3Zr_2O_{12}$ garnet. The studies illustrate neutron scattering aiding understandings of mechanisms to advance materials processing for energy storage applications.

10:30 AM CH03.06.05

INS Characterization of Defect Sites in Metal Organic Frameworks Lucas Cavalcante[1], Makena Dettmann[1], Luke L. Daemen[2], Bruce C. Gates[1], Ambarish Kulkarni[1] and Adam J. Moule[1]; [1]University of California, Davis, United States; [2]Oak Ridge National Laboratory, United States

Metal Organic Frameworks (MOFs) that incorporate metal oxide cluster nodes, exemplified by UiO-66, have been widely studied, especially in terms of their deviations from the ideal, defect-free crystalline structures. Although defects such as missing linkers, missing nodes, and the presence of adventitious synthesis-derived node ligands (such as acetates and formates) have been proposed, their exact structures remain unknown. Previously, it was demonstrated that defects are correlated and span multiple unit cells. The highly specialized techniques used in these studies are not easily applicable to other MOFs. Thus, there is a need to develop new experimental and computational approaches to understand the structure and properties of defects in a wider variety of MOFs. Here, we show how low-frequency phonon modes measured by inelastic neutron scattering (INS) spectroscopy can be combined with density functional theory (DFT) simulations to provide unprecedented insights into the defect structure of UiO-66. We are able to identify and assign peaks in the fingerprint region ($< 100\ cm^{-1}$) which correspond to phonon modes only present in certain defective topologies. Specifically, this analysis suggests that our sample of UiO-66 consists of predominantly defect-free fcu regions with smaller domains corresponding to a defective bcu topology with 4 and 2 acetate ligands bound to the Zr_6O_8 nodes. Importantly, the INS/DFT approach provides detailed structural insights (e.g., relative positions and numbers of acetate ligands) that are not accessible with microscopy-based techniques. The quantitative agreement between DFT simulations and the experimental INS spectrum combined with the relative simplicity of sample preparation, suggests that this methodology may become part of the standard and preferred protocol for the characterization of MOFs, and, in particular, for elucidating the structure defects in these materials.

Nanoscale Characterisation and Neutron Damage Testing of Organic Semiconductors for New Generation Photovoltaics Giuseppe M. Paternò[1], Franco Cacialli[2] and Victoria Garcia Sakai[3]; [1]Politecnico di Milano, Department of Physics, Italy; [2]Free University of Bozen-Bolzano, Italy; [3]ISIS Pulsed Neutron and Muon Source, United Kingdom

The work I will present here involves acquiring a comprehensive insight into the nanoscale arrangements of organic semiconductors used as active materials in photovoltaics, by combining neutron scattering techniques and fast neutron irradiation.[1]
Neutron scattering is a powerful and versatile tool to investigate these highly hydrogenated materials, since hydrogen shows the highest neutron scattering cross section among the isotope.
In the first part, I will go through the investigation of the nano-morphology of conjugated polymers/fullerene photovoltaic blends by means of quasi-elastic neutron scattering and reflectivity.[2–5] The large neutron scattering contrast between these two functional materials (usually around one order of magnitude), allows one to obtain detailed information about the nano-morphology in these blends that is complementary to the information acquired via electron-sensitive techniques, such as electron microscopies and X-ray scattering techniques. This is crucial, as their arrangement at the microscale is ultimately linked to the process of exciton splitting and charge generation.

Furthermore, intense and broadband neutron pulses can be used to study the effect of neutron irradiation on organic electronics, of importance when used in space and avionic applications. In particular, I will show that the different neutron radiation tolerance exhibited by two polythiophene derivatives stems from their different crystallinity and assembly features, which in turn is induced by a combination of different molecular design features.[6,7]

Investigation on Ionomer Structure in Catalyst Layer of Polymer Electrolyte Fuel Cell Masashi Harada[1], Shin-ichi Takata[2], Hiroki Iwase[3], Hiroyuki Aoki[2,4] and Norifumi Yamada[4]; [1]Toyota Central R&D Labs., Inc., Japan; [2]Japan Atomic Energy Agency, Japan; [3]Comprehensive Research Organization for Science and Society, Japan; [4]High Energy Accelerator Research Organization, Japan

A polymer electrolyte fuel cell (PEFC) generates electric current by an electrochemical reaction of hydrogen and oxygen in a porous composite material called a catalyst layer, consisting of platinum nanoparticles, carbon aggregates, and a fluorinated polymer having sulphonic acid groups (ionomer). In the catalyst layers, the platinum catalyst is loaded on the carbon support (Pt/C) and the Pt/C is coated with the ionomer binder. Because the ionomer coating on the Pt/C plays important roles in the transport of the hydrogen ions and oxygen molecules to the platinum surface, the structure of the ionomer in the catalyst layers has a great influence on the performance of a PEFC. Thus, analysis of the ionomer structure has been indispensable for PEFC development while electron microscopy and X-ray scattering hardly distinguish carbon particles and ionomer films in the catalyst layer. In this presentation, some examples of neutron application to the catalyst layer of PEFC will be shown, enabling us to reveal ionomer distribution in the inhomogeneous multi-component system through the unique interaction of neutrons with isotopes.
First, we present an example of contrast-variation small-angle neutron scattering to separate the ionomer in the catalyst layer into two types:

homogeneously adsorbed and heterogeneously deposited ionomer against Pt/C [1]. The catalyst layers were soaked in aqueous ethanol with different H/D ratios to separately analyze the scattering components of the ionomer and Pt/C. The obtained scattering curves were modeled with a fractal aggregate of polydisperse core-shell spheres, and the thickness of adsorption and the amount of deposition were evaluated.

Next, we present an example of the analysis on the interface structure between ionomer and Pt/C in a model thin film by the double-contrast neutron reflectometry method [2, 3]. The difference in the depth profiles of the scattering length density at humidity (80% RH) in H_2O and D_2O vapor reflects the water distribution in the ionomer exchanged in the vapor, and the distribution of ionomers can be evaluated subsequently. Comparing the concentration of the ionomer on a platinum surface with that on a carbon surface, it was found that the ionomer concentration was higher at the interface with platinum than at the interface with carbon, indicating the different interactions of the ionomer with the substrate.

In summary, neutrons have the potential for observing the inhomogeneous ionomer structure in the catalyst layer by utilizing the contrast between H and D. The distribution of the ionomer is separated into two types and the interfacial concentration is extracted for the platinum and carbon surfaces. These parameters of the ionomer will be introduced into advanced simulation models of catalyst layers to design optimal performance from their structure.

Acknowledgment: The neutron experiments were performed in J-PARC with the support of the instrument scientists.

Enhancement of Thermoelectric Performance in *n*-type Bi_2Te_3 Based Samples and its Correlation with Topological Insulating Properties Aritra Banerjee; University of Calcutta, India

Bi_2Te_3, a room temperature thermoelectric material, is also well known for its bulk (3D) topologically insulating properties. We report enhancement of thermoelectric performance in *n*-type Bi_2Te_3 based compounds and its correlation with topologically insulating properties. The case of nanostructured Bi_2Te_3/graphite composite and Co doped Bi_2Te_3, *viz.*, $Bi_{2-x}Co_xTe_3$ samples will be discussed. In-depth thermoelectric properties of the samples are probed both microscopically and macroscopically using x-ray diffraction, Raman spectroscopy, temperature dependent thermal conductivity κ, Seebeck coefficient S, resistivity ρ, and carrier concentration n_H. Further the results obtained for inelastic neutron scattering experiment on Bi_2Te_3/graphite nanocomposites and magneto-resistance (MR), as well as magnetization measurements performed on Cobalt-doped Bi_2Te_3, *viz.*, $Bi_{2-x}Co_xTe_3$ (x = 0, 0.05, and 0.1) samples will also be highlighted.

Raman spectroscopic analysis confirms that graphite introduces defects and disorder in the system. A large (~17%) decrease of κ with Graphite addition has been observed, which originates from strong phonon scattering effect. A low lattice thermal conductivity (κ_L) value of $0.77 Wm^{-1}K^{-1}$ is reported for Bi_2Te_3 + 1.0 wt. % graphite sample. Interestingly, this low value of κ_L tends towards the κ_{min} value estimated using the Cahill–Pohl model. Also improvements in other thermoelectric parameters, viz., Seebeck coefficient and resistivity, is observed with graphite addition in Bi_2Te_3 nanocomposite samples. Inelastic neutron scattering experiment performed at ISIS, STFC, UK (Instrument: MARI) depicts that Graphite dispersion alters the low-energy inelastic neutron scattering spectrum providing evidence for modification of the Bi_2Te_3 phonon density of states.

On the other hand for $Bi_{2-x}Co_xTe_3$ samples, the power factor, PF ($=S^2/\rho$) a measure of thermoelectric performance is found to increase by around 47% with Co doping. The MR measurements at low field and low temperature, depicting positive linear MR and nearly cusp like behavior, followed by fitting of the Magnetoconductance data with Hikami-Larkin-Nagaoka (HLN) equation confirms the presence of 2D weak anti-localization (WAL) effects in both the pristine and Co-doped Bi_2Te_3 samples. The field-dependent magnetization showing a cusp-like nature in the susceptibility data around zero field regions (± 5 kOe) signifies the existence of topological surface state (TSS). MR along with magnetization data confirms the robustness of TSS with Co doping. In this context, the case of highly anisotropic single crystalline Bi_2Se_3 sample exhibiting high thermoelectric PF along with anisotropic magnetization and topological insulating properties will also be highlighted. Our investigation unveils that Co doping can trigger the thermoelectric performance of Bi_2Te_3 keeping the TSS intact, which gives the dual advantages of being a good thermoelectric material along with a Topological Insulator from the application point of view.

Pressure-Functionalized Glassy Crystals Bing Li[1], Dehong Yu[2] and Jiangshui Luo[3]; [1]Chinese Academy of Sciences, China; [2]ANSTO, Australia; [3]Sichuan University, China

As a nontrivial solid state of matter, the glassy-crystal state embraces physical features of both crystalline and amorphous solids, where a long-range ordered periodic structure formed by the mass centers of constituent molecules accommodates orientational glasses [1-3]. Here, we discover and validate a glassy-crystal state in 2-amino-2-methyl-1,3-propanediol (AMP, $C_4H_{11}NO_2$) by neutron scattering and complementary broadband dielectric spectroscopy (BDS) measurements. The freezing process of the dynamic orientational disorder is manifested at relaxation times well described by the Vogel-Fulcher-Tammann (VFT) law and the strongly frequency-dependent freezing temperature ranging from around 225 K at 0.1 Hz to above room temperature in the GHz region. At room temperature, the supercooled state is extremely sensitive to pressure such that a few MPa pressure can induce crystallization to the ordered crystal state, eventually leading to a temperature increase by 48 K within 20 s, a significant reduction of visible light transmittance from about 95% to a few percentages, and a remarkable decrease of electrical conductivity by three orders of magnitude. These ultrasensitive baroresponsivities might find their applications in low-grade waste heat recycling, pressure sensors and non-volatile memory devices. It is expected that glassy crystals serve as an emerging platform for exploiting exotic states of matter and the associated fantastic applications [4].

Phase-Change and Ovonic Chalcogenide Materials for Innovative Electronic and Photonic Devices Pierre Noé; CEA-LETI, France

Chalcogenide materials have attracted a lot of attention over the years due to their wide range of applications. Among them, some compounds such as Ge-Sb-Te based alloys exhibit a unique portfolio of properties, which has led to their wide use for non-volatile memory applications such as optical data storage or more recently resistive phase change memory (PCM) [1,2]. In addition to a high IR transparency window and large optical nonlinearities [3], some chalcogenide glasses such as Se-based compounds exhibit an uncommon conductivity behavior under high electric field, called ovonic threshold switching effect (OTS) [4].
In this talk, I will show that materials science research through the coupling of advanced characterization tools, device characterization, and state-of-the-art simulation methods provides a powerful tool to correlate the complex structure, from long-range to local nanoscale/atomic order, and properties of prototypical chalcogenide compounds and heterostructures [5-9]. I will illustrate how such an approach applied to various chalcogenide materials used in PC memories, OTS selection devices, or photonics, provides valuable clues to understand the origin of their unique properties widely exploited so far in state-of-the-art memory devices, as well as the possibilities to go far beyond. Finally, based on this basic knowledge, we will propose new technological avenues to tailor the properties of chalcogenides, from atomic engineering to nanostructuring [10-12], to improve some of their macroscopic properties and overcome the many current technological challenges they face in many applications, while opening up new fields of application [13].

11:00 AM *EL01.01.02
A Machine-Learning Interatomic Potential for the $Ge_2Sb_2Te_5$ Phase Change Compound Omar Abou El Kheir[1], Luigi Bonati[2], Michele Parrinello[2] and Marco Bernasconi[1]; [1]Università di Milano-Bicocca, Italy; [2]Istituto Italiano di Tecnologia, Italy

In the last fifteen years atomistic simulations based on density functional theory (DFT) have provided useful insights on the structural and functional properties of phase change materials. However, several key issues such as the effect of confinement and nanostructuring on the crystallization kinetics, just to name a few, are presently beyond the reach of DFT simulations. A route to overcome the limitations in system size and time scale and enlarge the scope of DFT methods is the exploitation of machine learning techniques trained on a DFT database to generate interatomic potentials for large scale molecular dynamics simulations. The first example of the application of such an approach to the study of phase change compounds dates back to 2012 when an interatomic potential for GeTe [1] was devised within the neural network (NN) framework proposed by Behler and Parrinello [2]. The same scheme was also applied to elemental Sb [3]. The NN potentials were then used to address several issues such as the crystallization in ultrathin films [3] and nanowires, and the thermal conductivity and aging of the amorphous phase [4]. More recently, a different machine learning technique within the Gaussian approximation potential (GAP) framework was exploited to generate an interatomic potential for $Ge_2Sb_2Te_5$ [5].

In this talk, we report on the generation of an interatomic potential for the $Ge_2Sb_2Te_5$ compound within the neural network framework implemented in the DeePMD-kit package [6]. The interatomic potential allows simulating several tens of thousands of atoms for tens of ns at a modest computational cost. The validation of the potential and its application to the study of the crystallization kinetics in the bulk phase will be discussed.

11:30 AM EL01.01.03
Simulation of Phase Transformations Occurring in Ge-Rich GeSbTe Phase Change Memories—Coupling of Multi-Phase Field and Thermal Models Robin Miquel[1,2,3], Thomas Cabout[1], Olga CUETO[2], Mathis Plapp[3] and Benoit Sklénard[2]; [1]STMicroelectronics, France; [2]CEA-Leti, Univ. Grenoble Alpes, France; [3]Lab. Physique de la Matière Condensée, Ecole Polytechnique, CNRS, IP Paris, France

Phase change memories (PCM) rely on phase-change materials to store information. During memory operations (write and erase), the PCM cell undergoes Joule heating during the application of appropriate electrical pulses. Thanks to a highly resistive electrode in contact with the PCM layer, phase change occurs in a dome-shaped active zone of the phase change material located above this electrode [1]. Depending on heating and cooling profiles, the dome ends up in the amorphous or in the crystalline state, both states having different electrical resistivities.
The stoichiometric ternary compound Ge2Sb2Te5 (GST) is widely used in PCM technologies thanks to its interesting physical properties (ovonic switching, fast and congruent crystallization, large resistivity difference between the two states) [2]. However, because of its relatively low crystallization temperature, at which the amorphous state spontaneously crystallizes (effectively losing the stored information), GST is not suited for some industrial applications that require high operating temperatures, such as automotive microcontrollers [3]. To increase the crystallization temperature, GST can be enriched with germanium [4]. However, this leads to segregation during crystallization: two types of crystalline phases appear, germanium-rich phases and phases close to pure GST. The crystallization of GST is congruent, but that of Ge-rich GST is not.

In order to simulate the crystallization of the material after the microfabrication process and during memory operations, we have developed a multi-phase field model coupled with an orientation model [5]. This model is able to reproduce the segregation effect and to perform memory operations. However, it makes substantial approximations for the couplings to the thermal field and the electrical current that accompany memory operations.
In this work, we couple the multi-phase field approach with a thermal model that takes into account the multi-phase character of the material. Physical parameters such as thermal conductivities and specific heat have been determined with available experimental data, they are phase and temperature dependent when it is relevant. Such dependence is especially important for thermal conductivities because there are more than two orders of magnitude between their values in the different phases. Latent heats that were not taken into account by the previous model are also included to account for the heat produced during crystallization and absorbed during melting.
Chemical species diffusion and thermal diffusion are phenomena occurring at different time scales. This leads to a numerically stiff problem when they are coupled in simulations. We combine multiple numerical approaches and optimizations to keep our results accurate and simulation times low.
With this thermal multi-phase field model and with a heat source provided by an electrical model, first simulations are proposed and discussed. We investigate different electrical pulses and their effects on crystallization scenarios. While our model remains qualitative in nature, it can give insight on the crystallization mechanism occurring during memory operations.

11:45 AM EL01.01.04
Encapsulation Effects on Ge-rich GeSbTe Alloys at High Temperature Oumaima Daoudi, Emmanuel Nolot, Mélanie Dartois, Magali Tessaire, François Aussenac, Névine Rochat, Van-Hoan Le and Gabriele Navarro; CEA-Leti, Univ. Grenoble Alpes, F-38000 Grenoble, France, France

Phase–Change Memory (PCM) is a mature technology based on chalcogenide alloys, which has proven its suitability for next generation of non–volatile memory, in particular targeting embedded applications [1]. This result was achieved thanks to the intrinsic features of PCM in terms of scalability, fast programming and high endurance. Enrichment of GeSbTe (GST) alloys by Ge and doping by light elements demonstrated to be a successful solution to enhance the data retention in PCM, opening the possibility for this technology to target automotive applications featuring strict specifications in terms of stability in high temperature environment [2–4].
It has been shown that even a partial oxidation of the chalcogenide layer can affect the properties of the material and its evolution once exposed to high temperature, likely leading to a modification of the final device performances. Indeed, the oxidation phenomena in $Ge_2Sb_2Te_5$ and GeTe films lead to a reduction of their crystallization temperature [5]. Recently, a comparison between TiN encapsulated and air–exposed N–doped Ge–rich GeSbTe (GGST) layers, highlighted the appearance of heterogeneous interfacial phenomena in the air–exposed sample [6].
In this work, we propose the study of the interfacial effects on GGST alloys at high temperature, comparing different encapsulation materials: Carbon (C), Tantalum Nitride (TaN) and Titanium Nitride (TiN) and specific combination of them. The results are compared to the ones obtained from an air-exposed sample.
Carbon is interesting for its transparency in IR and Raman spectroscopy in the range of frequency of interest. Moreover, it has been used in devices to hinder the electrode/chalcogenide material intermixing [7]. TaN has a high chemical resistance [8] and it has been already integrated in memory devices [9]. Finally, TiN was studied as reference because of its adoption in state of the art PCM devices.
We show how carbon layer faces instability at around 400°C, while TaN encapsulated sample presents stress induced phenomena at high temperature and accelerated crystallization of the chalcogenide layer. Encapsulation by TiN electrode preserves up to high temperature (more than 450°C) the properties of the GGST layer.
We compared the results coming from different techniques in order to highlight the main properties of the samples upon annealing:
- Raman spectroscopy to follow the evolution of Ge atoms vibrations;
- IR spectroscopy to observe the evolution of Ge–N and Ge–O bonds;

- Transmission Electron Microscopy (TEM) after annealing at 500°C;
- X-ray diffraction (XRD) to compare the crystallization dynamics.

The investigations were performed at several increasing temperatures up to 500°C, in order to highlight the intermixing phenomena along with the segregation and crystallization of Ge and GeSbTe phases into the GGST layer. The thickness of TaN layer should be optimized to have the compromise between a good oxidation barrier and low stress effects.
In conclusion, we compared the evolution of different samples in terms of oxidation, interfacial diffusion and stress effects to highlight the advantage and drawbacks of each encapsulating material with respect to GGST alloys evolution in temperature.

Structure and Properties of Ultra-Confined Phase-Change Thin Films—The Important Role Played by Peierls Distortion Bart J. Kooi, Daniel Yimam, Jesse Luchtenveld and Majid Ahmadi; Univ of Groningen, Netherlands

In the present work GeTe and Sb films were grown using molecular beam epitaxy and pulsed laser deposition. Their structures have been analysed at atomic scale using scanning transmission electron microscopy (STEM). Optical properties of the films and their crystallization temperature were assessed by spectroscopic and dynamic ellipsometry, respectively. The properties of ultrathin GeTe and Sb films (grown on amorphous oxides or nitrides), like crystallization temperature and optical properties, turned out to depend strongly on film thickness. For Sb_2Te_3 and GeSbTe films this dependence was found to be more moderate. This difference in thickness dependence can be coupled to a Peierls-like distortion (PD) being present in GeTe and Sb and absent in Sb_2Te_3 and GeSbTe. The PD in crystalline GeTe and Sb films, as measured using STEM, was found to vary across the film thickness, being overall larger for thinner films. For crystalline films of about 10 nm or thicker the PD is sufficiently small such that films behave metallic (due to metavalent bonding). In the ultrathin crystalline films, the PD is larger, opens up the bandgap and crystalline films behave more insulating (due to covalent bonding like in the amorphous films). Moreover, it will be shown that in thicker GeTe films the PD is downward in the film close to the substrate and upward in the film close to the surface with the presence of a concrete antiphase boundary (APB) running largely parallel to the interface and surface. This shows that the PD is closely associated with passivating the interface and surface and also demonstrates that the ferroelectricity of GeTe cannot be a significant effect, because such APB should not exist in ferroelectric materials.

Crystallization in Carbon-doped $Ge_2Sb_2Te_5$ (C-GST) via Temperature Dependent Raman Scattering and DFT-Based Molecular Dynamics Thomas Beechem[1], Robert J. Appleton[1], Arihant Kaul[1], Jenna Smith[1], Fernando Vega[1], Alejandro Strachan[1] and David P. Adams[2]; [1]Purdue University, United States; [2]Sandia National Laboratories, United States

Doping $Ge_2Sb_2Te_5$ (GST) modifies its phase change and thus the performance of any device based upon its use. Assessing the physical mechanisms belying the interplay between doping and phase change in GST, therefore, provides a path to faster, more energy efficient, and robust phase change microelectronics and photonics. With this motivation, phase-change in carbon-doped GST (C-GST) was examined using a combination of temperature dependent Raman spectroscopy and density functional theory (DFT) based molecular dynamics (DFT-based MD). Practically, Raman spectra of C-GST films synthesized with carbon concentrations ranging from 0 to 12% were collected at temperatures spanning 80 to 300 K, which allowed the undoped material to progress from its amorphous state through the metastable rock-salt phase and finally into its trigonal form. Observed changes in the Raman responses were then compared to the vibrational density of states projected onto individual atomic species. This comparison, in turn, identified those bonds most impacted by carbon-doping.

Carbon doping increases the amount of tetrahedrally bonded Ge-atoms in GST. Increased tetrahedral bonding, in turn, delays crystallization as the metastable rock-salt phase requires octahedral bonding arrangements. This deduction is supported by both observations of increased spectral weight of the tetrahedrally bonded Raman signal of Ge near 220 cm^{-1} and analysis of the coordination numbers of Ge-atoms in the simulation. Carbon doping also slows the atomic ordering necessary for crystallization. Experimentally, this is seen by not just the higher temperatures required for crystallization but the increase in disorder as the crystallization initiates, as evidenced by broader Raman features. These results are corroborated computationally in a decrease in the number of primitive rings with the presence of doping. Taken together, carbon therefore affects the phase change of GST not just by altering bonding within the amorphous material but also serving as an impediment to the atomic movement necessary for the ordering implicit in crystallization.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

2:15 PM EL01.02.03
Effects of Carbon Concentration on the Local Atomic Structure of Amorphous GST Robert J. Appleton[1], Zachary D. McClure[1], Thomas Beechem[1], David P. Adams[2] and Alejandro Strachan[1]; [1]Purdue University, United States; [2]Sandia National Laboratories, United States

Ge-Sb-Te (GST) alloys are the phase-change materials of choice for data storage due to their fast phase transition between amorphous and crystalline states. To accommodate the data storage devices of the future, the stability of the amorphous phase must be enhanced. Experiments have shown that introducing carbon results in increased crystallization temperatures up to 50% higher than pure $Ge_2Sb_2Te_5$. Previous simulations have shown that carbon alters the local atomic environment in the amorphous phase favoring tetrahedral coordination, especially with Ge. Here we use density functional theory-based molecular dynamics to study the evolution of the atomic structure of amorphous GST-C with increasing carbon concentrations. We find that carbon increases the number of Ge atoms with tetrahedral bonding, stabilizing the amorphous structure. However, this effect saturates between 5% and 10% carbon where the additional carbons aggregate on long chains. This indicates that both changes in the atomic environment and the formation of long chains contribute to the hindering of crystallization. The relative potency is not known.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Influence of Film Thickness on the Crystallization Kinetics of Ge-rich Ge-Sb-Te Thin Films Philipp Hans[1,2], Cristian Mocuta[3], Yann Le-Friec[4], Philippe Boivin[4], Roberto Simola[4] and Olivier Thomas[1,2]; [1]Aix Marseille Universite, France; [2]CNRS IM2NP, France; [3]Synchrotron SOLEIL, France; [4]STMicroelectronics, France

Phase-Change Memory is a very promising non-volatile memory that is being considered by several companies for a wide range of applications (storage-class memory, in-memory computing, neuromorphic computing, eNVM for microcontrollers …). At STMicroelectronics a new Ge-rich Ge-Sb-Te alloy (GGST) has been developed with a crystallization temperature above 350°C [1] for addressing the specific needs of the automotive market where high operating temperatures are needed. To investigate the crystallization behavior of these GGST alloys we use X-ray diffraction as a function of temperature during annealing. Capped thin films are heated *in situ* under nitrogen atmosphere on the DiffAbs beamline of SOLEIL synchrotron facility. The incident beam is monochromatic (18 keV) and the incidence is fixed. A bidimensional detector collects the diffraction pattern and is corrected and integrated [2] to yield a 1D diffraction pattern. The diffraction peaks are then fitted with a Voigt function [3] that allows extracting the integrated intensity, integral breadth and position of the Bragg peaks. In a previous work [4] we have shown that crystallization proceeds in two stages with Ge crystallization preceding the crystallization of cubic $Ge_2Sb_2Te_5$. In the present study we have investigated the kinetics of crystallization by performing isothermal in situ diffraction measurements on films with thickness in the range (5 nm – 50 nm). A three-stage crystallization process is identified with very different activation energies (1.7 to 3 eV). Evolution of these parameters with film thickness will be presented and discussed. These results bear important consequences for the understanding of the crystallization process in memory cells.

Revealing Hidden Phases and Self-Healing in Antimony Trichalcogenides and Chalcoiodides Subila K. Balakrishnan[1], Priyakumari C. Parambil[2] and Eran Edri[1]; [1]Ben-Gurion University of the Negev, Israel; [2]Indian Institute of Technology Palakkad, India

The prevalence of self-healing semiconductors is restricted to a few selected cases, limiting understanding of the phenomenon. Herein, we report self-healing following photoinduced damage in antimony trichalcogenides and chalcoiodides—quasi-one-dimensional semiconductors with prospective applications in photovoltaics and other electronic devices. We relate the self-healing to photoinduced phase transition (PIPT) and the 'damaged' state to a hidden phase from which the 'damaged' semiconductors recover ('self-heal'). We elucidated intermediate species in the reaction and reaction dynamics using vibrational spectroscopy. Comparing four different materials with a similar crystal structure enabled us to uncover the common structural feature that leads to self-healing in these materials. By analyzing the chemical bonding, we rationalize the chemical reaction and point to bonding states at the bottom of the conduction band as central origins in propelling the hidden phase. Expanding the type and number of self-healing materials and uncovering the underlying solid-state reactions will facilitate the development of self-healing electronic building blocks for making animate electronic devices.

Exploring In_3SbTe_2 Chalcogenide Material for Multi-Bit Phase Change Memory Applications Anushmita Pathak and Shivendra K. Pandey; National Institute of Technology Silchar, India

Any information processing system must be able to store both temporary and permanent data, and SRAM, DRAM, and Flash memory, all being CMOS-based memories, have done this to date. However, in recent years, due to the massive global expansion of data and the practical limitation of the conventional transistor (CMOS) scaling, enormous efforts have been dedicated in delivering highly efficient storage memory. Phase change memory (PCM) technology is one of the possible contenders for the next generation emerging memory devices [1]. It uses the concept of differences in optical reflectance and electrical resistance between crystalline (low-resistance or SET state) and amorphous (high-resistance or RESET state) phases of chalcogenides/phase change material to record digital information. $Ge_2Sb_2Te_5$ (GST) ternary alloy, has been extensively utilized in both optical and electronic (PCM) data storage applications due to its ideal conditions [2]. However, this material shows some significant drawbacks such as a low crystallization temperature of ~160 °C, causing stability issues in devices [3] and a limited capacity for multi-bit storage. The scalability of PCM and the device optimization for the intended application such as determining the appropriate speed, retention, and durability tradeoff rely heavily on the phase change material characteristics. As a result, several attempts have been undertaken to explore novel chalcogenide materials and investigating their characteristics. This idea served as the foundation for investigating $In_3Sb_1Te_2$ (IST) chalcogenide alloy. IST has demonstrated high crystallization temperature of ~290 °C, proposing better thermal stability and a difference of six orders of magnitude in phases resistance, imparting the multiple bit storing potential for the PCM applications [3]. Therefore, it is essential to look at the viability of using IST material in PCM applications. The goal of this work is to investigate the optical properties such as optical bandgap and associated structural disorder of IST material during phase transition by the use of UV-Vis-NIR spectroscopy method. Amorphous phase of IST show an optical bandgap value of 0.998 eV whereas the crystalline phase show 0.449 eV, revealing IST bandgap is higher than widely used GST. A significant contrast in optical bandgap values contributes lesser threshold current and a higher signal-to-noise ratio, favourable for multiple data storing applications. Structural disorder, determined by the Tauc parameter slope, exhibit 22.7 % increment during transition to crystalline phase, revealing the ordered SET phase of IST. These results are assisted by X-ray Photoelectron Spectroscopy (XPS) and Raman spectroscopy findings showing atomic bonding modification upon crystallization. In_2Te_3, InSb, and InTe bonds present in the amorphous IST sample. Annealing of the amorphous sample at 300 °C reveals the phases splitting into crystalline InSb and InTe species having vibration modes associated with TO phonons with Γ_{15} symmetry and B_{1g} symmetry respectively. Further annealing at 400 °C led to the formation of stable cubic In_3SbTe_2 with Γ phonons vibration mode. A PCM device is fabricated using IST as the active layer and W (tungsten) as both bottom and top electrodes. A threshold voltage of 2.94±0.10 V is obtained upon applying a triangular pulse with 0 to 6 V sweep. The device change to conducting state at the threshold voltage and the device current rise sharply around 4.86±0.10 V upon further rising of applied voltage. These experimental results would aid in identifying the essential characteristics of IST phase change material and would be helpful in designing thermally stable, longer data retaining and multi-bit data storage PCM devices.

The Impact of Hyperbonding on the Static and Dynamic Properties of Amorphous Chalcogenides Taehoon Lee[1] and Stephen Elliott[2]; [1]Kyungpook National University, Korea (the Republic of); [2]University of Cambridge, United Kingdom

The spectrum of the application area of amorphous and crystalline chalcogenide materials is very broad. Among others, the phase-change (PC) tellurides are considered an important class of chalcogenide materials due to their unique properties inexplicable within conventional chemical bonding theories. In an effort to understand PC materials, the nature of chemical bonding has been intensively investigated recently. The hyperbonding concept provides a theoretical framework from which the structure and properties of PC chalcogenides can be comprehensively understood. The significance of this theory relies on its capability of establishing the structure-property relationships found in PC materials. In this talk, we extend the applicability of this theory to other amorphous chalcogenide materials, including pure chalcogens, binary, and ternary, alloys. The new concept of hypervalency, proposed based on multi-center hyperbonding theory, enables systematic classification of short-range structural order (or structural building motifs) and offers a theoretical basis for elucidating the static properties of many chalcogenide materials. Their dynamic properties will be also discussed based on the dynamic behaviour of constituting structural building motifs.

Raman Spectroscopy of Quasi-One-Dimensional $NbTe_4$ Weyl Semimetal Nanowires Zahra Ebrahimnatajmalekshah[1], Fariborz Kargar[1], Subhajit Ghosh[1], Sergiy Krylyuk[2], Albert Davydov[2] and Alexander A. Balandin[1]; [1]University of California, Riverside, United States; [2]National Institute of Standards and Technology, United States

Recently a new research field of quasi-one-dimensional (1D) van der Waals quantum materials has emerged from earlier work on low-dimensional systems [1-2]. The quasi-1D van der Waals materials have 1D motifs in their crystal structure [1]. Many of these materials reveal strongly correlated phenomena such as charge density waves (CDW) [1-2]. The CDW phase is a periodic modulation of the electronic charge density, accompanied by distortions in the underlying crystal lattice. Potential uses for CDW materials include memory storage and oscillators [3]. Raman spectroscopy can identify the CDW transitions to different phases via the appearance of phonon peaks due to emerging superstructure or the disappearance of certain peaks due to the loss of translation symmetry in the crystal lattice [3]. In this presentation, we report the results of the angle and temperature-dependent Raman scattering spectroscopy investigation of the mechanically exfoliated nanowires of the quasi-1D Nb van der Waals material. It is known that Nb forms in a tetragonal crystal structure with space group 124 (P4/mcc). Recently, this material attracted attention as a CDW material with multiple phase transitions, some of them, possibly, near room temperature. Little information is known on the Raman characteristics of this material. Our Raman data for different polarization angles show strong anisotropy in the response depending on the crystal direction. The most pronounced Raman peaks reveal strong temperature dependence. The results of the measurements will be compared with the theoretical predictions. Our data is important for further investigation of this quasi-1D CDW material for possible applications in phase-change memory and reconfigurable devices.

Materials Design of OTS Selectors and Phase-Change Materials for 3D Cross-Point Memory Technology Huai-Yu Cheng[1,2], Wei-Chih Chien[1,2], Alexander Grun[1,2], Matthew BrightSky[1,3] and Hsiang-Lan Lung[1,2]; [1]IBM/Macronix PCRAM Joint Project, United States; [2]Macronix International Co., United States; [3]IBM T. J. Watson Research Center, United States

With the increasing demand for high-capacity and high- performance memory, storage class memory (SCM) technology has aimed to fill the gap between storage and memory in the computer storage hierarchy of a modern system. The capability to fast read and write data in SCM is very important for big data analysis and AI applications. However, to boost the memory density, SCM technology requires NVM densely packed in “crosspoint” arrays to achieve $4F^2$

footprint with selecting devices capable of delivering high current and power. In addition, it is possible to integrating a repeating sequence of phase change memory layer and selector layer, achieving a 3D stackable structure increasing dramatically the density of SCM technology. Ovonic Threshold Switching (OTS) material/device show potential to meet all the selector requirements both from electrical and 3D integration point of view.
In the first part of this paper, we will discuss the role that the OTS selector plays in minimizing the leakage current through the many non-selected cells, while also delivering the right voltages and currents to the selected cell. We will focus on how to design OTS materials to meet the selector criteria enabling cross-point memory operation. OTS material based on Te-As-Ge-Si system have been demonstrated for a selector device since 1968 [1] and have been the primarily studied materials. However, insufficient cycling endurance and low thermal stability remains a key hurdle that inhibits these materials to be used in a large cross-point array. Different Ge, Si and As concentrations in Te-As-Ge-Si system [2] are tuned and optimal composition is proposed to reach endurance performance to 10^{11} cycles. However, the high leakage current (I_{OFF}) and high threshold voltage (V_{th}) drift are still the main concerns for TeAsGeSi-based materials. Se- based chalcogenides have demonstrated to be good selectors [3]. The doping effect of B, C, S, Si as well as In dopants into AsSeGe chalcogenide will be systematically discussed [4] where it will be providing the guideline for material engineering of OTS for 3D crosspoint memory.
In the second part of this paper, we will discuss the phase-change materials (PCM) suitable for storage-class memory with fast switching speed and high endurance. We will also focus on the need for researching new PCM material with uniform and stable V_{tS} (system threshold voltage when PCM is in SET state) and V_{tR} (system threshold voltage when PCM is in RESET state) distribution as well as lack of degradation of V_{tS} and V_{tR} memory window during the write cycling operation. The materials design for PCM based on the crosspoint memory specification will be reviewed and discussed, together with the impact that OTS have on PCM materials during programming operation and how it may affect V_{tS} and V_{tR} drift performance [5]. Therefore, it is desirable to find new PCM which can be matched with candidate OTS selector to optimize the 3D crosspoint memory performance.

Darancet[2]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States; [3]University of Illinois Chicago, United States

Computing the electronic properties of amorphous and disordered materials is challenging but of great importance to accelerate the discovery and design of phase change materials for high-efficient in-memory computing. While first-principles calculations based on Density Functional Theory (DFT) have demonstrated the numerical accuracy required for most nanoelectronics applications, amorphous and polycrystalline systems represent a particular challenge due to their heterogeneity and the associated size of their structural approximants. Tight-binding methods offer the scalability required, but rely on their prior parametrization, a complex tax for multivalent and phase changing materials. In this work, we use machine learning to parameterize a tight-binding ansatz for the electronic structure of complex phase change materials. Using the DFT results for small unit cells of single and multivalent GexSbyTez (0< x,y,z<1) alloys, we map the complex atomic configurations to a tight-binding Hamiltonian using an atom-centered basis set and the local overlap matrix. This atomic-configuration-dependent tight-binding Hamiltonian allows us to evaluate the electronic structure of large-scale phase change materials in both crystalline, amorphous, and mixed phases.

Reduction of Switching Current on GeSbTe Through Atomic Local Structure Engineering with Carbon Co-Doping Young Jae Kang[1], Changyup Park[2], Ha-Jun Sung[1], Donggeon Koo[2], Jongbong Park[1], Kiyeon Yang[1], Yongnam Ham[1], Minwoo Choi[1], Bonwon Koo[1], Wooyoung Yang[1], Yongyoung Park[1], Dongho Ahn[2], Kwangmin Park[2] and Chang Seung Lee[1]; [1]Samsung Advanced Institute of Technology, Samsung Electronics, Korea (the Republic of); [2]Semiconductor R&D Center, Samsung Electronics, Korea (the Republic of)

There is high demand for non-volatile memory technologies such as MRAM(magnetic random-access memory), PRAM(phase change random-access memory), RRAM(resistive random-access memory), thanks to high capacity and low power consumption.[1] Among all non-volatile memories, 3D cross-point phase change memory demonstrates long time of data retention, scalable array architecture and low costs, which device consisting of OTS(Ovonic threshold switch) and phase change materials can be switched between amorphous and crystalline phase of chalcogenide.[2,3] Considerable research efforts have been focused on the reduction of switching current and endurance improvement in the next generation of 3D cross-point PRAM device. It can be imagined that phase change properties should be modified by introducing new dopants.
With carbon doping, the reset current of GeSbTe can be reduced with increasing set resistance.[4] In this presentation, we will report the co-doping effects to improve switching current and reliability of GeSbTe. From the ab-initio calculations, we revealed that doped X element can decrease the number of Ge-Ge and Te-Te homopolar bonding. The X-dopant can suppress electron hopping sites, resulted in the set resistance increase of GeSbTe. From experimental works, we show co-substitution in GeSbTe can significantly reduce switching current (~38%) compared to carbon doped GeSbTe. Also, Carbon/X co-doped GeSbTe shows high cycling endurances of 10^6. We found that Carbon/X doped GeSbTe should be promising candidate materials for a next generation of 3D-cross point PRAM device.

An Analytical Approach to Understanding Mushroom-Type Phase Change Memories Stephan Menzel[1,2], Benedikt Kersting[1], Abu Sebastian[1] and Syed Ghazi Sarwat[1]; [1]IBM Research-Zurich, Switzerland; [2]Forschungszentrum Juelich, Germany

Mushroom-type phase change memories have been investigated for memory and computing-in-memory applications due to their non-volatility, good retention properties and compatibility to CMOS processing [1]. Phase change memory device can be programmed to analog resistance states, which makes

the highly interesting for analog computing-in-memory applications. The resistance states are encoded in the shape and size of the amorphous volume within the crystalline phase change material (PCM). The size of this amorphous volume determines further device characteristics such as the threshold voltages, the resistance drift, and the retention characteristics. To capture these properties accurately a suitable model should also contain the information about the size and shape of the phase-configuration. So far, most groups used physical continuum simulations, which accounts for the exact shape. Moreover, often the investigations were limited to large amorphous volumes (i.e the full RESET states). The drawback of this method, however, is the long computation time, which makes it unsuitable for circuit simulation.
In this work, an analytical model is presented for mushroom-type PCM cells that is based on the shape and size of the amorphous mark under different programming conditions. The model is framed for both projecting and non-projecting devices [2]. To this end, analytical equations for the differently shaped amorphous and crystalline regions are derived. One of the main features of the model is the inclusion of a current 'leakage' path which injects the current directly at the outer edge of the heater. It is shown that the model reproduces well the experimental programming curve and drift data of a PCM mushroom cell. The state-dependent drift observed in experiment can be well explained within the model due to the current flowing through amorphous and crystalline regions. The drift coefficient for the amorphous and crystalline regions remains constant. The model accounts also for the asymmetry of the current conduction with respect to voltage [3] and includes the field-dependent conductivity of the amorphous material. To simulate the threshold switching, the resistance model is coupled with two ordinary differential equations describing the temperature in the leaky path and the main current path. To this end, all resistance elements of the model are modeled as temperature dependent. The simulation results show that the initial threshold switching is triggered in the leaky path and then extends to the main current path. The model allows us to simulate the threshold switching behavior and the retention behavior as a function of the phase configuration. For example, the typical trends of the threshold switching such as switching delay, sweep rate-dependence or state dependence can be well reproduced. Our work provides a simple framework for understanding the characteristics of PCM devices and lays the basis for a fully dynamic compact model.

Multiply-accumulate (MAC) operations are at the core of Deep Neural Network (DNN) workloads. In-Memory Computing (IMC) enables hardware accelerators that achieve very high-throughput and energy-efficient MAC, thus tackling the issue of exploding computational costs in ever growing DNNs. In particular, non-volatile memory (NVM)-based analog accelerators materialize massively parallelized compute by leveraging Ohm's law and Kirchhoff's current law on arrays of resistive memory devices. Provided that weights are accurately programmed onto NVM devices and MAC operations are sufficiently linear, competitive end-to-end DNN accuracies can be achieved via this approach.
In this presentation, we describe an analog IMC chip consisting of more than 35 million Phase-Change Memory devices, analog peripheral circuitry, and massive parallel routing to accelerate communication between inputs, outputs, and analog cores. We demonstrate the speed and power advantages of analog computing when applied to multiple DNN inference benchmarks, with tasks ranging from image classification to natural language processing, and show that high accuracy can be retained by a careful combination of materials, circuit, architecture, and operational choices.

Realizing of a Selector Function in Hf-O-Te Amorphous Films with Modified Conduction Mechanism by Adjusting the Te Content Shogo Hatayama, Yuta Saito and Noriyuki Uchida; National Institute of Advanced Industrial Science and Technology, Japan

The non-linear current (*I*)-voltage (*V*) characteristics of an Ovonic threshold switch (OTS) material plays an important role for X-point device architecture. The *I-V* behavior of OTS material is characterized by Poole-Frenkel (PF) conduction and atomic rearrangement originating from chalcogen defects; thus, most OTS materials contain Se and/or Te. To avoid crystallization, in addition to these chalcogen elements, As is usually added to form rigid amorphous networks. However, since As and Se are toxic, the development of As- and Se-free OTS materials is strongly desired. To this end, a new strategy for material development to realize As- and Se-free OTS materials with a comparable or even superior performance should be established. In this work, we aimed to realize a selector function by introducing Te to a HfO_2 to modify the electric conduction mechanism from insulator to PF conduction. The optical and electrical characteristics of Hf–O–Te ternary amorphous films with various Te contents were investigated. The physical properties of the films showed a strong compositional dependence. The optical bandgap was found to be tuned in the range of 0.46–5 eV along with the modification of electrical properties by changing the Te content. The $Hf_{0.24}O_{0.55}Te_{0.21}$ film was revealed to exhibit PF conduction, resulting in a selector function with a selectivity of roughly two orders of magnitude. These results indicate that the inclusion of a heavy chalcogen, such as Te, is effective in altering the conduction mechanism of transition-metal oxides and realizing a selector function. The present findings will pave a way for developing novel As- and Se-free OTS materials [1].

Identification of Structural Phases in Al Doped HfO_2-Based Ferroelectric Films by DFT-Assisted EXAFS Analysis Mehmet A. Sahiner[1], Rory Vander Valk[1], Eric Kurywczak[1], Joshua Steier[1], Stephen Kelty[1], Bruce Ravel[2], Joseph Woicik[2], Jean Jordan-Sweet[3], Christian Lavoie[3] and Martin Frank[3]; [1]Seton Hall Univ, United States; [2]National Institute of Standards and Technology, United States; [3]IBM T.J. Watson Research Center, United States

HfO_2-based ferroelectrics have become important for future applications in CMOS technology such as negative capacitance low-power field effect transistor (FET) logic, FeRAM or FeFET memory, and FeFET- or ferroelectric tunnel junction (FTJ)-based neural network accelerators.
In our previous studies, we have used density-functional theory (DFT)-assisted extended X-ray absorption fine-structure spectroscopy (EXAFS) to identify the crystalline phases in the films of ($Hf_{0.46}Zr_{0.54}O_2$) as grown by atomic layer deposition [1]. In these films, Ferroelectric switching in TiN/$Hf_{0.46}Zr_{0.54}O_2$/TiN metal-insulator-metal capacitors is verified. We confirmed that the frequently invoked polar orthorhombic $Pca2_1$ phase is present in ferroelectric hafnium zirconium oxide, along with an equal amount of the non-polar monoclinic $P2_1/c$ phase. For comparison, we verified that paraelectric HfO_2 films exhibit the $P2_1/c$ phase. In this study we are extending our studies to identify the crystalline phases in Al-doped HfO_2 thin films. We have again used density functional theory (DFT)-assisted extended X-ray absorption fine-structure spectroscopy (EXAFS) to determine the structural symmetry of Al doped HfO_2 thin films. The 8-nm thick HfO2-based films were grown by atomic layer deposition in a metal-insulator-metal (MIM) stack configuration with varying doping levels Al and annealing temperatures. Grazing-incidence fluorescence-yield mode Hf L_3 and Zr K absorption edge EXAFS experiments were performed at the 6-BM beamline at the National Synchrotron Light Source II of Brookhaven National Laboratory. The results of the

EXAFS multiphase fitting and the effect of Al doping levels to crystalline phases will be discussed in conjunction with the electrical properties.

1:30 PM *EL01.04.01

Epitaxial Layered Phase Change Thin Films for Memory and Neuromorphic Applications Hagen Bryja[1], Jürgen Gerlach[1] and Andriy Lotnyk[1,2,3]; [1]Leibniz Institute of Surface Engineering, Germany; [2]Research Institute of Advanced Technologies, Ningbo University, China; [3]College of Physics and Optoelectronic Engineering, Harbin Engineering University, China

Chalcogenide-based phase change alloys are promising materials for optical and electronic memory applications. In this work, we propose to use epitaxial layered 2D-like Sb_2Te_3 thin films for memory and neuromorphic applications [1]. High-quality Sb_2Te_3 thin films were directly deposited on microelectronics-relevant Si(111) substrates by pulsed laser deposition (PLD) using low deposition temperature of 200°C. This offers an industry applicable large-scale method for the fabrication of memory devices, circumventing major challenges in the integration of 2D-like materials. Different top electrode metals were utilized to prepare vertical memory device structures.

The switching characteristics of Sb_2Te_3 -based cells were dependent on the used top electrode metals. The use of Ag and Cu electrodes showed pronounced bipolar memristive switching of memory devices. The devices utilizing Ag top electrode revealed analog programmability, stable multilevel retention, and endurance performance with a memory window larger than one order of magnitude. However, memory devices based on Cu top electrodes led to a memristive switching with smaller memory window and volatility of programmed states. In addition, memory devices with Cu and Ag top electrodes offer forming-free operation and self-compliance. Moreover, detailed structural and chemical characterization indicated diffusion of Ag and Cu into the Sb_2Te_3 thin films, suggesting that charge trapping is involved in the memristive switching mechanism. Overall, this work shows the high potential of epitaxial layered Sb_2Te_3 thin films for non-volatile memory applications, including neuromorphic computing.

Mitigating Analog Memory Non-Idealities for In-Memory Inference and Learning of DNN Valeria Bragaglia, Syed Ghazi Sarwat, P. V. Jonnalagadda, Benedikt Kersting, J. Luchtenveld, Tommaso Stecconi, Donato F. Falcone, Abu Sebastian and Bert Offrein; IBM Research Europe - Zurich, Switzerland

The rapid improvements in hardware accelerators and the availability of large data sets for training AI models have been pivotal for the progress in Deep Neural Networks (DNNs).
GPUs are an excellent match for Deep Learning (DL) workloads due to the high degree of parallelization. Nonetheless, such accelerators must carefully orchestrate the flow of vast amounts of data between on- or off-chip memories and highly-specialized processing units to perform the matrix manipulations at the core of DL. In in-memory analog computing, matrix manipulations are done on arrays of non-volatile memories (NVMs). These operations, that are inherent in the back-propagation algorithm of training models, can be performed at constant time and in parallel on arrays in which the weights are encoded in the NVM elements. Thus, these computations are performed locally avoiding moving weights from memory to the compute unit and back. This, together with the intrinsic high parallelism, created the recent interest for analog computing for DL [1], with the promise to provide further improvement in compute efficiency.
Several memristive technologies are under study for the implementation of neuromorphic hardware, and they rely on diverse physical mechanisms and materials. However, improvements in the device characteristics remains a necessity for optimal hardware acceleration in both performance precision and energy consumption. Device requirements are also dictated by algorithmic considerations, highlighting the multi-dimensional nature of analog accelerator designing.
Phase Change Memories (PCM) and filamentary-based Oxide Resistive RAM (OxReRAM) are the two most promising NVM candidates in neuromorphic hardware [2,3]. Their conductance change, which is directly mapped into synaptic weights, relies on a phase transition in the material for PCM. Instead, the rupture/formation of oxygen vacancies based conductive paths is responsible for the weight update in filamentary-based OxReRAM. Strength and challenges of the two classes of NVMs will be discussed, as well as the innovative design and material stack concepts that lead to enhanced operational characteristics. A discussion on the ideal class of applications for a more efficient use of PCM- or OxReRAM-based synapses will follow.

2:30 PM EL01.04.03

Chemical and Structural Characterization of Programmed Ge-Rich GeSbTe Non-Volatile Memory Cells Antonio M. Mio[1], Stefania M. Privitera[1], Giuseppe D'Arrigo[1], Stefano Cecchi[2,3], Marie-Claire Cyrille[4], Nguyet-Phuong Tran[4] and Raffaella Calarco[5]; [1]CNR-IMM Catania HQ, Italy; [2]Paul-Drude-Institut für Festkörperelektronik, Leibniz-Institut im Forschungsverbund Berlin e.V., Germany; [3]Department of Materials Science, University of Milano-Bicocca, Italy; [4]Leti, CEA, University Grenoble Alpes, France; [5]CNR-IMM Roma, Italy

Phase-Change Materials (PCMs), mainly represented by $(GeTe)_x$-$(Sb_2Te_3)_y$ (GST) alloys, are used for high-density data storage in optical media and for solid-state non-volatile memories. Enrichment of GeSbTe alloys with germanium has been suggested as a suitable approach to increase the crystallization temperature and therefore to improve data retention in high-temperature applications of non-volatile phase change memories, such as embedded or

automotive products. However, the tendency of Ge-rich GeSbTe alloys to decompose with the segregation of Ge still requires investigations on the processes involving element diffusion and compositional alterations both in thin films and devices.
The failure mechanism of phase-change memory devices is strongly related with mass transport occurring during device cycling. Mass transport induces phase separation and segregations and indeed these issues has been reported both in heater-based architectures, like vertical mushroom cells, and in self-heating planar architectures, like line cells.
The mass transport behavior observed in literature depends on the architecture and the programming conditions, but some general trends can be recognised. Therefore, one of the main efforts lies in finding compositional and operational condition such that the cell endurance is increased. To this aim, the structural and chemical analysis of devices after forming and cycling could provide an insight into the degradation mechanism.
In this work we report the behavior of non-confined Ge-rich GST mushroom cells in reset and stuck reset states. In these Single Cell Vehicle (SCV) devices, TiN heaters have been fabricated with a diameter ranging from 50 to 100 nm.
SCV devices has been characterized in terms of structural and chemical properties by High-Angle Annular Dark Field (HAADF) Scanning-Transmission Electron Microscopy (S-TEM), Energy X-ray Dispersive Spectroscopy (EDXS) and Electron Energy Loss Spectroscopy (EELS). The SCV devices were previously formed and programmed in the desired reset state and/or cycled up to 10^6 times and electrical characterized. SCV TEM Lamellae have been obtained by Focused Ion Beam.
The present study shows with high spatial resolution how the forming process modifies the initial elemental distribution.
The RESET stucks, occurring after 10^5-10^6 cycles, seem to obey expected failure mechanisms. In this state, voids are formed on top of the heater, preventing a proper current path between heater and top electrode.

Ge-Rich GST—The PCM Way to Fit Challenges and Requests of the Embedded Market from Automotive to IoT Massimo Borghi; STMicroelectronics SRL, Italy

The embedded market is trying to find a common platform to support the EV cars revolution with the adoption of more sophisticated ADAS features and widespread demand for chips capable to bring AI at the Edge (IoT). In this scenario, Microcontroller Units (MCU) are pushing the limits for embedded Non Volatile Memories (e-NVM) for what concern size, access time and temperature stability. Phase Change Memory (PCM) is one of the most promising technologies to replace State-of-the-art Floating Gate (FG) memories because it can be integrated in the BackEnd-Of-Line (BEOL), it is compatible with high-k/metal-gate (HKMG) process beyond 40nm and it can afford analog programming and single bit alterability which makes it a promising candidate also for IoT devices with onboard Artificial Intelligence (AI). The convergence of automotive and MCU markets about strong automotive data retention requirements and code integrity maintenance after soldering reflow thermal profile, has fostered the activity for material engineering allowing to develop a Ge-rich chalcogenide alloy (Gerich-GST) able to satisfy both. In the first part of the presentation a review of market trends for memory-enabled solutions with focus on PCM based ones will be given while, in the second part, a technical assessment on the achievements of the 3 years long collaboration within the EU funded project (H2020 - BeforeHand) with the aim to develop novel Ge-rich GST (bulk and heterostructures) alloys with reduced material segregation and programming power will be given.

Memristor Behavior in Epitaxial $Cu_{2-x}Se$ Thin Films Becker Sharif, Toyanath Joshi, Anh Nguyen and David Lederman; UCSC, United States

Materials with memristor properties are currently of interest because of their applications in neuromorphic circuitry and resistive switching devices. Memristors are suitable for neuromorphic circuitry due to their low energy consumption, high density, and CMOS compatibility. Additionally, low leakage current and high on-to-off current ratios are essential for efficient devices. Non-stoichiometric copper selenide is a promising material that exhibits the above behavior, where the resistive switching is believed to be attributed to the ionic conductivity of copper ions [1]. We will present the room temperature memory resistive behavior of epitaxially grown $Cu_{2-x}Se$ on Al_2O_3 using Molecular Beam Epitaxy (MBE). The films were characterized using Reflection High Energy Electron Diffraction (RHEED), X-Ray Diffraction (XRD), and Atomic Force Microscopy (AFM). Al interdigitated contacts were used to perform current-voltage (I-V) measurements. The (I-V) measurements showed resistive switching of $Cu_{2-x}Se$ at room temperature with over five orders of magnitude of on-off current ratios.

Density Functional Simulations of Ag Migration in a Conductive Bridging Random Access Memory Cell and Electron Localization Effects in Recrystallized $Ge_2Sb_2Te_5$ Jaakko Akola[1,2], Konstantinos Konstantinou[2] and Robert O. Jones[3]; [1]Norwegian University of Science and Technology, Norway; [2]Tampere University, Finland; [3]Forschungszentrum Jülich GmbH, Germany

We have performed density functional/molecular dynamics (DF/MD) simulations to investigate the drift of Ag atoms in an amorphous GeS_2 solid-state electrolyte between Ag and Pt electrodes in the presence of a finite electric field [1]. The atomistic model structure represents a conductive bridging random access memory (CBRAM) device, where the electric field induces the formation of conductive filaments across the chalcogenide. Simulations of a 1019-atom structure under an external electrostatic potential of 0.20 eV/Angst. at 480 and 680 K show significant atomic diffusion within 500 ps. Ag migration and the formation of percolating filaments occur in both cases. The electronic structure analysis of selected snapshots shows that dissolved Ag atoms become markedly cationic, which changes when Ag clusters form at the Pt electrode. The electrolyte does not conduct, despite percolating single-atom Ag wire segments. Sulfur becomes anionic during the migration as a result of Ag-S bonding, and the effect is most pronounced near the active (Ag) electrode. The formation of conductive filaments requires a percolating network of Ag clusters to grow from the Pt interface, and the weakest link of this network appers to be at the Ag electrode.

We also presents result for our latest electronic structure analysis of recrystallized $Ge_2Sb_2Te_5$ model systems based on our prior DF/MD simulations [2]. Understanding the relation between the structural disorder in the atomic geometry of the recrystallized state of PCMs and the localized states in the electronic structure is essential for fundamental understanding. Hybrid density-functional theory simulations are employed to ascertain the impact of antisite defects on the spatial localization of the electronic states in the bottom of the conduction band in recrystallized models of $Ge_2Sb_2Te_5$. Te−Te homopolar bonds are the local defective atomic environments mainly responsible for the electron localization of the conduction-band-edge states in the simulated structures, while Sb−Te chains can also induce spatial localization. Unoccupied defect-related electronic states can emerge in the band gap during a crystallization event, while Sb−Sb homopolar bonds have been identified in the defect environment of a deep localized state [3]. These findings are in accordance with the latest results for recrystallized model systems of $Ge_1Sb_2Te_4$ in Ref. [4]

Beyond CMOS Sensory Neuron Devices Based on Vanadium Dioxide for In-Sensory Computing Stefania Carapezzi[1], Aida Todri-Sanial[1,2] and Gabriele Boschetto[1]; [1]LIRMM, University of Montpellier, CNRS, France; [2]Eindhoven University of Technology, Netherlands

The Internet of Things (IoT) is projected to become an hyper-linked system with 30.9 billion of connected devices by 2025. A game-changer step for IoT further evolution will be represented by the development of smart objects that are context- and self-aware, with ability to “self-assemble” in smart units. In this respect, IoT sensory nodes are the key elements to embed ambient-awareness in IoT. Currently, IoT sensory nodes are an ensemble of four basic units, each one dedicated to a specific role: one for sensing, one for processing, the other two for transceiving signals and power supply. The stimuli incoming from the ambient are the inputs of the sensing module, whose output are unorganized data to be fed into processing module. The physical separation between sensing and processing units is the bottleneck for the performance of sensory systems, especially given the present deluge of sensory data that need to be analyzed. Thus, novel approaches are required to enhance the efficiency of IoT sensory nodes.

Recently, the in-sensor computing approach has gained the spot-light from both academic and industrial research, which consists into realizing the integration of sensing and computing functions into a single element. Indeed, this corresponds to mimic the elements of nervous system dedicated to sensory transduction of environmental information, the sensory neurons. In sensory neuron devices the response characteristics becomes not linear, and the thorough understanding of the physical mechanisms which connect the ambient input to the device output is key to control their response characteristics. In the present work, we explore the implementation of a sensory neuron device based on vanadium dioxide (VO_2) volatile memristor. Since the temperature triggers a volatile resistive switching in VO_2, volatile memristors can be fabricated as two-terminal VO_2 devices, where Joule effect is responsible for the resistance change of VO_2 channel. It is possible to fabricate compact and scalable relaxation oscillators [1] by inserting VO_2 volatile memristors into a simple RC circuits, which model the oscillations behavior of biologic neurons. We avail of a dedicated technology computer-aided design (TCAD) approach [2 - 4] to perform 3D electrothermal simulations of VO_2 neuron oscillators. We simulate the modulation behavior of the external temperature over the output of such devices, and thus we unravel the physical mechanism behind the temperature sensing of VO_2 neuron device. The insight we gain from our TCAD simulation is primordial to fully exploit the VO_2 sensory neurons.

Acknowledgments. Authors wish to thank Dr. S. Karg, IBM Research Europe, Zurich, Switzerland, for providing the experimental data used for the calibration of the TCAD model and the useful discussions about the experimental devices. Authors also wish to thank Dr. A. Nejim and Dr. A. Plews, of Silvaco Europe Ltd., Cambridgeshire, United Kingdom, for providing the customized version of PCM model [2] used to simulate the VO_2 material as well as for the useful discussions about the TCAD and mixed mode simulations.

4:30 PM EL01.04.08

Preliminary Study of Phase-Change Superlattices via Thin-Film Nanocalorimetry Jie Zhao[1], Asir Intisar Khan[2], Mikhail Y. Efremov[3], Zichao Ye[1], Xiangjin Wu[2], H.S. Philip Wong[2], Eric Pop[2,2] and Leslie H. Allen[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Stanford University, United States; [3]University of Wisconsin—Madison, United States

Phase transitions involving both stable and metastable phases in superlattices (SLs) are the underlying driving forces for the operation of SL-based phase-change memory (PCM) devices. These SL stacks with nanometer-thin sublayers have been proven promising for low-power PCM. Measuring bulk thermodynamic properties is typically done with calorimetry techniques. However, PCM samples are extremely thin (~65 nm), making them inaccessible for most calorimetry methods that require large sample size (>1,000 nm).

Therefore, we use thin-film Nanocalorimetry [1, 2] to probe thermal effects in the as-deposited SLs directly (TiN-capped, all deposited by the same process as functional PCM devices). This unique method allows us to investigate the sample in its natural form of thin-film SL stacks (strain, grain size, and stoichiometry) as in SL-based PCM device. Nanocalorimetry is capable of scanning rates up to 3,000,000 K/s for 1−60 nm thick samples and has quantitatively revealed the Arrhenius crystallization kinetics of 20 nm thick $Ge_2Sb_2Te_5$ in our recent work [3].

Here, we probe the phase transition of 65 nm thick $Sb_2Te_3/Ge_2Sb_2Te_5$ superlattices [4-6] using Nanocalorimetry. Our preliminary measurements quantitatively characterize the heat capacity of the SL samples in a broad temperature range (room temperature - 650 ºC) and reveal several thermal effects that could be classified as glass-to-liquid and melting phase transitions. These thermodynamic properties could provide insights into the low-power switching of the SL-based PCM and thus advancing our understanding of SLs for use in the next generation of energy-efficient data storage devices on rigid and flexible platforms.

5:00 PM EL01.05.02

Study of Chalcogenide Based Ovonic Threshold Switch Device from the Perspective of Thermal Analysis JuHwan Park[1], Myeong Jun Jung[1], Gun Hwan Kim[2], Min Kyu Yang[3], Dustin Kendig[4], Mohammad Shakouri[4] and Byung Joon Choi[1]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of); [3]Sahmyook University, Korea (the Republic of); [4]Microsanj, United States

Chalcogenide-based ovonic threshold switch (OTS) devices that exhibit volatile resistive switching depending on the external electrical field are being studied as the selector to solve the sneak path current issue. During repetitive switching, joule heating can occur, and such thermal effect may induce degradation of the devices. Also, the operation of the OTS device is not clearly understood, especially at elevated temperatures. To understand the relationship between volatile electronic switching and thermal effects, thermoreflectance (TR) imaging microscopy analysis was conducted.
In this study, we used TR imaging microscopy to observe the thermal image and real temperature during electrical operation using a Microsanj SanjSCOPE™ Transient Thermal Imaging System . A LED light source is injected onto the devices while an electrical bias is applied. After the CMOS camera captures the reflected light, the temperature is evaluated by comparing the change in reflectivity. For this analysis, $GeTe_x$ and Se- doped GeTe (SGT) based OTS devices which show superior threshold switching characteristics were fabricated on a Pt bottom electrode. A TiN metal layer was deposited on a chalcogenide thin film to see the thermal boundary resistance between the metal and chalcogenide-based material. A Au metal layer was deposited on the TiN metal layer as a photothermal transducer layer due to its stability and high thermoreflectance coefficient value. As a result of in situ TR imaging analysis, the temperature during operation and localized volatile resistive switching characteristics were observed, which has not been well characterized before. In addition, time-domain thermoreflectance (TDTR) analysis was also conducted by using Transometer™ (TMX Scientific Inc., US). When a heating pulse is applied to the thin film, thermal decay of thermoreflectance over time is observed while applying the probing pulse continuously. From this analysis, the thermal conductivity and thermal boundary resistance of the film stack can be calculated. Thermal conductivities of $GeTe_x$ films deposited under various conditions were compared to analyze their thermal effects. With multiphysics simulation, we try to understand the elevated temperature and furthermore, its effect on the OTS devices.

5:00 PM EL01.05.03

In-Operando Transmission Electron Microscopy Studies on Diffusion Induced Phenomena at the Dielectric-Electrode Interfaces in Ge_2Te_3-Based Memristor Devices Krishnamurthy Mahalingam[1,2], Austin Shallcross[2], Cynthia Bowers[1], Sabyasachi Ganguli[2], Eunsung Shin[3] and Guru Subramanyam[3]; [1]UES, Inc., United States; [2]U.S. Air Force Research Laboratory, United States; [3]University of Dayton, United States

The memristor is a two-terminal device derived from materials that exhibit resistance switching, wherein the resistance of the material is tunable by an applied electric field. This switching process is reversible, and is also non-volatile, so that the change in resistance is maintained for a long period of time even after the applied field is removed. A wide variety of materials are currently being investigated depending on microstructural mechanisms that triggers the switching process, such as those based on defect migration and phase transformation. Independent of the actual mechanism that drives this switching process, the dielectric-electrode interface plays a significant role in determining device properties and performance. In particular, maintaining interface chemistry and morphology during actual operation is critical to realizing devices with higher switching speed, lower power consumption, and higher endurance. Recent advancements in transmission electron microscopy makes it possible for examining interfacial phenomena in such devices in-operando at high spatial resolution and sensitivity.
In this contribution we perform an in-operando cross-sectional TEM study to investigate microstructural phenomena that control the integrity of the dielectric-electrode interface in Ge_2Te_3-based phase change materials. For the purposes of this study we have examined device structures: Pt/ Ge_2Te_3 (50 nm)/Ti/Pt, grown on (100)-Si substrates. Specifically we employ Z-contrast STEM imaging in combination with X-ray energy dispersive spectroscopy (XEDS) to examine the effect of Ti which is widely used as an adhesion layer prior to the deposition of electrode layer atop the dielectric (Ge_2Te_3) layer. Detailed examination of XEDS results upon electrical biasing clear reveal a deleterious effect of Ti, characterized by in-diffusion of Ti to form a reactive telluride layer and out-diffusion of Ge, resulting in its enrichment at beneath the top Pt electrode. Further studies under systematic electrical biasing and heating conditions reveal that this diffusion process can be significant, leading to progressive degradation of the dielectric-electrode interface. Additional studies aimed at combating this process will be presented. Furthermore, the role of residual surface oxide layer generated during the device fabrication process will also be discussed.

SESSION EL01.06: Nanophotonic Phase Change Devices

Session Chairs: Harish Bhaskaran, Wolfram Pernice and Carlos Ríos
Thursday Morning, April 13, 2023
Moscone West, Level 3, Room 3001

8:30 AM EL01.06.01

Rapid Discovery, Development, and Integration of Visible-Frequency Materials with Metavalent Bonding Mark Polking[1], Kevin Tibbetts[1], Steven Vitale[1], Juejun Hu[2] and Christopher Roberts[1]; [1]MIT Lincoln Laboratory, United States; [2]Massachusetts Institute of Technology, United States

Materials that exhibit metavalent bonding character have emerged as a promising avenue to dynamically reconfigurable and tunable nanophotonic devices. Conventional materials with metavalent bonding, however, are typically narrow-gap chalcogenides with high free carrier densities, limiting their utility for practical photonic integrated circuits and metamaterials requiring low insertion losses and operation in the visible-NIR frequency band. In this presentation, a new approach to rapid discovery, development, and integration of materials with metavalent bonding character and high optical transparency in the visible-NIR range will be described. This approach begins with a new method for prediction of metavalent bonding character based on consideration of the contributions of individual atomic/ionic species to the overall refractive index. Simple calculations based on this method enable accurate predictions of the refractive indices of crystalline materials lacking metavalent bonding and of the amorphous phases of known phase-change materials. First-principles theory calculations of the electron localization function (ELF), charge density, and Born effective charges for promising materials revealed by the initial screening protocol revealed new families of materials, including binary IV-VI chalcogenides and group III, IV, and V-halide materials, with substantial metavalent bonding character and band gaps as large as 2.6 eV. Preliminary experimental measurements of amorphous and crystalline samples of several of these materials indicate index amorphous-crystalline index contrast values of 0.3-1.1 and low optical losses. This presentation will further describe recent developments in the scalable fabrication of integrated photonic components and metasurfaces using these novel high-frequency metavalent materials at the

200 mm wafer scale. Specifically, selenide-containing phase-change materials such as $Ge_2Sb_2Se_4Te_1$ and Sb_2Se_3 have been integrated with silicon photonic devices such as Mach-Zender interferometers and ring resonators. These allow non-volatile reconfigurability of photonic integrated circuits for practical applications such as switch matrices, optical communications, and photonic quantum computing.

8:45 AM *EL01.06.02
Measuring the Dynamic Thermal Response in Electrically Programmable Phase Change Photonics Nicholas Nobile[1], John R. Erickson[1], Carlos Ríos[2,2], Yifei Zhang[3], Steven Vitale[4], Juejun Hu[3], Feng Xiong[1] and Nathan Youngblood[1]; [1]University of Pittsburgh, United States; [2]University of Maryland, United States; [3]Massachusetts Institute of Technology, United States; [4]Lincoln Laboratory, MIT, United States

Phase-change materials (PCMs)—such as $Ge_2Sb_2Te_5$ (GST), $Ge_2Sb_2Se_4Te_1$ (GSST), Sb_2Se_3, and others—show great potential for next generation reconfigurable photonic circuits, in-memory computing platforms, and tunable metasurfaces. This is made possible by high speed, high contrast, and nonvolatile changes in the refractive index of these materials, making them suitable for applications requiring optical memory or tunability. In the past, the majority of experimental works have demonstrated bistable switching between the amorphous and crystalline states of PCMs using either optical pulses or thermal annealing on a hot plate, which has limited scalability for real-world applications. Thus, integrated approaches are needed which enable electrical switching of areas much larger than the optical wavelength.

Here, we present methods for the design and characterization of foundry-compatible on-chip microheaters for electrically programmable phase-change photonic devices. In the first part of this talk, computational modeling approaches will be applied to various microheater designs (i.e., metallic, resistive, and diode-based silicon microheaters) and insights for optimizing switching speed and energy efficiency will be presented. In the second part of this talk, recent experimental work on optically mapping the dynamic thermal response of these microheaters will be presented and compared with our computational models. Our complementary experimental and computational approach allows us to model and validate the fast heating and cooling dynamics of fabricated devices with diffraction-limited resolution—a crucial step towards optimizing the energy efficiency and operation speed of electrically reconfigurable phase-change photonics.

Integration of Optical Phase Change Materials in On-Chip Silicon Photonic Devices Sharon M. Weiss and Richard Haglund; Vanderbilt Univ, United States

Advances in silicon photonics have contributed to faster data transfer speeds in data centers and other application areas. However, in order to further increase data rates to meet the demand for higher-capacity data communication systems, alternative solutions are needed. A hybrid structure consisting of a silicon photonic backbone and an incorporated optical phase change material (O-PCM) may provide a solution for realizing broadband, low power, small footprint photonic devices capable of achieving record switching speeds. In this presentation, we discuss theoretical and experimental work integrating O-PCMs in silicon photonic devices, including sub-picosecond optical switching using a hybrid silicon-vanadium dioxide waveguide and a lower power, higher extinction ratio optical switch based on a hybrid silicon-vanadium dioxide subwavelength engineered photonic crystal.

On-Chip Wavelength-Selective and Non-Volatile Reconfigurability in a Single Photonic Element June Sang Lee[1], Nikolaos Farmakidis[1], Samarth Aggarwal[1], Wen Zhou[1], Wolfram Pernice[2] and Harish Bhaskaran[1]; [1]Oxford University, United Kingdom; [2]Universität Heidelberg, Germany

The functionality of photonic circuits relies on their ability to process multiplexed information in wavelength, polarization and phase. While optical signals can carry such multidimensional information, independent modulation of multi-wavelength signals in a single carrier has been challenging. Here, we demonstrate independent and non-volatile modulation of wavelength-multiplexed optical signals within a single photonic element. Our chips rely on the formation of standing wave patterns in a microring resonator which can be individually addressed according to their mode number (i.e. wavelength). By combining this concept with phase-changing nanoantennas, we demonstrate for the first time non-volatile, wavelength-selective modulation. This allows realizing an on-chip, reconfigurable and multi-spectral filter operating within a single element. This novel approach provides a pathway for exploring additional degrees-of-freedom in tunable photonic networks and provides a compact photonic framework for optical storage, routing, and neuromorphic/in-memory computing.

Theoretical and Experimental Studies of Metal-based Phase Change Materials toward Optical and Terahertz Applications Kotaro Makino[1], Yuta Saito[1], Shogo Hatayama[1], Masashi Kuwahara[1], Hitoshi kawashima[1] and Paul Fons[1,2]; [1]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [2]Keio University, Japan

Optical applications based on phase change materials (PCMs), that exhibit a significant change in optical properties upon non-volatile amorphous-crystalline phase change, have attracted a lot of attention. The optical response of a material is governed by the complex index of refraction, namely the refractive index (real part) and the extinction coefficient (imaginary part). Recently, Sb_2S_3, Sb_2Se_3 and $Ge_2Sb_2Se_4Te_1$ have been reported to be suitable for low-loss optical phase shifter and plasmonic devices because these materials have a wider band gap [1-3], namely a smaller extinction coefficient than the conventionally used material $Ge_2Sb_2Te_5$ (GST), although GST is still useful for some applications utilizing absorption change and mid-infrared applications [4]. In this sense, PCMs with a wide band gap and a significant change in refractive index upon phase change are highly desirable for efficient optical device applications.
In this work, we focused on the optical properties of PCMs composed of transition metal and chalcogenides such as MnTe and other compounds. We carried out first principles calculations to evaluate the corresponding electronic and optical properties. By using Vienna Ab initio Simulation Package (VASP), we obtained the complex index of refraction for both the crystalline and amorphous phases of PCMs. The amorphous structures were obtained via melt–quench ab initio molecular dynamics simulations (AIMD). We also carried out spectroscopic ellipsometry measurements and terahertz (THz) time-domain spectroscopy for sputter-deposited thin films. It was found that the transition metal-inclusive PCMs are promising for terahertz and 6G telecommunication technology as well as optical applications such as optical switches and program optical resonators.
Part of this presentation is on the result obtained from the commissioned research (03701) by National Institute of Information and Communications Technology (NICT), JAPAN.

The ability to reconfigure the optical behavior of a device enables many applications ranging from imaging to sensing and signal control. Such optical devices can be compacted via meta-surfaces, patterned structures with feature sizes below the incident wavelength. Leveraging geometry in addition to material properties and CMOS fabrication techniques has allowed meta-surfaces to operate as lenses, holograms, beam steerers, and more. To incorporate multiple optical functions into one device, various methods of device control have been implemented such as stretching of flexible substrates, tuning the refractive index of the comprising meta-atoms via the electro-optic or the thermo-optic effects, phase transition materials such as VO_2, and more. Chalcogenide glasses used as optical phase change materials, such as $Ge_2Sb_2Te_5$ (GST), have gained increased traction in the optics community for potential use in the NIR and MIR, including the telecom bands. Various chalcogenides such as Sb_2Se_3, Sb_2S_3, $Ge_2Sb_2Se_5$, and $Ge_2Sb_2Se_4Te$ (GSST) have been investigated due to their broad NIR or MIR transparency window and large changes in refractive index. In their amorphous phase, these materials usually display a lower refractive index & low absorption when compared to their crystalline state which displays a higher refractive index and typically larger extinction coefficients. The amorphous-crystalline reversible switching can be done on-chip via fast melt-quenching processes triggered by laser heating or electrical impulses, which rely on a substrate as a heat sink. The potential of PCMs in photonic devices can be limited by intrinsic material limitations as well as by device fabrication issues. To explore the cyclability of GSST, a PCM with large refractive index contrast, on-chip electrothermal switching on a silicon-on-insulator platform has been done to analyze potential failure mechanisms from both a material and device perspective. A brief outline of the instrumentation and phase change contrast analysis is provided. Dewetting of the PCM, delamination of and damage to the PECVD SiN_x protective layer, elemental migration in the PCM, and optical contrast decay have been observed in cycled GSST devices. Guidelines for device performance improvement are proposed and an improved design with greater endurance is shown in this work.

11:00 AM EL01.06.08

Antimony as a Tuneable Element in Integrated Photonics Samarth Aggarwal[1], Tara Milne[1], Nikolaos Farmakidis[1], Johannes Feldmann[1], Xuan Li[1], Yu Shu[1,2], Zengguang Cheng[1,3], Martin Salinga[4], Wolfram Pernice[5,2] and Harish Bhaskaran[1]; [1]University of Oxford, United Kingdom; [2]Kirchhoff-Institute for Physics, Germany; [3]State Key Laboratory of ASIC and System, China; [4]Universität Münster, Germany; [5]University of Münster, Germany

Over past decade there has been a surge in interest for reconfigurable photonic. A number of ways of achieving such reconfigurability have been explored including using heaters exploiting thermo-optic effect , electro-optic devices based on $LiNbO_3$ substrate , charge injection based modulators and phase change materials (PCMs) . Unlike other methods of reconfigurability PCMs like GST and AIST are non-volatile , resulting in low system energy requirements. Besides reconfigurability, phase change materials have also found their application in non-volatile optical switches and for in-memory computing.

Conventional PCMs like GST and AIST are ternary and quaternary alloys with special elemental compositions. Small deviation in elemental composition can result in degradation of device performance. However controlling the composition of alloys is quite challenging and maintaining the composition uniformity over large area has limited the commercial use of conventional phase change materials. Another drawback of using such alloys is of phase segregation. PCMs undergo multiple thermal cycling and this results in elemental segregation at grain boundaries and therefore resulting in variation of alloy composition and hence a degraded device performance. These issues can be circumvented by use of a single element phase change material.

Here we demonstrate the use of elemental antimony as a memory element in integrated photonic[1]. We show a thin film of Sb with thickness under 5 nm can be reversibly switched between amorphous and crystalline phase using femtosecond pulses. We then show a binary memory operation with energy as low as 190 pJ. Further we show multilevel memory operation , similar to conventional PCM like GST , by varying switching pulse energy from 120-230 pJ to achieve intermediate amorphous states. We demonstrate up to 7 memory levels equivalent to 3 bit memory operation. Further using pump probe technique we investigate the switching speed of our antimony based photonic memory. We observe a switching speed of 500 MHz therefore showcasing ultrafast device speed. Next we explore tuneable volatile property of our memory cell. By varying probing and switching energy we study the memory retention time for potential applications ranging from all photonic neurons to leaky integrators for computing.

Phase Change NEMS - A New Paradigm for Phase Change Materials in Nanomechanics Harish Bhaskaran; University of Oxford, United Kingdom

Phase change materials have been widely used in optical discs, electronic memories and more recently in emerging optoelectronic applications such as displays and neuromorphic photonic computing. Yet, in spite of the widespread use of these materials, the change in their mechanical properties had not yet been exploited. In this talk, I shall present recent work on the use of phase change nanowires in mechanical tuning applications - both electronic and photonic, showing that in the unique nanowire configuration, these devices present extraordinary quality factors and tunability.

Superlattice Chalcogenides for Low-Power Memory and Neuromorphic Computing Asir Intisar Khan, Xiangjin Wu, Alwin Daus, Sumaiya Wahid and Eric Pop; Stanford University, United States

Phase change memory (PCM) technology could play an important role in future high-density computing systems, including neuromorphic computing. However, PCM based on traditional chalcogenides like $Ge_2Sb_2Te_5$ (GST) requires relatively large power consumption and suffers from resistance drift [1]. This talk will address our recent efforts to tackle these challenges using various types of superlattice PCM (SL-PCM) materials, made of alternating ultrathin (~nm) layered chalcogenides. From a device perspective, we have demonstrated memory with superlattices based both on GeTe/Sb_2Te_3 [2] and GST/Sb_2Te_3 [3,4], showing up to ~10x lower reset current density and 10x lower resistance drift than control GST PCM with the same mushroom cell structure. We uncovered that the quality of the interfaces within the SL plays an important role in the memory behavior [3,4]; in other words, more good-quality interfaces means better thermal and structural confinement, but interfacial intermixing degrades the drift coefficient. Given that thermal confinement plays such an important role in low-power behavior, we also demonstrated SL-PCM with the lowest switching current density to date (~0.1 MA/cm^2) on flexible polyimide substrates, which have ultralow thermal conductivity [5]. Importantly, all our SL-PCM devices show multiple resistance states and scalability with the bottom electrode diameter, offering further promise in ultra-scaled devices.
From a materials perspective, extensive transmission electron microscopy (TEM) revealed van der Waals (vdW)-like interfaces in the superlattices, which facilitate the electro-thermal and structural confinement [2-4]. We found lower cross-plane thermal conductivity and higher electrical anisotropy of the polycrystalline SL stack compared with polycrystalline GST, due to the internal interfaces within the SL [6]. We also explored lateral transport in chalcogenide films and multilayers, measuring good Hall mobilities for GeTe/Sb_2Te_3 superlattices (~18 cm^{2}V^{-1}s^{-1}), 2–3x higher than the other films [7]. These results provide key insights towards new superlattice material design and optimization, and could pave the way to high-density storage and neuromorphic applications using superlattice PCM materials.

Defect Engineering in VO_2 Thin Films via He^+ Irradiation Rebeca M. Gurrola[1], Adelaide Bradicich[1], Ryan M. Schoell[2], Khalid Hattar[2], John M. Cain[2], Tzu-Ming Lu[2], Timothy D. Brown[3], A. A. Talin[3], Matt Pharr[1] and Patrick Shamberger[1]; [1]Texas A&M University, United States; [2]Sandia National Laboratories-NM, United States; [3]Sandia National Laboratories-CA, United States

Vanadium dioxide is a desirable material for neuromorphic computing applications due to its nonlinear electrical transport properties. These are the result of a metal-insulator transition (MIT) that can be accompanied by up to a four orders of magnitude change in electrical conductivity. At ~68°C, the MIT is coupled with a structural phase transition (SPT) as VO_2 transforms from an insulting monoclinic phase to a metallic rutile phase. In order to utilize VO_2 as a dynamically controllable material, it is critical to understand how to control 1) the electrical conductivities of two phases, and 2) aspects of the structural transition itself, including the extent of phase coexistence. Previous research has attempted to alter the MIT by use of chemical dopants that either decrease the MIT transition temperature, such as W and Mo, or increase the transition temperature, such as Ge [1-2]. Irradiation has also been used to modify MIT behavior, primarily by creating vacancy and interstitial defects that in turn alter the phase transition behavior [3-4]. Finally, the use of different substrates to grow highly oriented VO_2, notably Al_2O_3 and TiO_2 single crystal substrates, has been shown to shift the transition temperature as low as 35°C and as high as 80°C due to the resulting anisotropic compression/tension on the c-axis of VO_2 [5-6]. However, less research has focused on the intersection of strain and defects caused by irradiation.
The goal of this research is to establish the effect of defects caused by irradiation on the MIT behavior and electrical transport in VO_2 thin films. Polycrystalline VO_2 thin films were grown on SiO_2(100nm)/Si, while epitaxial VO_2 was grown on Al_2O_3 (0001). Photolithography was used to make both 4-terminal and 2-terminal devices at unique crystallographic directions [10-10] for sapphire, due to the six-fold symmetry. To study device switching performance, a range of device widths and lengths were used ranging from 1 to 60 um and 1 to 25 um. These films were irradiated with He+ ions under two distinct energy regimes(10 keV, and 2 MeV), and fluences ranging from 5E13 to 5E16 cm^{-2}. We will describe the conjunction of coupled strain and irradiation defects on the electrical conductivities of the two phases of VO_2, as well as the hysteresis, width of phase transition, and temperature of transition. In this study, VO_2 is shown to be fairly resistant to irradiation and can also be used for rad-hard material applications. This research furthers the exploration of the limits of the metal-insulator transition in VO_2 via nanoscale material manipulation for neuromorphic applications.

Physics of Resistive Switching in $LaCoO_3$ Revealed by X-Ray Absorption Spectromicroscopy Mahnaz Islam[1], Christopher Perez[2,1], Rajashree Bhattacharya[3,4], Sumaiya Wahid[1], Timothy D. Brown[2], Matthew Marcus[5], Hendrik Ohldag[5], Vincent Gambin[3], Suhas Kumar[2] and Eric Pop[1]; [1]Stanford University, United States; [2]Sandia National Laboratories, United States; [3]Northrop Grumman Corporation, United States; [4]University of California, Los Angeles, United States; [5]Lawrence Berkeley National Laboratory, United States

Insulator-metal-transition (IMT) oxides exhibiting volatile resistance switching upon electrical excitation are intensely studied for applications as selectors in nonvolatile memory, radio-frequency switches, electrostatic discharge clamps, etc. [1, 2]. Popular IMT oxides such as VO_2 and NbO_2 exhibit an abrupt reduction in resistance, driven by a Mott transition, when their temperature exceeds a threshold value. This threshold temperature is too low for VO_2 (~340 K) and too high for NbO_2 (~1100 K) to be suitable for commercial electronics. When localized Joule heating is used to drive the IMT by applying a current, the abrupt change in resistance also leads to large dynamical current and local temperature overshoots, causing device damage. Such limitations inspire the need for IMT materials beyond Mott insulators for use in commercial electronics.
In this work, we study $LaCoO_3$ (LCO), which undergoes a gradual thermally-driven IMT between 350-650 K, induced by an electron-spin-state transition, thus offering favorable on-chip operating temperatures [3, 4]. Crystalline 49-106 nm thick LCO films were epitaxially grown on (100) $LaAlO_3$ substrates at 973 K by DC sputtering of metal La and Co targets. Two-terminal lateral devices with LCO channels of lengths 2-8 μm and widths 4-15 μm with Pd (20 nm)/Au (80 nm) electrodes were lithographically defined. We find that, despite the gradual thermally-driven IMT, LCO exhibits a sharp and abrupt

electrically-driven volatile resistive switching upon increasing voltage bias, enabled by the non-linearity in its resistance-temperature property. Upon increasing current bias, we also find a region of current-controlled negative differential resistance (NDR), underlying the voltage-driven resistive switching characteristics.

We perform *in-situ* scanning transmission X-ray microscopy (STXM) at the oxygen K edge on two-terminal LCO devices under increasing bias, to study the evolution in the X-ray absorption features arising from an electrically-driven IMT. For this study, polycrystalline LCO deposited on thin SiN_x membranes was biased with Pd electrodes at increasing current levels, chosen to measure spectra below, within, and above the start of the NDR, as identified from the *I-V* measurements. We observe creation of t_{2g} states within the bandgap, evident by the gradual shift in spectral intensity from 529.6 (unoccupied e_g states) to 528.7 eV (unoccupied t_{2g} states), with increasing bias levels that were large enough to put the device in the NDR region. Spectra measured for low bias levels below the NDR region did not show such changes and were identical to spectra without applied bias. For comparison, we also perform STXM on ambient-temperature-controlled LCO thin films, which exhibit identical spectral changes compared to bias-driven measurements. These changes are consistent with a distinct low to high electron-spin-state transition in the Co^{3+} ion, as reported for a thermally-driven IMT in bulk LCO [4].

In summary, we show an electrically-driven abrupt transition in LCO utilizing the non-linearity in its resistance-temperature behavior. We measure volatile spectral changes during volatile electrical switching in LCO, consistent with thermally-driven low to high spin-state transition in the Co^{3+} ion. Our work introduces LCO as a suitable on-chip and energy-efficient electrical switching material.

This work was supported in part by the Stanford Graduate Fellowship (M.I., S.W.), the Stanford SystemX Alliance and by Lab. directed R&D at Sandia Labs under DE-NA0003525.

Epitaxial VO_2 on Si 100 via TiN Buffer Layer for CMOS Applications Rama Satya S. Ventrapragada, Arvind S. Rajnarayan, Yeswanth Pattipati, Sandeep Vura and Sushobhan Avasthi; Indian Institute of Science, India

Vanadium oxide (VO_2) exhibits an insulator-to-metal (IMT) transition at 68 °C from a low-temperature insulating phase ($P2_1/c$) to a high-temperature metallic phase ($P4_2/mnm$). The optical or electrical excitation can trigger the IMT resulting in an abrupt change in resistance ($x10^4$) of VO_2. Due to IMT, VO_2 is used in bolometers, electro-optic modulators, and infrared photodetectors [1]. VO_2 films are grown on single crystalline substrates like Al_2O_3, which severely limits its applications. Integrating epitaxial VO_2 films on Si (100) (complementary metal-oxide-semiconductor) platform enables integrated electro-optic devices and temperature sensors. Moreover, preserving the symmetry of the substrate in some form would pave the way for integrating further oxides epitaxially on top of the VO_2 film. Yun et al.[2] had seen superior performance of UV detector by integrating ZnO on VO_2. The formation of amorphous SiO_2 at the VO_2/Si interface limits its heteroepitaxial integration on Si (100). An epitaxial TiN interlayer layer deposited by reactive pulsed laser deposition (RPLD) [3] is introduced between Si and VO_2 to overcome the same. This work focuses on the growth, crystallography, and IMT characteristics of VO_2/TiN/Si.

Epitaxial VO_2 films on TiN buffered Si is achieved through pulsed laser deposition (PLD) using a V_2O_5 target in oxygen ambient. The deposition pressure is finely tuned to find the narrow growth window for the VO_2 phase [4]. Dual-stage growth is employed, in which an initial few layers (2-5 nm) of deposition at low pressure is followed by high-pressure deposition. The VO_2 film growth is monitored in situ using reflection high energy electron diffraction (RHEED) and shows clear diffraction spots confirming the epitaxial growth of VO_2 on TiN/Si. The VO_2 films grow on TiN/Si in a 3D growth mode in which islands of films nucleate and merge to form continuous films. The high-resolution X-ray diffraction (HRXRD) pattern shows only VO_2 (011) and (022) peaks which indicate the films are phase pure with (011) orientation in the out-of-plane. The symmetric rocking curve FWHM is 1.8°, which reveals the mosaic nature of the films in the out-of-plane direction. For (200) VO_2 Bragg condition, 8-Bragg reflections were seen, vs. (111) TiN 4-Bragg reflections in the merged pole figure of TiN(111) and VO_2(200), suggesting the presence of in-plane rotation variants [5]. Temperature-dependent XRD and electrical measurements were done to confirm IMT behavior. A comprehensive study on the epitaxial orientation relationship between these variants investigated by X-ray diffraction and electron microscopy (HREM and SAED) and IMT characteristics will be discussed at the conference.

3:45 PM EL01.08.04
Phase Change Materials from the Thermal Point of View Nele Harnack, Pengyan Wen, Olivier Maher, Siegfried Karg and Bernd Gotsmann; IBM Research Europe - Zurich, Switzerland

Materials with a structural phase transition are interesting as emerging devices for neuromorphic and in-memory computing. Most prominent are non-volatile phase-change memory devices (PCMs) based on chalcogenides that utilize a transition between amorphous and crystalline states. Persistent states with different resistance are set by controlling the relation between heat generation and dissipation. In contrast, materials with an insulator-to-metal transition (IMT) exhibit a structural phase change upon heating but return to the original state when cooling back to room temperature. This behaviour can be exploited for oscillators rather than memories. As an example, VO_2 transitions from a monoclinic to a rutile crystalline structure accompanied by a resistance change of up to 5 orders of magnitude.

Processes in these materials are inherently tied to temperature changes and thermal transport. In PCMs, the (re)crystallization is driven by Joule heating to a certain temperature and subsequent (slow) cooling, leading to a stark change in resistance. In VO_2, the IMT can be induced by temperature rise due to self-heating in the highly resistive state, which is highly non-uniform due to inhomogeneities of the material. The complex interplay between resistive heating, heat spreading, and the thermal phase-transition correlated with a strong change of resistance makes investigation challenging. Current filaments that form are similar to resistive oxide memories.

Thermal imaging can elucidate the thermal processes in resistance switching devices. A valuable characterization technique for this task is Scanning Thermal Microscopy (SThM) due to its high spatial and temperature resolution. Moreover, it can image original devices in-operando and give quantitative values in a non-destructive, non-interfering manner. The SThM method determines the local temperature by measuring the heat flow between the device and an AFM-like cantilever with an integrated heating and sensing element [1]. We have developed and advanced the SThM method for devices with non-linear and volatile characteristics and applied it to various applications.
For example, we were able to quantify local temperature distributions caused by heat-dissipating current filaments at sub-10 nm resolution in VO_2 and resistive RAM devices in different voltage-dependent states. It was found that the form and position of the current filament in a lateral, polycrystalline VO_2 device varies when the voltage is changed to switch between insulating and metallic state. This explains the undesirable varying oscillator characteristics during operation and suggests the development of new device designs. The temperature of vertical resistive RAM elements was imaged through the top electrode, revealing the position of a current filament which stays stable during cycling and does not change when switching between high and low resistive state. The dimension of the filament and the heat spreading radius can be estimated from the thermal image, which can be utilized to determine the minimum device size and the maximum packing density of those memories.
In conclusion, the thermal imaging method developed here can be used to map the temperature distribution in a variety of devices during their operation, including those showing volatile and non-volatile switching. The interpretation of the resulting temperature maps can reveal thermal processes and guide design decisions and fabrication processes.

The Time Scale of Metal-Insulator Transitions by Electrostatic Gating in a Solid-State Three-Terminal VO_2 Device Satoshi Hamasuna, Satya Prakash Pati and Takeaki Yajima; Kyushu University, Japan

Vanadium dioxide (VO_2) exhibits a metal-insulator transition (MIT) above room temperature and the electrical resistivity of VO_2 abruptly changes by three orders of magnitude. At room temperature, this transition can be easily triggered by Joule heating, and therefore, various VO_2-based applications have been proposed including analog crossbar switches, oscillator networks, and neuromorphic computing [1]. The transition is induced not only by temperature change but also by electron doping, and its static characteristics have been studied in detail over many years [2]. On the other hand, its transient characteristics are not yet fully understood. The major challenge is the difficulty to control fast and precisely the temperature that causes the transition at the transition temperature (T_{MIT}). Although the transient characteristics were partially elucidated in laser-induced transition [3] and Joule heat-induced transition [4], the high nonequilibrium nature of laser-induced electronic excitation or the thermal runaway in conductive filaments makes the situation more complicated. Our research group has recently developed a solid-state electrostatic gating device that causes MIT by electron accumulation via high-permittivity titanium dioxide (TiO_2) gate dielectric [5,6]. Although the modulation is relatively small, this device has the potential to control the MIT with high speed and precision, being ideal for investigating the transient characteristics. In this study, we exploited this solid-state gating device to systematically investigate the transient characteristics of the MIT in the VO_2 channel. We found that the transition occurs in the time scale of several ten milliseconds, and this time scale is exponentially shortened by increasing the gate voltage. When the influence of the gate voltage is converted to the equivalent temperature effect, we found the transition speed is accelerated by three orders of magnitude per 1 K. These results provide the underlying physics for the high-speed operations of VO_2-based devices and enable further applications of this material to neuromorphic and other functionalities.
Epitaxial VO_2 films (7 nm) were grown on the Nb (0.05 wt.%) doped TiO_2 substrate and were patterned by photolithography. The fabricated device is a three-terminal device consisting of the substrate as the gate electrode, VO_2 film as the channel (35 μm × 50 μm), and the depletion layer formed inside the doped TiO_2 substrate as the gate insulation layer [5]. The VO_2 channel of the device showed an abrupt resistance change around 309 K. Next, the drain voltage of the three-terminal device was fixed at 0.1 V, a pulse voltage was applied to the gate terminal at the temperature slightly below T_{MIT}, and the time variation of the source current was measured. The measurement results showed that the transition was induced by the applied gate voltage and the speed of the transition can be enhanced up to three orders of magnitude by changing the gate voltage from 1 V to 5 V. When the electron accumulation effect due to gate voltage converted to the equivalent temperature effect, the speed of the transition can be enhanced up to three orders of magnitude per 1 K. The origin of this high-speed transition is attributed to the collective nature of the domain growth during MIT. These results provide the underlying physics for the high-speed operations of VO_2-based devices and enable further applications of this material to neuromorphic and other functionalities. [1] B. Y. Phase-Change Memristive Materials for Physically Unclonable Anticounterfeiting Devices Shao Xiang Go[1], Qiang Wang[1], Kian Guan Lim[1], Tae Hoon Lee[2], Natasa Bajalovic[1] and Desmond K. Loke[1]; [1]Singapore University of Technology and Design, Singapore; [2]University of Cambridge, United Kingdom

Anticounterfeiting devices driven by physical unclonable functions (PUFs), as one of the emerging tools against counterfeiting, are easy to create but challenging to replicate due to intrinsic randomness. Phase-change memristive materials show large degree of randomness suitable for high performance and down-scalable PUF devices. Herein, we demonstrate the utilization of high-degree-of-randomness amorphous (A) state variations concomitant with different operating conditions via thermal fluctuation phenomena, together with a hybrid framework for in memory computing and next generation security primitive, i.e., A PUF, for attaining secure key generation and device authentication. Rapid crystallization process enables large-size key reconfigurability in A-PUF, while in-memory computing empowers a strong eXclusiveOR (XOR-) and-repeat A PUF construction to avoid machine learning attacks. Near ideal uniformity and uniqueness without additional initial writing overheads in weak memristive A-PUF is achieved. These PUF devices could provide a potential system to realize unbreakable anticounterfeiting.

Atomic-Scale Characterizations of Phase Transitions in Ge-Sb-Te Alloys Wei Zhang; Xi'an Jiaotong University, China

Tailoring the degree of structural disorder in Ge-Sb-Te alloys is important for the development of non-volatile phase-change memory and neuro-inspired computing. In this talk, I will present the atomic-level details of the multi-fold structural transitions, including crystallization, amorphization, vacancy ordering/disordering induced crystal-crystal transitions, in Ge-Sb-Te alloys by in situ high-resolution transmission electron microscopy experiments and ab initio density functional theory calculations. The impact of atomic ordering on altering the electronic and optical properties of Ge-Sb-Te alloys will be discussed in detail, which is relevant to practical applications. At last, I will also discuss the challenges and progress on atomistic modelling of Ge-Sb-Te alloys at the device scale. References: [1] T.-T. Jiang, X.-D. Wang, J.-J. Wang, H.-Y. Zhang, L. Lu, C. Reversible Optical Switch of Sb2S3 Thin Films for Tunable Nanophotonic Applications Capucine Laprais[1,2], Lotfi Berguiga[1,3], Nicolas Baboux[1,3], Guillaume Saint Girons[1,2] and Sébastien Cueff[1,2]; [1]Institut des nanotechnologie de Lyon, France; [2]Ecole Centrale Lyon, France; [3]INSA Lyon, France

Phase change materials (PCM) have emerged as a promising solution for developing active nanophotonic devices. The reversible and significant change in the optical properties of their amorphous and crystalline state can enable multi-functionality and reconfigurability of the devices. Additionally, PCM exhibit a rapid (ns) and non-volatile phase transition between their amorphous and crystalline state allowing for low energy consumption [1]. Low loss PCM specifically have been a subject of increasing interest in the photonic community as their extinction coefficient nearly vanishes in the near infrared for both phases. Sb_2S_3 is one of this emerging PCM presenting exciting properties: above 780 nm it has no absorption in neither phase while its refractive index contrast remains significant ($\Delta n=1$) [2]. This makes Sb_2S_3 interesting for novel tunable nanophotonic applications in the visible and near infrared regime. However, this material is not well known yet when it comes to its switching properties, chemical stability, endurance, etc. There are also some integration issues to address, especially to control the phase switching mechanisms at the device level [3].

In this work, we use optical switching to induce the phase transition in Sb_2S_3: by properly choosing the laser pulse duration and energy it is possible to locally crystallise or amorphise the PCM. We show that we can reversibly switch Sb_2S_3 thin films from the crystalline to the amorphous phase using a pulsed laser. With a laser fluency lower than the ones reported in the literature [4][5], we successfully switched different thin films thicknesses of Sb_2S_3 deposited by ebeam evaporation on various substrates. We could also achieve partial amorphisation in the depth of the PCM, which is promising for multi-states switching. Here, we discuss the physical mechanisms behind the laser-induced change of phase using multi-physics considerations to draw conclusions on potential optimizations of the reversible phase switching of Sb_2S_3. This should lead to a full control of the multi-level optical switch of Sb_2S_3, and show promise in using this material for rewriting optical devices multiple times, encoding multi state information in the depth of the PCM, designing holograms,...

Multistate phase transition and polymorph stability through interface engineering in vanadium dioxide system Ujjwal Chitnis[1], Sooraj Kumar[1], Syed A. Bukhari[2], Ram K. Ghosh[3] and Ankur Goswami[1]; [1]Indian Institute of Technology, Delhi, India; [2]National Research Council of Canada, Canada; [3]Indraprastha Institute of Information Technology, Delhi, India

Transition metal oxide systems are notably known for their phase transition behaviour, of which vanadium dioxide (VO_2) has gained prominence due to its reversible metal-insulator transition (MIT) at critical temperature (T_c) of 340 K by change in its electrical, optical, structural and thermal properties. The structural transition, occurs from the initial monoclinic (M1) polymorph to the final rutile (R), through a metastable monoclinic (M2) polymorph. Both M1 and R have caught the most attention due to their easy synthesis and MIT behaviour but other metastable polymorphs like VO_2 (A), VO_2 (B), VO_2 (T), VO_2 (P), etc, also exists, which are challenging to stabilize around room temperature ranges. Achieving reduction in T_c with multiple polymorphs near room temperature will facilitate application of VO_2 in resistive switching, reconfigurable memory, frequency controlled and neuromorphic devices[1-3]. As the devices are subjected to heating during any operation, it can potentially lead to thermal throttling, noise signals, and energy losses in any electrical system, leading to reduction in the device efficiency and limiting the application of VO_2 in low power devices and computing units. To overcome this challenge, unique out-of-plane device architecture along with interface engineering can contribute to modification of structural and electronic properties by reducing the transition temperature much closer to room temperature. Through this work, focus on highlighting the effect of titanium dioxide (TiO_2) interface in modifying the microstructural and electrical properties of VO_2 system is presented. Thin films gown by pulsed laser deposition (PLD)[4] are investigated for device application due to uniform surface morphology[5]. Reduction in T_c due to interface misfit strain and modified carrier behaviour is observed. Electrical measurement across the TiO_2 interface uncovers stable multistage phase transition which is then confirmed using spectroscopy techniques that indicate presence of polymorphs and phases like M1, R, M2, T and V_2O_3, etc in the system. Surface topological measurement using KPFM indicates interface driven work function change which possibly leads to stabilization of metastable polymorphs like M2, T and other phases. Further, DFT calculations were performed incorporating misfit strain which reveals a decrease in Tc, much closer to the room temperature value. Thus, through selecting a suitable device architecture and interface engineering, VO_2 devices can be tuned to achieve higher efficiency for applications in reconfigurable memory, computation units and multistate devices.

Improving VO_2 Granular Films' CMOS Compatibility to Perform Oscillation-Based Computing Olivier Maher, Nele Harnack, Roy Bernini, Bernd Gotsmann and Siegfried Karg; IBM Zurich, Switzerland

Olivier Maher, Nele Harnack, Roy Bernini, Bernd Gotsmann, Siegfried Karg
IBM Research GmbH-Zurich Research Laboratory, Säumerstrasse 4, 8803 Rüschlikon, Switzerland

The growing interest in polycrystalline phase-change materials to develop brain-inspired learning and novel computing approaches makes VO_2 a first-choice material, with its ability to switch from a high to a low resistive state around room temperature (68°C). Natural oscillations triggered by running a current through this material are offering the means to fabricate electronic oscillators that once coupled, create an oscillating neural network (ONN), best suited to compute pattern recognition tasks and solve optimization problems [1, 2, 3]. This type of network shows the promise of energy-efficient computing by processing data locally while avoiding issues related to the different frequency operations from the memory access to the processor's calculation times [1, 3, 4]. Improving CMOS compatibility with pristine material quality and a highly reliable fabrication process to produce uniform devices is paramount for industrial purposes [5, 6].
The integration of VO_2 layers on a Si-based platform typically results in polycrystalline films presenting granular structures with a rugged surface topology [5]. This introduces undesired variability among our electrical oscillators that needs to be reduced to a minimum before their integration in a compound circuit, such as our ONN [6]. To minimize device-to-device variations, VO_2-based oscillators in planar and crossbar configurations have been fabricated. The devices excel in high-frequency operation and power efficiency.
A 50 nm thick Vanadium oxide film is deposited by a water-based ALD reaction on a $Si/SiO_2/HfO_2$ substrate for CMOS compatibility. A post-annealing step is required to turn the amorphous film into a crystalline VO_2 layer. We use two different annealing techniques which vary in steepness of temperature ramps and oxygen pressure to obtain reproducible behavior in our devices. The impact of the different annealing methods on the grain size, the surface roughness, the electric behavior, and the quality of the resulting VO_2 film are studied through Raman Spectroscopy, Atomic Force Microscopy (AFM), and by measuring the resistance of the film as a function of temperature. The devices are then placed in a circuit to measure the resulting natural oscillations before being coupled with one another. The power efficiency and the oscillation frequency could be significantly improved by device scaling and optimizations.
Our network of VO_2-based oscillators shows the promise of an attractive and scalable computing unit for hardware accelerators [3, 4], thanks to its high-performance switching properties and CMOS compatibility.
This project has received funding from the EU's Horizon 2020 program under projects No 871501 (NeurONN) and No 861153 (MANIC).

9:20 AM EL01.09.06
High Temperature Phase Change Materials Nacer Ibaroudene, Md. Khirul Anam and Ethan Ahn; The University of Texas at San Antonio, United States

Chalcogenide thin films that exhibit a reversible transition between crystalline and amorphous phases has been the important material platform for data storage and emerging neuromorphic computing applications. For the past decades, a wide variety of phase change alloys, including GST ($Ge_2Sb_2Te_5$) – the most commonly used for phase change memory, have been studied in a general effort of increasing the speed performance or energy efficiency of modern electronics and computing hardware. However, the (semiconductor) chip shortage is still one of the biggest challenges in the nation, and in particular, a high temperature application domain has strong demands for novel scientific and engineering approaches to develop materials of the highest reliability and stability. For example, the use of high temperature electronics (operating at above 125 °C) continues to grow in an automotive industry, and thus, heat-resistive metals, plastics, and semiconductors need to be further researched and developed. Phase change materials are identified as an essential semiconducting component of high temperature electronics for data storage, sensing, and energy harvesting and conversion.

Here in this work, we performed a systematic study on phase change materials for far-reaching applications in the high temperature domain. It has been understood that GeSb possesses the high potential to become the next-generation platform for high temperature electronics due to its relatively high crystallization temperature (T_C). We synthesized 50 nm-thick $Ge_{14}Sb_{86}$ thin films by using the RF sputtering technique, and carefully measured the resistivity vs. temperature characteristics. It is found that T_C of our $Ge_{14}Sb_{86}$ thin film reaches the value as high as 230 °C, which is in good agreement with the literature. This is best attributed to the growth-driven crystallization kinetics of GeSb (i.e., crystallization tends to start occurring at the crystalline-amorphous interfaces). However, it still remains unanswered if GeSb can satisfy the multiple requirements of contemporary high temperature electronics because a holistic study that further investigates GeSb beyond its high T_C is still missing. For example, GeSb is known for relatively slow (SET) switching speed, and the topic of enhancing the switching speed of GeSb while still affording the high T_C remains unexplored. Therefore, our work is expected to greatly advance the field by exploring the performance of GeSb in multiple aspects, including the crystallization temperature, crystallization (SET switching) speed, data retention, and reliability.

It is highlighted that our experimental approach is based around the idea that doping is key to best engineer the phase change materials and find the optimal balance among properties desired for high temperature applications. In this work, we fabricated a wide variety of phase change materials such as (undoped) GeSb, Ti-doped GeSb, and Al-doped GeSb, and found that Al-doped GeSb achieves the T_C value of greater than 230 °C, excellent data retention (10-year data retention @ around 140 °C), and switching speed of a few tens of nanoseconds at a moderate amount of current applied. We're currently investigating the effect of other dopants as well, such as Hf and Ta, while performing comparative studies and analyses with reference samples that consist of undoped or doped conventional GST thin films. Therefore, our study features a holistic approach to investigate both phase change materials of GST and GeSb that are either undoped or doped by various transition metal elements in terms of high temperature application-specific performance criteria.

Development of Robust Perovskite Solar Cells Using Interfacial Materials Lee Yih Wang[1], Hsin-Hsiang Huang[1], Hsinhan Tsai[2,3], Rathinam Raja[1], King-Fu Lin[1], Wanyi Nie[2] and Sergei Tretiak[2]; [1]National Taiwan University, Taiwan; [2]Los Alamos National Laboratory, United States; [3]University of California, Berkeley, United States

The power conversion efficiency (PCE) of perovskite solar cells (PSCs) has risen rapidly from 3.8% to a certified 25.7%. However, their relatively short operational lifetime remains a critical hurdle for commercialization. Herein, we present two simple ways to enhance the environmental stability of PSCs. In the first approach, a tiny amount (0.01 wt%) of exfoliated montmorillonite (*ex*MMT) was incorporated into the perovskite precursor solution and these *ex*MMT nanoplates were able to self-organize into an ultra-dense top layer with a thickness of around 50 nm and strongly bonded to the perovskite crystalline grains through cationic exchange with organic cations during the spin-drying process. Such self-assembled layer acted as an effective protection shell that retarded the penetration of gases and moisture into the perovskite during environmental aging, achieving extremely stable photovoltaic cells against moisture, thermal and photo stresses. The thus prepared unencapsulated devices exhibited exceptionally steady PCE, which showed negligible degradation after 4680 h of storage in 50% relative humidity and room temperature. In the second route, a fluorine-containing fullerene adduct (5F-PCBP) was introduced to replace PCBM as an electron-transporting layer (ETL) to establish PSCs that delivered an excellent PCE of 21.27%. The fluorinated ETL not only increased the surface hydrophobicity but also filled the surface iodine vacancy and immobilized the ion migration, thus protecting the solar devices against harsh environment. As a result, The CsFAMA perovskite solar devices with 5F-PCBP ETL without physical encapsulation exhibited a T_{80} over 1920 hours under industrial relevant conditions i.e., relative humidity of 85% and heat stress at 85°C.

2:00 PM *EL02.01.02
Heterointerface and Intragrain Microstructures of Perovskite Semiconductors Yuanyuan Zhou; Hong Kong Baptist University, China

Heterointerface and intragrain microstructures can be key factors influencing performance of perovskite semiconductors, which have been less studied. In my talk, I will discuss our recent advances on the high-resolution characterization and novel tailoring of these microstructures, advancing our fundamental understanding of microscopic structure-property-performance relationship in perovskites. Specifically, I will first illustrate several unique structural designs of perovskite heterointerfaces (interpenetrating, elastic, or de-doped) which mitigate the major issues of perovskite solar cells in different device setting. Then, I will discuss on leveraging a novel scanning transmission electron microscopy methodology to unravel performance-limiting intragrain interfaces in perovskite solar cells.

2:30 PM EL02.01.03
Engineering the Wettability Problem of SAMs Hole Transport Layers for Highly Efficient Sn/Pb- Perovskite Solar Cells Matteo Pitaro[1], Javier S. Alonso[1], Jane Kardula[1], Lorenzo Di Mario[1], karolina Tran[1], Malin B. Johansson[2], Erik Johansson[2], Ryan Chiechi[3] and Maria Antonietta Loi[1]; [1]University of Groningen, Netherlands; [2]Uppsala University, Sweden; [3]NC State university, United States

Mixed tin-lead perovskite materials are the most promising option to reduce Pb content in hybrid perovskite solar cells (HPSC) and to tune the band gap towards the near infrared. Recently, self-assembled monolayer of (2-(9H-carbazol-9-yl)ethyl)phosphonic acid (2PACz) have been reported as alternative candidates to poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT: PSS) as hole transporting material (HTL).[1] However, the adoption of 2PACz as HTL opens challenges for the deposition of the perovskite active layer in a reproducible manner, due to the poor wettability of the perovskite precursor solution on carbazole group. Here we demonstrate that by depositing an additional interlayer, which exposes polar groups, between the carbazole-based monolayers and the perovskite active layer the wettability problem can be solved, opening to the use of carbazole-based molecules HTL for large area devices.
We implemented Br-2PACz molecules as HTL, and as interlayer we synthetized 9H-Carbazole-9-butane-1-ammonium iodide ($4NH_3CzI$). We expect that the two carbazole groups, one from Br-2PACz and the other from $4NH_3CzI$ will interact through a π-π stacking giving rise to a surface of exposed ammonium groups, which drastically improves the wettability for the $Cs_{0.25}FA_{0.75}Sn_{0.5}Pb_{0.5}I_3$ precursor solution.
Solar cells with Br-2PACz and $4NH_3CzI$ acting as HTL showed an efficiency of 19.45% for 0.04 cm^2 active area devices (while 19.25% was obtained without the interlayer. The interesting result is the improved reproducibility of the double-layer HTL compared to Br-2PACz. In fact, the Br-2PACz- based solar cells present an average value on 20 devices of 9.65 ± 9.62% with several not working solar cells due to a poor substrate coverage for the perovskite layer. On the contrary, the solar cells with the double-layer HTL present an average PCE of 18.98 ± 0.28%.
While this is a record efficiency for this perovskite composition, the most important result is the in the area scaling of the efficiency. Devices of 0.8 cm^2 area fabricated with the two-layer HTL showed an efficiency of 12.5%, while the ones using only Br-2PACz where not working. Finally, the two-layer HTL has also a strong effect on the stability under continuous 1.5 AM solar illumination. Devices maintain 80% of the initial efficiency after 365 hours respect to the 230 hours reached by the Br-2PACz-only.

2:45 PM EL02.01.04
2D/3D Heterostructures with Conjugated Organic Cations for Stable and Efficient Perovskite Solar Cells Jiaonan Sun and Ke Ma; Purdue University, United States

Surface passivation is proven an effective way to enhance the efficiency and stability of perovskite solar cells (PSCs). However, a key challenge faced by most of the passivation strategies is reducing the interface charge recombination without imposing energy barriers to charge extraction. Herein, a series of novel semiconducting organic ammonium cations were designed as interface modifiers between the light-harvesting perovskite film and the hole transporting layer. We show that the conjugated cations can directly extract holes from perovskite efficiently. Together with delicate energy level tuning and stabilized interface in devices, we demonstrate a FAPbI3 based triple cation perovskite solar cell with an excellent power conversion efficiency of 23.64%, and the suppressed ion migration and halide phase segregation, which lead to a long-term thermal stability over 2000 hours and light stability over 500 hours. Our strategy provides a new practical method of interface engineering in perovskite solar cells towards improved efficiency and stability.

Halide Perovskite Direct X-Ray Detector with an Extremely Low Dark Current via Interfacial Engineering Ganbaatar Tumen-Ulzii, Oliver Moseley, Tiarnan Doherty, Miguel Anaya and Samuel D. Stranks; University of Cambridge, United Kingdom

X-ray detection technology has been developed and frequently used for medical imaging diagnostics, security inspection and scientific research areas. In a scintillator-type detector, a semiconducting material is excited by a probing X-ray and emits ultraviolet-visible (UV-Vis) light into a photodetector, which in-turn outputs an electrical signal and, ultimately, forms an image. However, this technology suffers from strong self-absorption and afterglow emission leading to a blurred image.[1]
In contrast, X-ray direct detectors which convert X-ray photons into electric charges have a superior resolution than scintillators and are more efficient since they don't suffer from optical losses. However, current commercial solutions (e.g. amorphous Se) are not suitable for high-energy X-ray applications such as computed tomography (CT) for cancer detection because of their low atomic number (Z). Recent innovations based on Cadmium Telluride (CdTe) or Cadmium Zinc Telluride (CZT) semiconductors with high Z are promising for high-energy CT relevant X-rays. However substantial challenges in the fabrication and deployment of the active layer material have limited their widespread adoption. For instance, high-quality CdTe crystals take 3 months of high-temperature growth to fabricate at a cost in excess of \$1500 per cm^3.
Recently, halide perovskite (PVK) materials have emerged as promising materials for direct X-ray detection, already demonstrating excellent mobility-lifetime products (μτ) comparable to CZT and CdTe, detector-grade bulk resistivity, and high stopping power at high-energy X-rays.[2] To date, high sensitivity up to 10^6 μC Gy_{air} cm^{-2} and a very impressive lowest detectable dose rate (LoD) of <10 nGy s^{-1} have been achieved.[3] However, the dark current is still large >1 nA cm^{-2} which is one of the main obstacles to commercialising PVK X-ray direct detection technology. One of the origins of the large dark current is related to the interface defects at the PVK material and charge transport layers in the device stack.

In this talk, we present a high-performing, direct X-ray detector with a device structure based on an alloyed perovskite single crystals synthesized via a state-of-the-art inverse temperature crystallisation (ITC) method. We introduce the use of a fluoride-based buffer layer to attain control over the device's dark current to reach an impressive low dark current of ~10 pA cm^{-2}. This value establishes a new record, 10x lower than conventional CZT and CdTe direct detectors. Furthermore, the detector showed a clear X-ray-induced current and the LoD of 167 nGy s^{-1}. This study will open a new direction for PVK X-ray detectors with extremely low dark current towards integration with application-specific integrated circuit (ASIC) chips/backplanes for multi-pixel detection.

Implications of Dynamic vs. Static 2D/3D Halide Perovskite Interfaces on Solar Cell Stability Alan Kaplan, Xiaoming Zhao, Quinn C. Burlingame and Lynn Loo; Princeton University, United States

Employing a 2D perovskite or ammonium-halide salt passivation layer is a promising method to improve the stability and efficiency of halide perovskite solar cells (PSC). Recent work has revealed that the initial structure of this passivation layer may evolve during PSC aging, depending on the identity of the halide salt employed. Our work has indicated that the nature of the organic ligands that form the 2D perovskite passivation layer can also impact the operation stability of the resulting solar cells. Specific to this investigation, we have examined the structural evolution of several 2D/3D perovskite interfaces comprising different organic ligands using ex-situ photoluminescence and x-ray diffraction measurements. We found the 2D/3D perovskite interface to be "dynamic" when mono-functional ammonium ligands, i.e., butylammonium and 4-fluorophenethylammonium, are used to form the 2D perovskite layers atop the 3D perovskite, as the structure of the 2D perovskite layers evolve substantially during aging. Replacing the mono-functional ammonium ligands with a bifunctional diammonium ligand, i.e., 1,4-butanediamine, instead results in a "static" interface in which the structure of the 2D perovskite layer remains stable during aging. Given the chemical difference in the organic ligands, we ascribe the difference in stability of these 2D/3D perovskite interfaces to the extent of binding the organic ligands have with their adjacent inorganic layers within the 2D perovskites, with a greater extent of binding enhancing the structural stability of the interface.

4:00 PM EL02.02.04
Rational Design of Photoelectrochemical Perovskite-BiVO$_4$ Tandem Devices for Scalable Solar Fuel Production Virgil Andrei[1,1], Geani M. Ucoski[1], Robert Jagt[1], Chanon Pornrungroj[1], Demetra S. Achilleos[1], Katarzyna Sokol[1], Judith MacManus-Driscoll[1], Robert Hoye[2], Richard Friend[1] and Erwin Reisner[1]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom

Metal halide perovskites have emerged as promising alternatives to commonly employed light absorbers for solar fuel synthesis, enabling unassisted photoelectrochemical (PEC) water splitting[1,3] and CO_2 reduction to syngas.[2,4] While the bare perovskite light absorber is rapidly degraded by moisture, recent developments in the device structure have led to substantial advances in the device stability. Here, we give an overview of the latest progress in perovskite PEC devices, introducing design principles to improve their performance and reliability. For this purpose, we will discuss the role of charge selective layers in increasing the device photocurrent and photovoltage, by fine-tuning the band alignment and enabling efficient charge separation. A further beneficial effect of hydrophobicity is revealed by comparing devices with different hole transport layers (HTLs).[1,3] On the manufacturing side, we will provide new insights into how appropriate encapsulation techniques can extend the device lifetime to a few days under operation in aqueous media.[1,2] To this end, we replace low melting alloys with graphite epoxy paste as a conductive, hydrophobic and low-cost encapsulant.[3,5] The combined advantages of these approaches are demonstrated in a perovskite-BiVO$_4$ tandem device archiving selective unassisted CO_2 reduction to syngas.[4] These design principles are successfully applied to an underexplored BiOI light absorber, increasing the photocathode stability towards hydrogen evolution from minutes to months.[6] Finally, we take a glance at the next steps required for scalable solar fuels production, showcasing our latest progress in terms of device manufacturing. A suitable choice of materials can decrease the device cost tenfold and expand the device functionality.[7] Such materials are compatible with large-scale, automated fabrication processes, which present the most potential towards future real-world applications.[8]

4:15 PM EL02.02.05
Photoelectrochemical Water-Splitting Device Based on a Halide Perovskite Solar Cell Protected by a Single Crystal TiO$_2$ Choongman Moon, Jaehyuk Koh and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Photoelectrochemical (PEC) water splitting is a renewable way to produce hydrogen by introducing electrocatalysts on the surface of photovoltaic materials. Compared to a system electrically connecting separate photovoltaic and electrochemical devices, PEC has a simpler structure because it can remove peripheral components (e.g. Ag metal grid or power electronics) and it may lead to a significant reduction in system cost and efficiency loss. However, one of the greatest challenges in PEC is that light-absorbing materials are in contact with (or in the vicinity of) electrolytes, and it would cause severe damage to the light-absorbing materials. This issue becomes more serious when it comes to a halide perovskite light absorber. The halide perovskite solar cell is an emerging photovoltaic material with great potential, however, because of its instability when in contact with water or oxygen, PEC devices forming a solid-liquid junction between halide perovskites and electrolytes have been showing poor stabilities. A typical approach to protect a PEC device is depositing a protection layer with a tens or hundreds nanometer thickness over the light-absorbing materials, however, a protection layer completely impermeable to an electrolyte has not been demonstrated yet. Furthermore, processing for protection layer deposition often requires a high temperature, which is not applicable to thermally vulnerable halide perovskite materials. For these reasons, PEC devices based on halide perovskites have been showing

only several hours of device lifetime.
In this study, we improve the stability of a perovskite PEC device by transferring a single crystal TiO_2 wafer (1cmX1cm) onto a halide perovskite cell. In order to form an ohmic contact on a TiO_2 wafer, indium tin oxide (ITO) was deposited on one side, while the other side was decorated with Pt for catalyzing hydrogen evolution reaction. The TiO_2 wafer was transferred onto a halide perovskite solar cell by bridging the perovskite cell and ITO contact with a transparent conductive adhesive, which is prepared by embedding Ag particles into paraffin. The PEC device showed an open circuit potential of ~1.1 V and short-circuit current density of ~14 mA/cm^2, and was able to operate for ~2 days without degradation in current density.

Understanding and Realising Stable Perovskite Optoelectronic Device Operation Samuel D. Stranks; University of Cambridge, United Kingdom

The efficiency of halide perovskite optoelectronic devices including solar cells and LEDs continue to rise, yet operational stability remains a challenge. Here, I will outline recent developments towards understanding and realising stable perovskite device operation in both solar cell and LED platforms on different length scales. I will show a variety of multimodal operando microscopy measurements to understand device degradation, realising generalised understanding of instability pathways. I will show how material and contact optimisation and passivation leads to greatly increased device stability, opening up pathways to realise long-term stability.

11:00 AM *EL02.03.02
Chalcogenide Molecule-Based Interface Passivation for Enhancing the Stability of Perovskite Solar Cells Lydia H. Wong; Nanyang Technological University, Singapore

Over the last decade, perovskite solar cell (PSC) has emerged as very promising future-generation solar cell technology with a power conversion efficiency (PCE) of over 25%. However, the long-term stability of PSC still remains a barrier to its commercialization. For improving the stability of the PSC different classes of defect passivators have been investigated [1-3]. Among them, Lewis base-based passivators have been shown to be particularly effective owing to their ability to passivate various Pb^{2+} and Pb^0 related defects. Nonetheless, there is a lack of clear understanding regarding the defect passivation mechanism of these Lewis bases, resultantly, the predictability of the passivation strength of different Lewis base molecules is poor. This creates a challenge in selecting the superior passivator molecules among the plethora of options that are available.
In this talk, I will speak about our group's effort to understand the comparative interface passivation strength among different chalcogenide-based defect passivators. In our recent work, we use three different organic passivators (of similar structure) decorated with different chalcogenide atoms, (O, S, and Se) to study their effect on the stability of the devices. We observe that the sulfide and selenide passivated devices show superior stability compared to both un-passivated and oxide-passivated ones. This excellent stability with the sulfide and selenide passivators is most likely due to their strong interaction with the Pb cation, which can be explained using the hard-soft-acid-base principle. By taking the idea forward, we have used Al-doped CuS (Al-CuS) as sulfur-based inorganic hole transport layers (HTL) in inverted architecture PSC [1]. Al-CuS HTL-based devices show superior stability compared to NiO HTL-based control devices. After 650 hours of storage (at 30% RH, 20 °C), sulfide HTL-based devices retain more than 60% of their initial stability. In contrast, their oxide counterparts retain less than 40% of their original value in the same timeframe.

11:30 AM EL02.03.03
Chelation with Polydentate Ligands for Effective Passivation of Pb-related Defects Towards Stable and Efficient Perovskite Solar Cells Seongheon Kim[1], Seong Ho Cho[1], Kiwan Jeong[2], Jieun Lee[1], Yonghoon Jung[1], Mansoo Choi[1,2] and Yunseog Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Global Frontier Center for Multiscale Energy Systems, Korea (the Republic of)

Organic-inorganic hybrid perovskite based solar cells (PSC) have shown tremendous progress in photovoltaic performance demonstrating a record power conversion efficiency (PCE) over 25%. However, attaining long-term stability under operation conditions is still challenging issue for commercialization. The key factor to achieve long-term stability as well as high PCE is to synthesize high-quality perovskite thin-films which can be represented by a lower defect density. In particular, Pb-related defects such as Pb clusters and uncoordinated Pb^{2+} ions are reported to accelerate the degradation of the devices. To mitigate the defect-induced degradation, various passivation strategies have been employed, mostly by introducing additional passivation layers between perovskite and charge transport layer. Among them, surface passivation methods utilizing materials with functional groups that can donate electrons on the defect site have shown significantly improved passivation effect. Therefore, chelation with polydentate ligands with the electron-donating functional groups can be employed for more effective passivation.
In this study, we investigate a novel strategy that can further enhance the chelation-driven defect passivation effect of perovskite thin-films. Chelating ligands possess stronger affinity to metal ions compared to conventional monodentate ligands which would be more advantageous to passivate Pb-related defects. Thus, we introduce various carboxylic acid based chelating agents with different numbers of functional groups during the synthesis process of the perovskite thin-films. We show that the number of functional groups that forms chelating bond is more significant, in this case, carboxyl group. Citric acid (CA), which contains three carboxyl group and one hydroxyl group, demonstrated the highest film quality regarding Pb-related defect passivation. Nuclear magnetic resonance spectroscopy and Fourier transform infrared spectroscopy are carried out to investigate the chelating bond between CA and Pb. Furthermore, we discover that the chelation at the nucleation and crystallization steps are highly effective for defect passivation. Finally, we demonstrate the CA chelation during the crystallization process results in higher performances of PSCs as well as the device stability.

11:45 AM EL02.03.04
Chemical Vapor Deposition of Cuprous Iodide as a Hole Transport Material for Perovskite Photovoltaics Eliza Spear[1], Luke Davis[2] and Roy Gordon[1]; [1]Harvard University, United States; [2]Tufts University, United States

A typical perovskite solar cell (PSC) requires both an electron and a hole transport material (ETM and HTM, respectively). The commonly employed organic HTMs are a significant source of instability in PSCs: the organic HTMs themselves have high resistivities, on the order of 10^5 Ohm cm, and require dopants, which can migrate and wreak havoc throughout the cell [1, 2]. Inorganic HTMs have the potential to improve both device stability and performance due to their own inherent stability and higher conductivity, which eliminates the need for dopants.

Inorganic HTMs, which include NiO_x, VO_x, copper delafossites, and cuprous iodide, are relatively underexplored, which motivates the development of new inorganic HTMs and techniques for depositing device-quality films of those HTMs. In considering deposition techniques for inorganic HTM candidates, vapor methods such as chemical vapor deposition (CVD) and atomic layer deposition (ALD) could enable rapid scaling and conformal coatings even on textured substrates [3, 4]. This makes them especially attractive for application in tandem silicon/perovskite devices where a perovskite cell is deposited directly atop a textured crystalline silicon cell [4, 5].

The optically transparent p-type semiconductor cuprous iodide (CuI) is a promising HTM candidate, with a band gap ~3.1 eV, low resistivity (~10^{-2} Ohm cm), and high hole concentration and mobility (~10^{19} cm^{-3} and ~1-10 $cm^2V^{-1}s^{-1}$, respectively) [6]. PSCs employing CuI as the HTM have achieved up to 17.6% photoconversion efficiency [7], but while CuI crystallite arrays have been obtained by CVD [8], CVD of continuous CuI thin films has only been accessed through a two-step vapor conversion process, requiring initial deposition of a copper chalcogen followed by vapor-phase conversion to the halide [6].

We have recently developed a CVD technique capable of direct deposition of continuous films of CuI at temperatures as low as 50 °C [9]. X-ray diffraction and Rutherford backscatter spectrometry confirm deposition of stoichiometric zincblende CuI. Progress in depositing continuous CuI films on substrates relevant to both n-i-p and p-i-n PSC device configurations will be discussed.

1:30 PM *EL02.04.01
Opportunities and Challenges for Perovskite PV R&D—A Perspective from US DOE SETO Timothy Siegler; Solar Energy Technologies Office, U.S. Department of Energy, United States

Halide perovskite photovoltaics is an emerging photovoltaic technology. They have recently achieved power conversion efficiencies (PCEs) of over 25% in 0.1 cm^2 small-area solar cells and over 32% in 1 cm^2 hybrid silicon tandems. While small area performance continues to push forward, demonstration of larger area performance is required if perovskite PV will contribute to aggressive domestic solar manufacturing and deployment goals required to meet the United States' current decarbonization targets. The U.S. Department of Energy Solar Energy Technologies Office (SETO) has a history of funding perovskite PV technology focused on increasing scale and demonstrating durability in large area modules. In this talk, SETO will discuss their perspectives on halide perovskite PV. This presentation will highlight some of the future opportunities of this technology, as well as the ongoing challenges required to advance this technology in the areas of efficiency at scale, durability, manufacturing and process control, and bankability.

2:15 PM *EL02.04.02
American-Made Challenges Perovskite Startup Prize Countdown Celebration Timothy Siegler; Solar Energy Technologies Office, U.S. Department of Energy, United States

The American-Made Challenges (AMC) Perovskite Startup Prize is a $3 million prize competition designed to accelerate the growth of the U.S. perovskite industry and to support the rapid development of solar cells and modules that use perovskite materials. This competition has two stages: "Countdown" and "Liftoff." In the initial Countdown stage, new startup entities incorporated after September 24, 2020, competed for a $200,000 prize. Winners of the Countdown prize were eligible to advance and compete for the $500,000 Liftoff prize. The submission deadline for the final Countdown competition was March 23, 2023. To celebrate the end of the Countdown Contest, the U.S. Department of Energy Solar Energy Technologies Office (SETO) will highlight and celebrate winners of the Countdown Contest. After a short introduction, Countdown Contest winners from previous cycles (Beyond Silicon, Verde Technologies, SoFab Inks, and MujiElectric) will participate in a pitch showcase where each winner will have 5 minutes to highlight their technologies and companies. This will be followed by a networking meet-and-greet between the startup companies, conference attendees, and SETO.

3:00 PM BREAK

3:30 PM *EL02.04.03
US Perovskite Industry Roundtable—Challenges and Opportunities for the Academic Community Timothy Siegler; Solar Energy Technologies Office, U.S. Department of Energy, United States

While halide perovskite PV has made significant progress in laboratory research, much less than 1 MW of perovskite PV installations have been commissioned globally. In this roundtable discussion, SETO and members of the US solar industry involved in perovskite research and development (R&D) will sit down and discuss the challenges of effectively translating this lab progress with perovskites to large-scale deployment. We will discuss how academic researchers can partner with the perovskite PV industry to aid in scale-up processes and will highlight which research questions are most interesting for industry R&D efforts. Further, we will discuss the tools and skills students need to be able to perform innovative, relevant solar R&D in the halide perovskite PV industry and will talk about strategies students may use to best position themselves for their post-graduate careers.

SESSION EL02.05: Novel Structure I

Wednesday Morning, April 12, 2023
Moscone West, Level 3, Room 3002

8:15 AM *EL02.05.01
External Stimuli, Timescales and the Structure of 2D and 3D Perovskites Mercouri G. Kanatzidis; Northwestern University, United States

Understanding and tailoring the physical behavior of halide perovskites under external stimuli is critical for designing efficient optoelectronic devices. We found that continuous light illumination leads to a contraction in the out-of-plane direction in two-dimensional hybrid perovskites, which is reversible and strongly dependent on the specific superlattice packing. Constant light illumination causes the accumulation of positive charges in the terminal iodine atoms, thereby enhancing the bonding character of inter-slab I-I interactions across the organic barrier and activating out-of-plane contraction. This results in a threefold increase in carrier mobility and conductivity, consistent with an increase in the electronic band dispersion predicted by first-principles calculations. Flux-dependent space-charge-limited current measurement reveals that light-induced interlayer contraction activates interlayer charge transport. The enhanced charge transport boosts the photovoltaic efficiency of two-dimensional perovskite solar cells by increasing the fill factor and open-circuit voltage. The dynamic behavior of MAPbI$_3$, under optical stimulation using X-ray diffraction, also revealed unexpected phenomena. We identified several nonequilibrium structures and phenomena that have not been shown in studies where the structure is measured in equilibrium. Using ultrafast X-ray diffraction techniques, we identified and characterized the dynamic, photo-excited structures of MAPbI$_3$. We observed anisotropic distortions and rates of change along specific directions of the lattice as the material transitioned from the starting phase to a higher-symmetry, metastable excited structure over 1 ns following photoexcitation. The dynamics of these nonequilibrium structures demonstrate the flexible lattice response of metal halide perovskites, which facilitates favorable properties and provides further insight to enable new device architectures.

8:45 AM EL02.05.03
High-Efficiency and Durable MA and Br Free Phase-Pure Dion Jacobson 2D Lead Halide Perovskites for Perovskite-Perovskite Tandems Ayush Agrawal, Jin Hou, Siraj Sidhik and Aditya D. Mohite; Rice University, United States

Three-dimensional (3D) metal halide perovskite solar cells have displayed tremendous progress in photo conversion efficiencies in the last decade. The tunable bandgaps enable mixed halide perovskite compositions to be used as the wide bandgap (WB) sub-cell in perovskite-perovskite tandems. However, halide segregation and ion migration under photo-illumination create bandgap instability that limits the long-term durability of these wideband gap sub-cells. 2D halide perovskites, on the other hand, have demonstrated better durability against moisture and photo-illumination due to their large organic cations but still lag in efficiency due to >2eV band gaps and charge extraction barriers. The methylammonium (MA$^+$) cation is also hygroscopic and can limit the long-term moisture stability of the perovskite. Here, we synthesize formamidinium (FA$^+$) based 2D Dion Jacobson (DJ) perovskite solar cells with a diammonium 3-(aminomethyl)piperidinium (3AMP$_{2+}$) organic spacer cation. Optical absorption on FA 2D DJ reveals a band gap of 1.7-1.8eV for (3AMP)-FA$_2$Pb$_3$I$_{10}$ (n=3), which is ideally suited for building bottom cells for perovskite-perovskite and perovskite/Si tandems. Films fabricated using the phase-selective memory seeds process preserved the phase purity of the (3AMP)-FA$_2$Pb$_3$I$_{10}$ 2D perovskite and yielded solar cells with a PCE of 17% with a Voc approaching 1.2 V. More importantly, FA 2D DJ perovskite solar cells demonstrate commercially viable durability against temperature, moisture, and maximum power point (MPP) tracking. These properties make FA 2D DJ perovskites promising candidates for wide bandgap subcells in perovskite-perovskite tandems.

10:00 AM *EL02.06.01
Chemical Design for Metal Halide Perovskites Nanostructures Loredana Protesescu; Nanomaterials Chemistry/Zernike Institute for Advanced Materials/RUG, Netherlands

Metal halides perovskites with nanoscale geometries have revolutionized the field of solution-processed photovoltaics and light-emitting devices due to their strong absorption and exceptional photoluminescence properties combined with a remarkable tolerance to structural defects. However, the further development of these materials to practical commercialization is hindered by their toxic components like lead and their inherent structural lability. Moreover, we still have little understanding of their crystallographic structures, chemical and physical interactions, and surface chemistry at a fundamental level.
The chemical design of metal halide perovskites proved to be the key to addressing those issues. Our recent findings confirm that a direct transition of the synthetic approach at nanoscale from Pb to Sn halide perovskites is not feasible. For Sn-based perovskites nanostructures, the structural dynamics between 3D cuboids and 2D Ruddlesden-Popper nanosheets colloids are highly dependent on the synthetic strategy. The presence of both species has a direct impact on the optoelectronic properties. Moreover, heterostructures containing halide perovskites nanocrystals are the next step towards obtaining accessible materials for industry. With the help of polymers or metal-organic frameworks, we can access air stable materials or ultra-small quantum dots.

10:30 AM *EL02.06.02
Improving the Stability of Halide Perovskite by Building Perovskite Hetero-structures Hsinhan Tsai; University of California, Berkeley, United States

Halide perovskites are outstanding semiconductors for high performance opto-electronics, the drawback is their material instability in humid environment, and the poor device operational stability under external stress like electrical fields or illumination. In this talk, I will present two types of hetero-structure that can stabilize the material. In the first part, I will discuss a bilayer heterostructure to stabilize the interface. We grow a fluorinated small molecule on the perovskite thin film to increase the surface energy. This hetero-structure suppresses the voltage induced ion diffusion. As a result, we demonstrate a radiation detector that can operate under high electrical field stress. In the second part, I will present how we stabilized the perovskite nanocrystals embedded in metal-organic frameworks (MOFs). Here we assembled perovskite nanocrystals in MOF matrix that can enhance the material stability and inhibit crystal merging problems. Finally, I will discuss the device performance using these strategies in optoelectronics applications such as light-emitting diodes, X-ray detector and photovoltaics.

Quantum-Dot-in-Matrix Stabilizes Metal Halide Perovskite Solid by Deterministic Strain Engineering Yuan Liu[1,2], Tong Zhu[2], Luke Grater[2] and Edward H. Sargent[1,2]; [1]Northwestern University, United States; [2]University of Toronto, Canada

Phase transitions, segregation, and decomposition of MHPs occur with the presence of humidity, light, heat, oxygen, and electrical fields. With these factors, perovskite-based devices suffer steady performance losses. Strain engineering is proven to improve the stability of perovskite materials[1,2]. Here, we propose to stabilize perovskite solid using perovskite quantum dot (QD) implants. The strain is created due to the manipulated lattice misalignment between the QD and matrix lattices.
Prior QD-in-matrix solid studies using PbS QDs show enhanced stability of $CsPbI_3$ perovskite but failed to exploit optical properties of the perovskite matrix[3,4]. This prevents the use of covalent quantum dots as implants and limits the universality of this material platform.
Our method is universal and practical because perovskite QDs are versatile as they can be compositionally engineered to meet bandgap and lattice parameter requirements. Given the range of lattice parameters and composition of the QD, this method estimates their capability towards stabilizing the matrix of choice before diving into lengthy synthesis.
We examined mixed halide perovskite, α-$CsPbI_3$ and α-$FAPbI_3$ and found that the compressive strain introduced by QD implants enhanced the stability of the optically desired phases. For solar cell application, perovskite QD ensures a type-I band alignment where the QD features a larger bandgap, and therefore allows efficient extraction of the electron-hole pairs from the matrix perovskite. Solar cells using QD-in-mixed halide perovskite matrix solid show an open circuit voltage of 1.35 V, a power conversion efficiency of 20 %, and operation stability of over 200 hrs. This fills the gap between the configuration of QD-in-matrix and utilization of matrix perovskite for photovoltaic application, compared to prior QD-in-matrix methods.

Perovskite Quantum Dots for High-Efficiency Solar Cells and Beyond Lianzhou Wang; University of Queensland, Australia

Halide perovskite solar cells have witnessed great successes recently while their instability is a big hurdle for practical application. Herein we discuss our recent progress in addressing the stability of perovskite solar cells, including introduction of capping layers to improve the stability against moisture and heat, and perovskite size engineering to suppress phase segregation. In particular, quantum dots (QDs) have the advantages of quantum confinement effect, defect-tolerant nature, and processability for flexible devices. We discuss a new surface ligand engineering strategy in designing new hybrid perovskite QDs with controllable compositions and sizes The QDs have been used as building blocks in quantum dot solar cells delivering a certified world-record efficiency of 16.6% with excellent long-term operation stability. By using QDs as light absorbing materials, the QD based photocatalysts also exhibited good stable performance in photocatalytic hydrogen production. The integration of perovskite solar cells and rechargeable batteries have led to a single module type rechargeable solar batteries with an overall storable solar energy conversion efficiency of >12%. The composite of perovskite quantum dots with metal organic frameworks (MOFs) resulted in ultrastable photoluminescent property of >10000h.

Zwitterions in 3D Perovskites: Organosulfide-Halide Perovskites Jiayi Li[1], Zhihengyu Chen[2], Santanu Saha[3], James Utterback[4], Michael Aubrey[1], Rongfeng Yuan[4], Hannah L. Weaver[4], Naomi S. Ginsberg[4], Karena Chapman[2], Marina Filip[3] and Hemamala Karunadasa[1]; [1]Stanford University, United States; [2]Stony Brook University, United States; [3]University of Oxford, United Kingdom; [4]University of California, Berkeley, United States

Lead halide perovskites are extensively studied in solar-cell applications, achieving high power-conversion efficiencies. However, weak metal-halide bonds may be responsible for their moisture/thermal instability, hindering large-scale implementation. In this work, we propose to introduce sulfide into the halide perovskite lattice and demonstrate a synthetic strategy to do so by using organosulfides under mild conditions. We show that a zwitterionic organosulfide (L), can serve as both the X site and A site in the ABX_3 halide perovskites, yielding the first examples of 3D organosulfide-halide perovskites: $LPbX_2$ (X = Cl or Br). The structures are determined by single-crystal X-ray diffraction and pair distribution function analysis. Notably, the band structures of $LPbX_2$ capture the direct bandgaps and dispersive bands of $APbX_3$ perovskites. The sulfur orbitals compose the top of the valence band in $LPbX_2$, affording unusually small direct bandgaps of 2.31 eV and 2.16 eV for X = Cl and Br, respectively, falling in the ideal range for the top absorber in a perovskite-based tandem solar cell. Measurements of the carrier dynamics in $LPbCl_2$ suggest carrier trapping, possibly due to defects or lattice distortions. The highly desirable bandgaps, band dispersion, and improved stability of the organosulfide perovskites demonstrated here motivate the continued expansion and exploration of this new family of materials. Our strategy of combining the A and X sites with zwitterions may offer more members in this family of mixed-anion 3D hybrid perovskites.

From Composition to Composite Design—Chemical Tricks that Stabilize Halide Perovskites Shijing Sun; Toyota Research Institute, United States

Despite the outstanding optoelectronic properties of hybrid organic-inorganic perovskites (HOIPs), prototypical halide perovskites, such as methylammonium lead iodide ($MAPbI_3$, MA = CH_3NH_3), suffer from poor environmental stability. From ionic substitutions at an atomic level to post-synthesis treatment at a microscopic level, there has been intensive research in the community of materials chemistry to increase the structural and chemical stability of $MAPbI_3$. However, obstacles exist efficiently navigating this large and complex materials design space. A question that often gets asked is: how far can we extend the stability lifetime of a perovskite photoactive material, without lowering its optoelectronic performance?

In this talk, I will demonstrate three distinct approaches to delay the onset of HOIP degradation and discuss their relative advantages and disadvantages in perovskite electronics applications. I will start by discussing how stability changes non-linearly as a result of composition engineering in a combinatorial space, where the MA ions in $MAPbI_3$ are partially replaced by less volatile cations such as Cs and formamidinium.[1] Without modifications on the $MAPbI_3$ lattice, I will then move to capping methods, where a capping layer serves the dual function of forming a protective layer against oxygen and water, as well as improving the interface passivation.[2] I will then share our most recent findings in additive engineering, where porous organic cage molecules were introduced for the first time in perovskite films, forming perovskite-cage composites that show remarkable resistances to high humidity and temperature.[3] I will end my talk by briefly mentioning the role of machine learning in helping guide the experimental exploration of materials design and optimization in our projects.

2:00 PM EL02.07.03
Robot-Assisted Study on the Crystallization Pathway of FAPbI3 in Air Simon M. Arnold[1,2], Edward Barnard[1], Stephen Whitelam[1], Carolin M. Sutter-Fella[1] and Christoph J. Brabec[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Organic-inorganic halide perovskites allowed for the most rapid increase in power conversion efficiency of single junction solar cells ever seen from any photovoltaic technology. For some time now, it has become a major goal for the community to fabricate and stabilize pure α-FAPbI3 due to its - compared to other perovskites - superior photovoltaic properties, such as small bandgap, long carrier lifetime and low defect state density. Unfortunately, the photoactive cubic α-phase is only metastable at room temperature and transforms into the photoinactive hexagonal δ-phase over time. Recent efficiency improvements of α-FAPbI3-based perovskite solar cells have been enabled by insights and application of compositional, intermediate phase and dimensionality engineering, all enhancing the phase purity and stability of α-FAPbI3.

In this talk, I will report on the investigation of the mutually influencing effects of precursor composition, thin film synthesis conditions, and annealing profile, on the crystallization process of FAPbI3 in a sequential two-step spin coating process in air. Thereby, we first screened the high-dimensional parameter space using a robotic spin coating platform for automated thin film synthesis, annealing and in-line optical characterization (UV/vis, photoluminescence). We paired the platform with external X-ray diffraction measurements and neural networks which are trained on the time-dependent annealing process to optimize the synthesis protocol for crystal quality and optical properties in a closed-loop.
In a second step we used multimodal in-situ characterization techniques (GIWAXS, UV/vis, absorption) for certain composition/process conditions and annealing profiles to better understand the effects of described parameters on the crystal phase formation and phase stability of FAPbI3. These insights may help to develop a robust and reproducible synthesis protocol for high quality and stable α-FAPbI3 in air, which further propels the commercialization of perovskite solar cells.

3:30 PM *EL02.08.01
Topological Transport and Charge-Spin Conversion in Lead Halide Perovskites Alessio Filippetti; University di Cagliari and CNR-IOM, Italy

Spin-orbitronics has been recently rising tremendous excitement in the route towards a novel nanoelectronics with superior performances in terms of low energy consumption, operational speed, and information storage density. At the core, there is the idea of exploiting the spin-orbit coupling to implement new functionalities controlled and manipulated by electric, magnetic, strain, thermal, or radiative fields. A remarkable example is charge-spin (or the reversed spin-charge) conversion, which can foster visionary applications such as spin-diffusive transistors and electrically controlled magnetic memories.

Lead-halide perovskites appear as promising spin-orbitronic materials, featuring a set of key properties instrumental to the aim, first and foremost a strong SOC at the band gap extrema, together with good electron mobility, tendency to develop electric polarization, flexibility of structural and chemical design, easy integration in 2D heterostructures and devices, low-cost processing.

In this talk we review the fundamental electronic properties of LHP's, with particular emphasis on the detailed description of the band edges where SOC is displayed in spectacular form in terms of Rashba spin splitting and chiral spin texturing. Our analysis reveals a topological band transformation from low-density, genus-1 to high-density, genus-0 Fermi surfaces. The implications of this transition on the transport properties are discussed on the basis of a

Bloch-Boltzmann theoretical approach. Also, a model is developed to describe Rashba-Edelstein charge-spin conversion in both 3D and 2D lead-halide prototypes. Our results furnish a strong assessment to the remarkable potential of LHP's in the spin-orbitronic playground.

4:00 PM *EL02.08.02
Modeling of Charge Dynamics in Low-Dimensional Halide Perovskites Sergei Tretiak; Los Alamos National Laboratory, United States

Hybrid organic−inorganic perovskites (HOPs) have demonstrated an extraordinary potential for clean sustainable energy technologies and low-cost optoelectronic devices. For example, crystalline two-dimensional (2D) layered perovskites demonstrate exceptional properties for light emission and x-ray detection. The photophysics of 2D materials is defined by an interplay of strongly bound excitons and lower-energy states associated with the edges of the perovskite layers. Using molecular dynamics with time-domain density functional theory methods at room temperature, we compare the dominant non-radiative electron-hole recombination and dephasing processes in several low-dimensional lead halide perovskite materials. Our study demonstrates that performance limiting nonradiative carrier recombination processes greatly depends on the electron–phonon interactions induced by structural fluctuations and instantaneous charge localization in these materials. Overall, our results provide insights towards the material design principles for 2D perovskites to strategically tune their optoelectronic properties.

4:30 PM EL02.08.03
Predicting Thermodynamic and Phonon Transport Properties of 13,205 Single Perovskite Structures—Toward Stable Perovskite Electronics Ming Hu; University of South Carolina, United States

Although first-principles based anharmonic lattice dynamics method coupled with the phonon Boltzmann transport equation has been developed to obtain the phonon properties including lattice thermal conductivity at highest accuracy ever, the costly and time-consuming nature of the required interatomic force constants calculations renders high-throughput infeasible when facing tens of thousands of new materials. Here, a high-dimensional multi-element deep neural network is trained, dubbed Elemental Spatial Density Neural Network Force Field (Elemental-SDNNFF), achieving a competitive force root mean square error and a speed-up of 3 orders of magnitude in comparison to first-principles. The effectiveness and precision of the Elemental-SDNNFF approach is demonstrated on a set of >100,000 inorganic crystalline structures spanning 63 elements in the periodic table by prediction of complete phonon properties such as phonon dispersions and lattice thermal conductivity. We then use our trained neural network model to predict and screen full phonon properties of 13,205 perovskite structures. Due to the inherent structural feature of dynamical disorder, the perovskite structures have shown diverse thermodynamic and phonon transport properties. Thermodynamic stability of all 13,205 perovskite structures is predicted by screening negative frequencies in the Brillouin zone. Four-phonon scattering and two-channel thermal transport are also analyzed and screened. The underlying mechanism is analyzed in deep at the electronic level. This study demonstrated that our algorithm is very powerful for predicting phonon properties of large-scale inorganic crystals and is also promising for accelerating high-throughput search of novel phononic materials for emerging applications.

SESSION EL02.09: Poster Session I

Wednesday Afternoon, April 12, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM EL02.09.01
Determinatnion of the Exciton Binding Energy in Quasi- Low Dimensional Perovskite Namhee Kwon[1,2], Kitae Kim[2,1], Wonsik Kim[1], Yeonjin Yi[2] and Soohyung Park[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

In recent years, the two-dimensional (2D) perovskites has been considered as promising optoelectronic materials for their interesting optical and electronic properties. Particularly, 2D perovskites has been reported to have exotic excitonic behaviors represented by large exciton binding energy that is hardly been observed in neither three-dimensional perovskites such as $MAPbI_3$ or $FAPbI_3$ nor other semiconductors. Since the exciton binding energies of perovskites are directly related with quantum yields and power conversion efficiency of light emitting didoes and solar cells, respectively, it is important to understand them to utilize 2D perovskite as devices successfully. However, characteristic charge and dielectric confinement effects originated from their innate multiple quantum well structure make it hard to determine their exciton binding energy, remaining the reported values controversial.
Herein, we demonstrate the exciton binding energies of 2D perovskites with general formula $(C_nH_{2n+1}NH_3)_2PbI_4$ where n stands for the number of carbon atoms in the organic cation. Each investigated perovskite was fabricated by using different type of organic cations which are ethylamine (EA), Propylamine(PA), Butylamine(BA), Amylamine(AA), Hexylamine(HA), Octylamine(OA) and Dodecylamine(DA) in order from the shortest to the longest. The information on valence band and conduction band was respectively collected via ultraviolet photoelectron spectroscopy (UPS) and inverse photoelectron spectroscopy (IPES). From them we were able to precisely measure the electrical bandgaps of each 2D perovskite. With help of the density functional theory (DFT) calculations, each 2D perovskites were followed for further analysis. As a results, the exciton binding energies were calculated by comparing the electrical bandgap with optical bandgap measured by absorption and photoluminescence spectrum. We figured out that the dielectric constant became smaller as the number of carbon atoms in the organic cations decreases and therefore modifies the exciton binding energy. EA_2PbI_4, the perovskite with the shortest organic cation exhibited the smallest exciton binding energy, on the other hand, it was confirmed that the perovskite with the longest organic spacer, DA_2PbI_4 showed the highest exciton binding energy. We believe that our findings will provide essential information on 2D perovskite band structures and understandings for the development of optoelectronic devices with 2D perovskite in the future.

5:00 PM EL02.09.02
Wide-Bandgap Perovskite Solar Cells for Multi-Junction Photovoltaics Simone V. Laar, Kunal Datta, Martijn M. Wienk and Rene A. Janssen; University of Technology Eindhoven, Netherlands

The ability to easily tune the bandgap (E_g) of perovskite semiconductors makes them excellent candidates for multi-junction applications. By combining narrow-bandgap lead-tin perovskites (E_g ~ 1.2 eV), iodide-based mid-bandgap perovskites (E_g = 1.4 – 1.5 eV), and mixed-halide wide-bandgap perovskites (E_g ~ 2.0 eV), high efficiency triple-junction devices can be developed[1]. High quality wide-bandgap perovskites are a primary bottleneck in the development of these devices. Specifically, the deposition of smooth, mixed-halide perovskite layers is a key challenge. High open-circuit voltage (V_{oc}) losses in such devices are also detrimental to their efficacy in multi-junction solar cells[2]. Another important hurdle in developing multi-junction devices is the poor photostability of wide-bandgap perovskites as a result of light-induced halide segregation, which impairs their operational stability[3].

This work investigates the organic-inorganic $FA_xMA_{1-x}Pb(Br_yI_{1-y})_3$ (FA: formamidinium, MA: methylammonium, Br: bromide, I: iodide) and fully-inorganic $CsPb(I_{1-y}Br_y)_3$ perovskites for triple-junction photovoltaics. Several aspects such as phase purity, morphology, photostability and photovoltaic performance are examined through *in-situ* and *ex-situ* characterization tools.

First, $FA_{1-x}MA_xPb(I_{1-y}Br_y)_3$ perovskite films with different MA and Br contents are prepared using a one-step antisolvent-based process to approach $E_g \sim$ 2.0 eV. We observe that the composition strongly affects surface morphology; the films with high Br content demonstrate surface wrinkling, with features as high as 1 – 2 µm and widths around 5 – 10 µm. The wrinkling correlates to a preferential vertical crystal orientation, as observed by grazing incidence wide-angle X-ray scattering. However, the presence of wrinkles increases surface roughness that impedes the use of such layers in solution-processed multi-junction solar cells.

In contrast, a sequential interdiffusion method to prepare $FA_xMA_{1-x}Pb(Br_yI_{1-y})_3$ is found to yield unwrinkled films with $E_g \sim$ 2.0 eV[4]. However, we find that such films show the presence of de-mixed I-rich and Br-rich phases that lead to low-energy photoluminescence (PL) emissions. Under continuous irradiation, using *in-situ* PL spectroscopy, we find that ion migration further exacerbates the formation of I-rich and Br-rich domains. Upon subsequent storage in the dark, entropy-driven halide remixing causes the PL emission to blue-shift to ~ 2.0 eV, indicating the formation of a homogeneous mixed-halide phase. Thereafter, the process of halide segregation and remixing can be cycled by light-dark exposure in these materials. When used in *p-i-n* solar cells, the efficiency of 2.0 eV organic-inorganic mixed-halide cells decreases as a result of light-induced halide segregation, dominated by a loss in J_{sc}, while the V_{oc} is hardly affected. Nevertheless, the high efficiency (> 10%) of the solar cell is undermined by its limited photostability, making it less ideal for multi-junction use[5].

Finally, fully-inorganic *p-i-n* $CsPb(I_{0.67}Br_{0.33})_3$ (E_g = 1.9 eV) solar cells are prepared, yielding an efficiency of over 9%. A high-energy PL peak (maximum at ~ 1.9 eV) confirms the I-Br homogeneity of the film. Furthermore, under prolonged illumination the PL peak displays only a marginal red-shift, indicating superior stability compared to organic-inorganic counterparts. Similarly, $CsPb(I_{0.67}Br_{0.33})_3$ solar cells demonstrate negligible performance degradation under operational conditions, emphasizing their photostability.

This work demonstrates key elements in the processing and compositional engineering of wide-bandgap perovskites to develop triple-junction-compatible materials. The results highlight the high performance and stability of inorganic mixed-halide perovskite solar cells.

5:00 PM EL02.09.04

Dimension-Controlled SnO_2 Nanostructures for High Performance Flexible Perovskite Solar Small-Modules (900cm^2) Da Seul Lee, Ki Woong Kim, You-Hyun Seo, Myung Hyun Ann, Jaehoon Chung, Gabkyung Seo, Nam Joong Jeon, Jangwoon Seo and Seong Sik Shin; Korea Research Institute of Chemical Technology, Korea (the Republic of)

In the past decade, organic-inorganic hybrid metal halide perovskites have attracted much attention as potential photovoltaic (PV) materials owing to their attractive advantages such as high absorption coefficients, tunable bandgaps, long carrier diffusion length, low cost, flexibility, and low processing temperature. In particular, owing to low crystallization temperature (<150 ^{o}C), perovskites can be applied to a polymer substrate. This would make it possible to develop flexible perovskite solar cells (PSCs) that could open the door to low-cost mass production through roll-to-roll processes in the near future. In addition, the development of flexible PSCs has shown great potential in the field of wearable power supplies and integration with architectures in the future. However, despite the rapid development of low-temperature-processed PSCs, the power conversion efficiencies of flexible PSCs using polymer substrates are still inferior owing to the limitation of the electron transport layer (ETL) using colloidal nanoparticles (NP). Furthermore, ensuring both the efficiency and stability of flexible PSCs remains a considerable challenge for their commercialization.
In this study, we found for the first time that these solar cells suffer from a trade-off relationship between efficiency and stability due to the off-balance between surface coverage and the charge-transporting property of electrodes fabricated from a conventionally used colloidal Tin(IV) oxide (SnO_2) nanoparticles (NP). To resolve this trade-off, we designed a new electrode by controlling the dimensionality of the NPs. The development of multidimensional (MD) electrodes enables a PCE of 22.0% (0.094 cm^2) on a flexible substrate. When applied to the large area module, flexible modules show a PCE loss of nearly 10% by module size from mini-module to small-module (Type of Module is divided into mini-module (< 200cm^2), sub-module (200-800cm^2) and small-module (800-6500 cm^2) depending on the size of modules). Moreover, when the MD electrode is applied to the flexible sub-module (400cm^2) and small-module (900cm^2), the PCEs of MD electrode f-PSMs are 17.3% (active areas: 364cm^2) and 17.7% (active areas: 837cm^2). These results are the highest PCE reported to date. Furthermore, PSCs and the f-PSM based on the MD electrode retain 86% and 80% after 500h and 300h under continuous operation conditions, respectively. We believe that our strategy provides a new way to realize highly efficient and stable flexible perovskite photovoltaics.

5:00 PM EL02.09.05

Combinatorial Synthesis Process—A New Library Excepted Halide Perovskite-Based Materials of Photovoltaic Devices SangMyeong Lee, Won Bin Kim, Jae Myeong Lee, Hee Jung Kim, Oh Young Gong, Geon Woo Yoon and Hyun Suk Jung; Sungkyunkwan University, Korea (the Republic of)

Halide perovskites (HPs) has been conceived as next generation photovoltaic devices; this is due to their tunable band gap, excellent absorption properties, and excellent carrier mobility. However, some compositions of HPs are discarded until new applications are discovered due to limitations in their photovoltaic properties. Herein, this study reports a new library of HPs including HPs with ambiguous properties by using a combinatorial synthesis process. Firstly, the basic optoelectronic properties of synthesized HPs were measured and classified according to composition by using combinatorial synthesis process. Then, the study of band structure, band gap, hole effective mass, and electron effect mass via first-principles simulations explains the basic optoelectronic properties of synthesized HPs. Additionally, the library was formed that can be used as a variety of photovoltaic devices by controlling the crystalline phase of HPs. This paper suggests the new possibilities of HPs with ambiguous properties for photovoltaic devices.

5:00 PM EL02.09.06

Efficient and Stable Perovskite Solar Cell with Safe-to-Use Zhen Li and Zonglong Zhu; City University of Hong Kong, Hong Kong

Presently, over 85% of the world's energy is provided by non-renewable fossil fuels with concealed consequences on health and the environment. Developing and engineering novel materials and devices to provide efficient and sustainable energy is imperative. Metal halide perovskite solar cells (PSCs) have attracted enormous attention from academic and industrial communities due to their great promise of addressing the scalability challenges for affordable clean energy.

Power conversion efficiencies (PCEs) as high as 25.7% have been realized for single-junction conventional (n-i-p) PSCs, comparable to state-of-the-art crystalline-silicon solar cells. Inverted (p-i-n) devices have exhibited greater stability and lifetimes because of their un-doped hole-transporting layers (HTLs) and the formation of highly crystalline perovskite films, while their PCE still lag the conventional devices. Interfacial engineering to mitigate the interface recombination in the heterojunctions between perovskites and charge-transporting layers was considered as one of the promising strategies to further improve the photovoltaic performance and long-term stability of PSCs. Another concern occurs from the toxic element lead (Pb), a significant portion of the active layer in the most efficient PSCs. The potential risk of lead leaking due to damage by natural factors becomes the biggest challenge in entering the market.

To understand the impacts of the interface on perovskite, we systematically study interfacial engineering with respect to molecule design. We have developed a ferrocene-based organometallic interface material ($FcTc_2$), the functional groups assembled in the side arms of the ferrocene unit can provide chemical solid Pb-O binding between perovskite and molecule, effectively reducing surface trap states. Moreover, the electron-rich and electron-delocalized ferrocene units can accelerate interfacial electron transfer. These synergetic effects of $FcTc_2$ contribute to a record PCE of inverted PSCs and superior device operational stability, leading to a PCE of 25.0% (with certified 24.3%) and maintaining> 98% of its initial efficiency after continuously operating at the maximum power point for 1500 hours under simulated AM1.5 illumination. It is noteworthy that the $FcTc_2$-based device exhibited satisfactory durability under damp heat environment, which meet the IEC61215:2016 qualification (*Science* 2022, 376, 416-420).

For the lead leakage prevention in PSCs, we designed and synthesized novel lead trapping materials. Cation exchange resin (CER) and sulfonated graphene aerogels (S-GA) were first assembled in rigid and flexible perovskite PV encapsulation structures. The extremely low-cost CER with a sulphonic acid group (SO^{3-}) in Na^+ form possesses efficient adsorption capability of Pb^{2+}. More than 90% of the Pb^{2+} from the degraded perovskite PV solar modules (PSMs) could be captured under simulated severe weather conditions. The lead leaching of perovskite solar modules could meet the requirement of the US Resource Conservation and Recovery Act Regulation (RCRA) (*Nano Energy* 2022, 93, 106853). The large specific area of sulfonated graphene aerogels and their high binding energy with Pb^{2+} give them superior lead adsorption capacity in an aqueous solution. The encapsulant can capture over 99% of Pb^{2+} from the degraded flexible PSMs under different simulated conditions (scratching, bending, and thermal circling) to reduce the lead leakage to ≈10 ppb (*Adv. Energy Mater.* 2022, 12, 2103236). We also designed the thiol-functionalized 2D conjugated MOF as an electron extraction layer at the perovskite/cathode interface for electron extraction and Pb leakage prevention (*Nat. Nanotech.* 2020, *15*, 934). These works pave the way for the real-life application of perovskite photovoltaic technology.

5:00 PM EL02.09.07

$FAPbI_3$-based Thin Single Crystal Perovskite for Efficient, Stable Perovskite Solar Cell Muhammad N. Lintangpradipto and Osman M. Bakr; King Abdullah University of Science and Technology, Saudi Arabia

Perovskite solar cells (PSCs) have been rising in the last decade with solvent, compositional, and interface engineering methods to improve film crystallinity, optimize light absorption wavelength, inhibit intrinsic defect and passivate surface charge accumulation sites, reaching device efficiency of 25.7%. However, the lackluster stability performance remains lingering due to a large number of perovskite defects existing on the surface and grain boundaries inducing ion migration and interface degradation from moisture, oxygen, and other constituent ions thus limiting the operational stability of PSCs. Countless works have reported enhancing PSCs stability by using stable transport layer and metal contact especially passivating perovskite defect and grains boundaries to stop the degradation process from its root. Nevertheless, the source of the degradation remains as the intrinsic defect and grains boundary are always present in the polycrystalline film.

Single crystal as free-grain perovskite is an appropriate candidate for stable perovskite solar cells with defect density a few magnitude orders lower than polycrystalline film. Recent works on inverse temperature crystallization (ITC) demonstrated the fabrication of thin single crystal perovskite that is proportional to the solar cell application. 22.8% PCE has been achieved by employing formamidinium (FA) cation to $MAPbI_3$-based perovskite solar cells. However, as the advantages of $FAPbI_3$-based perovskite is obvious with a narrower band gap, superior crystal quality, and higher thermal stability, the move to $FAPbI_3$-based perovskite is inevitable. Nevertheless, synthesizing $FAPbI_3$ pure alpha-phase is challenging with non-perovskite delta-phase as stable form at room temperature and limitation of precursor volume on space confined ITC method.

Here in this study, we demonstrated the growth of thin single crystal $FAPbI_3$-based perovskite with cesium incorporation for stable alpha-phase PSCs. We confirmed the presence of cesium in the crystal with EDX SEM following the stoichiometric reaction. We performed a double 85 test to observe the crystal under harsh conditions. The alpha-phase $FAPbI_3$-based single perovskite is stable more than two-fold than its polycrystalline counterpart and the current best single crystal PSC $MA_xFA_yPbI_3$ under relative humidity 85%, and temperature 85°C test conditions. With a bandgap closing to ~1.47 eV, we show the possibility of an exceeding 23% efficiency device owing to the high current density reaching 27.8 mA/cm^2 enabling thin single crystal perovskite closer to the highest efficiency p-i-n polycrystalline perovskite devices to date. We also performed MPPT tracking to observe device operational stability under light irradiation in an inert atmosphere.

Carbazole Based Self-Assembly Monolayers for Highly Efficient Sn/Pb- Based Perovskite Solar Cells Matteo Pitaro[1,2], Javier S. Alonso[1], Lorenzo Di Mario[1], karolina Tran[1], Malin B. Johansson[2], Erik Johansson[2] and Maria Antonietta Loi[1]; [1]University of Groningen, Netherlands; [2]Uppsala University, Sweden

Highly performing mixed tin-lead perovskite materials are among the most promising options as an alternative active layer in perovskite solar cells to reduce Pb content. Moreover, these compounds open the possibility of fabricating full perovskite tandem devices, owing to their reduced band gap. The most efficient single junction mixed Sn/Pb perovskite solar cells have been fabricated using methylammonium cations (MA^+), and a p-i-n structure where poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT: PSS) is implemented as hole transport layer (HTL).[1] The record devices were reported to show limited stability, this can be attributed to two major reasons: i) MA^+ cations easily desorb at high temperature (85 C°) from the perovskite surface, introducing MA vacancies; ii) PEDOT: PSS, due to its hygroscopic and acid nature, reacts with the perovskite active layer, affecting the long-term stability.

In this work we employed a MA^+ free perovskite composition, namely, $Cs_{0.25}FA_{0.75}Sn_{0.5}Pb_{0.5}I_3$ and 2-(9H-carbazol-9-yl) ethyl) phosphonic acid (2-PACz), and [2-(3, 6-dibromo-9H-carbazol-9-yl) ethyl] phosphonic acid (Br-2PACz) as hole transport layers, with the aim of replacing PEDOT: PSS. Moreover, the fact that 2PACz and Br-2PACz can form a monolayer may allow reducing parasitic recombination.

$Cs_{0.25}FA_{0.75}Sn_{0.5}Pb_{0.5}I_3$ deposited on SAMs showed absence of pinholes, higher crystallinity (XRD), and larger grain size (SEM) when compared with the layers of PEDOT: PSS.

The fabricated solar cells using PEDOT: PSS as HTL exhibited a champion device efficiency of 16.33%, while devices fabricated on 2PACz and Br-2PACz showed an improved efficiency of 18.44% and 19.57%, respectively. The 19.57% efficiency is the record for the aforementioned perovskite composition.

It furthermore interesting to note that encapsulated Br-2PACz based solar cells retained 80% of the initial efficiency after 230 hours under continuous working condition, while device fabricated on PEDOT: PSS maintained 79% only for 72 hours. In addition, the shelf-life test in N_2 atmosphere showed much more stable devices when using Br-2PACz, with 89% of the initial efficiency after 42 days, when compared to PEDOT: PSS based devices, which solely preserve the 71% of the initial PCE. Moreover, the Br-2PACz-based device retained the 80% of the initial efficiency after 138 days in N_2 atmosphere.

Tetraalkylammonium Halide-Based One-Pot Ligand Engineering of Organic–Inorganic Hybrid Perovskite Nanocrystals for Enhanced Long-Term Stability and Controlled Photoluminescence Han-Jung Ryu and Jae-Seung Lee; Korea University, Korea (the Republic of)

Organic–inorganic hybrid perovskite nanocrystals have attracted scientific attention owing to their efficient and controlled photoluminescence, which is highly advantageous for optoelectronic applications. However, the limited long-term stability of organic–inorganic hybrid perovskite nanoparticles (OIHP NPs) has significantly hindered their practical and reliable application. Despite several synthetic strategies and encapsulation methods to stabilize OIHP NPs, complicated multi-step procedures are often required. In this study, we introduce a one-pot ligand engineering method for stabilizing and controlling the optical properties of OIHP NPs using tetraalkylammonium (TAA) halides with various molecular structures at different concentrations. Our one-pot ligand engineering substantially enhanced the stability of the OIHP NPs without post-synthetic processes. Moreover, in certain cases, approximately 90% of the initial photoluminescence intensity was preserved even after a month under ambient conditions. To determine the role of ligand engineering in stabilizing the OIHP NPs, the surface binding properties of the TAA ligands were thoroughly analyzed using Raman spectroscopy. Specifically, the permanent positive charge of the TAA cations and consequent effective electrostatic interactions with the surfaces of the OIHP NPs are pivotal for preserving the initial photoluminescence properties. Our investigation is beneficial for developing OIHP nanocrystals with improved stability and optical tunability for various optoelectronic applications, such as light-emitting devices, photosensitizers, photodetectors, photocatalysis, and solar cells.

5:00 PM EL02.09.11

Temperature-Controlled Slot-Die Coating for Antisolvent-Free-Processed Efficient and Stable Inverted Perovskite Solar Cells You-Hyun Seo[1,2], Nam Joong Jeon[1] and Seok-In Na[2]; [1]Korea Research Institute of Chemical Technology, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of)

The perovskite solar cells (PSCs) have continued to show their potential as a next-generation power source, achieving record power conversion efficiency (PCE) of over 25% due to their excellent optoelectronic characteristics. However, despite the impressive advances in the PCE to date, most high-performance PSCs are still fabricated with laboratory-scale production (i.e., a spin-coating process associated with anti-solvent dripping), which limits the path to large-area and mass production for commercialization of PSCs. To overcome these issues, it is important to develop high-quality perovskite films in scalable fabrications without spin-coating and/or anti-solvent steps and shift from laboratory scale to industrial scale that guarantees to upscale high-efficiency PSCs.
In this work, for the purpose of practical and scalable fabrication in PSCs, the temperature-controlled slot-die coating method is presented. This concept is further extended to control the solution temperature by using a thermistor-connected slot-die head that releases a hot solution onto a hot substrate. By careful cross-checking the bed and head temperature with coating speeds and its effect on the device performance, it was found that the introduction of the hot head can significantly influence the perovskite film morphology, and a PCE of 17.05 % could be realized at optimized-processing condition (head: 75 °C, bed: 150 °C, coating speed: 3 mm s-1) without spin-coating steps and anti-solvent dripping, which is a higher value than that of the device (12.61 %) without hot head condition. Systematic investigation of device characteristics, film morphologies, and carrier dynamics to reveal the origin of the enhanced PCE shows that the use of the hot-head produces a highly-oriented pinhole-free perovskite morphology with larger and thicker film, which results in enhanced light-harvesting capability, efficient charge carrier transport, and suppressed carrier recombination, leading to the remarkable enhancement in device performance. In addition to the device performance, optimized film condition can also show significant retardation of the decomposition of perovskite films, which lead to long-operation time in the ambient air and thermal condition. Finally, the optimized hot slot-die coating condition is directly utilized to fabricate the scaled device, showing a very close efficiency for spin coating-based PSCs without further modification. As a result, considering the compatibility of slot-die coating that is highly suitable for roll-to-roll (R2R) and sheet-to-sheet line production, hot slot-die coating approaches can provide a simple and useful way to manufacture perovskite films to achieve highly efficient and reliable PSC for industrial purpose

5:00 PM EL02.09.12

High Stable Perovskite Solar Cells using Ionic-liquid Addition and Cesium Halides Intercalation Technology Md. Shahiduzzaman, Munkhtuul Gantumur, Feng Yue, M. Nakano, Makoto Karakawa, Jean M. Nunzi and Tetsuya Taima; Kanazawa University, Japan

The rapid development of perovskite solar cells with a certified power conversion efficiency (PCE) of 25.7% is already at the level of commercialization. Still, long-term operational stability has become a major concern owing perovskite's intrinsically soft ionic crystal structures. Very recently, we used the ionic liquid (IL) aided-CH3NH3PbI3 (MAPbI3) perovskite nanoparticles (NPs) as a seeded-growth approach to fabricate high moisture-stable perovskite solar cells with a PCE of around 20%.1 It retained above 80% of its initial output even after 6000 hours of storage at ambiance with relative humidity (RH) range of 30−40% (non-encapsulated).
In the first half, I will talk about the nanoscale investigation of with and without IL-based perovskites. In this study, we investigated the nanoscale degradation mechanisms of why the higher stability was achieved by high-speed atomic force microscopy (AFM). We found that IL-aided MAPbI3 NPs form in the grain boundary of the CsFAMA perovskite crystal domains. This implies that the embedding of IL-aided MAPbI3 NPs in the CsFAMA perovskite crystal domain showed increased hydrophobicity (water contact angle of 72.3°) than pristine CsFAMA (water contact angle of 54.1°) by repelling moisture and preventing drop water infiltration under humid conditions.
In the second half, I will talk about cesium halides (CsX: CsCl, CsBr, CsI) intercalation technology for efficient and stable PSCs. Previously, we intercalated vacuum deposited cesium iodide (CsI) into solution processed host MAPbI3 perovskite framework and achieved a PCE of 18.43% and remained above 80% of their initial output after 6000 h storage in open air (non-encapsulated) for the first time.2 In this study, we introduced vacuum deposited CsX (CsCl, CsBr and CsI) thin layers into solution processed host MAPbI3 perovskite film from the up, down or both layers to promote precise intercalation, resulted in high-quality perovskite film for high stable PSCs. The use of CsX layer greatly altered the MAPbI3 morphology to produce large grain sizes, as a result of the precise intercalation of the CsX molecules into the host MAPbI3. We tested thermal stability at 85 °C on hot plate at RH range of 50−60% for more than 30 hours, Cs-containing perovskite films showed higher stability (no color changed, retained black) than pristine MAPbI3 film (color changed and degraded). The light-soaking of devices prepared with CsCl, CsBr and CsI intercalation remained 76.9%, 77.2% and 71.2%, respectively, of their initial PCEs, while the pristine MAPbI3 device showed only 4.3% of its initial PCE after 120 minutes of continuous light illumination (1 sun). More importantly, a similar trend with the CsCl, CsBr, and CsI-based PSCs were observed for the moisture stability for 3000 h storage at ambient with a RH range of 50–60% (non-encapsulated). This ILs and CsX intercalation technology will enable a significant improvement in the device operational stability.

Bulky Organic Cations with Large Steric Hinderance Inhibit Structural Degradation and Enhance Open Circuit Voltage in Perovskite Solar Cells
Sakshi Sharma, Carlo Andrea Riccardo Perini and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Despite the growth in power conversion efficiencies of lead halide perovskite solar cells to over 25% in recent years, interfaces at the active layer/charge transport layers prove to be a key factor in limiting charge extraction. Organic ammonium cations such as PEA$^+$ commonly used for passivation of interfacial defects can cause reconstruction of the cubic perovskite phase upon thermal exposure, affecting charge extraction and long-term device performance. Here, we have explored molecules with extended π-conjugation length in the form of ammonium halide salts such as 2-([2,2'-bithiophen]-5-yl)ethan-1-aminium iodide (2TI), 2-(3‴,4′-dimethyl-[2,2′:5′,2″:5″,2‴-quaterthiophen]-5-yl)ethan-1-ammonium iodide (4TmI) to explore the structural changes and defect passivation induced at the perovskite/Hole Transport Layer interface. Our XPS studies suggest lowering of Iodine and undercoordinated lead defects on perovskite films with passivation. However, lattice distortion is triggered by formation of low dimensional Ruddlesden Popper phase as 2TI penetrates the bulk on thermal treatment. On the other hand, large steric hinderance in 4TmI inhibits octahedral tilting in the inorganic $[PbX_6]^{4-}$ layer by preventing the ammonium head from replacing the A site cations in the perovskite lattice. The limitation on the reconstruction of the interface along with defect passivation translates to enhanced charge extraction and reduced nonradiative charge recombination. These mechanisms will be confirmed by GIWAXS and Photoluminescence measurements. Differences in layer uniformity and grain morphology for varying steric sizes of the cations are highlighted in SEM images. Using conjugated 2TI and 4TmI molecules acting as a shielding layer over the perovskite film, we have fabricated solar cells showing highest open circuit voltage of 1.09 with over 20% efficiency.

5:00 PM EL02.09.14
Chlorine Incorporation in 1.8 eV Wide Bandgap Perovskite Solar Cells to Enhance Efficiency and Photostability Severin Siegrist, Victor A. Marrugat, Ayodhya N. Tiwari and Fan Fu; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Monolithic all-perovskite tandem solar cells show the potential of high efficiency at low manufacturing cost. In the 2-terminal device configuration, the current matching condition requires an optical bandgap of 1.8 eV for the wide bandgap top cell, to optimally pair with the 1.25 eV narrow bandgap bottom cell in the stack. To develop 1.8 eV bandgap perovskite, 40 mol% of Br is generally alloyed with I in the perovskite. However, solar cells with such high Br fractions in perovskite absorber suffer from low open-circuit voltages and exhibit poor photostability. Adding Cl to form triple halide (I, Br, Cl) perovskite compositions is a promising approach to obtain 1.67 eV perovskite materials without using high Br fractions.
In this contribution, we present our results on Cl incorporation to achieve 1.8 eV wide bandgap perovskite compositions with much lower Br fractions. We investigate Cl-containing precursors with respect to their effectivity to incorporate Cl into the perovskite lattice. Furthermore, we probe the limits of Cl incorporation for given Br fractions and perform steady-state and time-resolved photoluminescence measurements to check the photostability of the triple-halide perovskite films as well as the charge carrier lifetimes. Additionally, we investigate the uniformity and spatial distribution of Cl in the perovskite film by XPS and ToF-SIMS depth profiling. Finally, we implement the most promising films in solar cells to evaluate the PV performance as well as the thermal and the light-soaking stability.

5:00 PM EL02.09.15
Electrical Analysis of Mobile Ion Reaction According to the Applied Voltage for Lead Halide Perovskite Solar Devices JaeGwan Sin[1], Gisung Kim[1], Mijoung Kim[1], Moonhoe Kim[1], Geon Park[1], Jaeho Kim[1], Jinpyo Hong[2] and JungYup Yang[1]; [1]Kunsan National University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Lead halide perovskite has significantly improved efficiency and stability over the past decade. This has been achieved by various passivation and surface treatment, such as understanding the trap density and interface of the perovskite thin film. For trap density analysis, dark current-voltage curve is typically used by various fitting formulas of space charge limited current (SCLC). In addition, it is possible to extract charge carrier, depletion region, built in potential (V_{bi}), and trap density inside the device measured by capacitance-voltage (C-V) curve. However, perovskite still has limitations in exactly device analysis due to its unusual electrical behavior. Especially, mobile halogen elements cause perturbation with peripheral carriers by continuous electric fields. Since the general electrical measurement methods applied to the device by continuous voltage, it is difficult to exclude the effect of mobile halogen ions. Here, we have investigated the dark current-voltage and capacitance-voltage characteristics using pulsed voltage for more accurate analysis of perovskite solar device. The use of pulsed voltage could be measured by limiting the movement of halogen elements and changing the inside of the perovskite film from an abnormal state to a normal state. In the case of methyl-ammonium lead tri-iodide ($MAPbI_3$), migration of halogen ions was suppressed, and reproducible V_{bi} was observed even after multiple measurements. The calculated trap density from the low temperature C-V curve was obtained as $5x10^{16}$ cm^{-3}, which is equivalent to the value extracted from the SCLC curve measured by pulse voltage.

5:00 PM EL02.09.19
Unraveling the Advantages of 3-Terminal Perovskite/Silicon Tandem Solar Cells Seyma Topcu[1], Michael Saliba[1,2] and Stephanie Essig[1]; [1]Institute for Photovoltaics (ipv), University of Stuttgart, Germany; [2]Institute for Energy and Climate Research (IEK-5), Forschungszentrum Jülich, Germany

Perovskite/silicon tandem solar cells are of increasing interest due to their high power conversion efficiencies (PCE) of over 30% and low fabrication costs. However, the stability of the perovskite cells cannot compete with the superior lifetime of silicon (Si) photovoltaics (> 20 years), which threatens their commercialization. So far, most record perovskite/silicon tandem cells have been monolithically integrated and feature 2-terminal (2T) configuration. Hence the sub-cells are connected in series and the highest efficiencies can only be achieved if the perovskite top and Si bottom cells generate the same photocurrent. While the current matching can be well controlled by optimizing the bandgap of the top cell, a faster degradation of the perovskite top cell compared to the silicon bottom cell may cause a severe current mismatch during ageing. This current mismatch dramatically deteriorated the tandem efficiency to values lower than single-junction devices. To pinpoint this stability disparity and its consequences we have performed a thermal degradation study in a dry atmosphere. To overcome this limitation of 2T perovskite/Si tandem cells, we employ a 3-terminal (3T) tandem architecture which does not require current matching. Consequently, the long-term performance of 3T perovskite/Si cells will surpass the one of 2T devices.
Here we show the first implementations of 3T tandem cells with *nip* and *pin* triple-cation perovskite top cells deposited on laser processed Interdigitated Back Contacted Silicon solar cells (Si IBC) with 1 cm^2 cell area. Our studies include current-voltage (I-V) and External Quantum Efficiency (EQE) analysis of the 3T tandem cells before and after ageing. Furthermore, Scanning Electron Microscope (SEM) imaging is used to check the conformal coating of the textured Si solar cells.

5:00 PM EL02.09.20

Pb-Sn Halide Perovskites for Photovoltaics—Understanding Carrier Extraction with a Doped Active Layer Antonella Treglia[1,2], Francesco Ambrosio[2,3], Giulia Folpini[2], E Laine Wong[2], Filippo De Angelis[4], Isabella Poli[2] and Annamaria Petrozza[2]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Istituto CNR di Scienze e Tecnologie Chimiche "Giulio Natta" (CNR- SCITEC), Italy; [4]University of Perugia, Italy

The possibility of extending the absorption of lead based metal halide perovskites (LHPs) to the near-infrared region by partially substituting Pb with Sn has attracted great attention for the possible applications in tandem devices[1] and single junction solar-cells[2]. In addition to the nonlinear reduction of the band gap, the gradual substitution of lead with tin also changes significantly the photophysical properties of the material.[3,4] Despite the optoelectronic quality of tin halide perovskites (THPs) being inherently comparable to LHP[5], device efficiency and stability are still limited.[6,7]
With a combination of steady-state, time-resolved and pump-probe spectroscopy techniques we address the interplay of radiative and non-radiative processes occurring in tin-halide perovskites $FA_{0.85}Cs_{0.15}Sn_xI_3$. Recombination dynamics are explored as a result of electronic and chemical doping, oxidation and density of surface to bulk trap states. Carrier dynamics simulations and density functional theory calculations of defects are adopted to understand experimental results and identify the dominant processes occurring in different regimes of photoexcitation. We demonstrate that when the material is highly doped Auger recombination plays a fundamental role in limiting performances even at low photoexcitation density.[8,9]
We also investigate the fundamental optoelectronic properties of THPs when integrated in a device. The currently used architecture of lead-based solar cells, where an intrinsic absorber is sandwiched between two organic extraction layers (pin), is intrinsically not suitable for THPs as it would result in a p-p-n structure (as long as the THP remains intrinsically p doped). The short carrier lifetimes deriving from the intrinsic p-doping and the upshifted valence and conduction bands result in a reduced extraction capability. The bulk-free carrier dynamics in the presence of extraction layers are probed with transient absorption spectroscopy from the fs to time scales. We find changes in the extraction of electrons and holes in different temporal regimes and identify the presence of long-lived trap states. This information is correlated with spatial and time-resolved photoelectron spectroscopy (tr-PEEM)[10,11] at the interface of THPs with an evaporated extraction layer. The band alignment, surface trap distribution and charge transfer are probed for mixed $FA_{0.85}Cs_{0.15}Pb_{1-x}Sn_xI_3$: as the lead-based perovskite is alloyed with tin, its doping density, valence band position and bandgap can be gradually tuned, resulting in a modified energetic landscape of photogenerated carriers affecting carrier extraction.

Fabrication of Hybrid Low-Dimensional Perovskite Solar Cells by Combing Scalable Doctor Blade Coating and Methylamine Post Treatment
Tung-Yu Hung and Chih-Liang Wang; National Chung Hsing University, Taiwan

Three-dimensional (3D) metal-halide perovskites have been paid much attention for use in solar cells due to the high absorption coefficient, great ambipolar charge mobility, long carrier diffusion length, and low exciton binding energy. However, the poor stability of 3D perovskite from the hydrophilic nature limits the practical application. In this regard, the hybrid low-dimensional perovskites are developed by combing the doctor blade coating and methylamine post-treatment process. A series of different hybrid low-dimensional perovskites are facilely made by the addition of phenethylammonium iodide (PEAI) in the doctor blade coating solution of $MAPbI_3$ perovskite based on the hot-casting approach. The result shows that the addition of PEAI can form a low-dimensional perovskite layer on top of the 3D $MAPbI_3$ perovskite film right after the doctor blade coating, which improves the perovskite stability but lowers the device performance due to the large bandgap and poor charge transportation. To find a compromise between the device stability and performance, the methylamine post-treatment process is employed on such a hybrid low-dimensional perovskite. The SEM, XRD, Raman microscopy, Kelvin probe force microscopy (KPFM), and UV-Vis are carried out to understand the morphology, crystallization, contact potential difference and optical property of the hybrid low-dimensional perovskites before and after the methylamine post treatment. More details related to the perovskite device stability and performance, affected by the amount of added PEAI and methylamine post treatment, will be mentioned in the presentation.

5:00 PM EL02.09.22

Photo De-Mixing in Mixed Halide Perovskites—the Role of Dimensionality Ya-Ru Wang[1], Alessandro Senocrate[1], Marko Mladenović[2], Algirdas Ducinskas[2], Gee Yeong Kim[1], Ursula Roethlisberger[2], Jovana V. Milic[2], Davide Moia[1], Michael Grätzel[2] and Joachim Maier[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]EPFL, Switzerland

Photo induced phase separation observed in mixed halide perovskites(Photo de-mixing) has opened important questions on the thermodynamics of energetically pumped systems. In addition, the improved phase stability observed experimentally in low dimensional perovskites under light[1] compared with classic 3D hybrid perovskites, raises questions on the influence of dimensionality on the defect chemistry and the phase properties of these mixtures.

Here, we investigate the dependence of the phase behavior of mixed halide perovskites with different dimensionality under light. We consider thin films of 3D, 2D and nanocrystalline (size ~10 nm) mixed halide perovskites and we probe the changes in absorption properties and conductivities when the films are exposed to light. We find that nanocrystalline films show no de-mixing in contrast to 2D and 3D under similar illumination intensities, consistent with previous observations[2] and with the role of interfacial energy in the formation of de-mixed phases.[3]We then consider Dion-Jacobson mixtures based on $(PDMA)Pb(Br_{0.5}I_{0.5})_4$ (PDMA: 1,4-phenylenedimethanammonium spacer) as a model system for evaluating thermodynamic properties of photo de-mixing, given their superior stability compared to 3D films. We demonstrate that 2D mixed halide perovskites undergo photo de-mixing with direct transformation from the pristine phase to the de-mixed phases. Almost complete re-mixing of these phases occurs when the sample is left in the dark, showing that the process is reversible in terms of optical and structural properties. We further conduct temperature-dependent absorption measurements under light to extract the photo de-mixed compositions and to map the photo-miscibility-gap with three different methods.[4] We finally compare the kinetics and thermodynamics of photo de-mixing in 2D and 3D systems.

Mechanism Study of High Efficiency Perovskite Solar Cells Based on Planar or Mesoporous Metal-Doped TiO_2 Electron Extraction Layer Yin-Hsuan Chang, Shih-Hsuan Chen, Ching-Mei Ho, Shun-Hsiang Chan, Ying-Han Liao and Ming-Chung Wu; Chang Gung University, Taiwan

Organic-inorganic halide perovskite solar cells (PSCs) is considered as one of the renewable energy sources. Over the last decade, the power conversion efficiency (PCE) of PSCs has rapidly promoted from 3.8% to 25.7%. The charge collection and defect states in a device are the most significant issues hindering the progress of PCE. On the other hand, hysteresis phenomenon in n-i-p PSCs, namely mismatch current density at different scanning directions, is one main issue that needs to deal with. Note that several factors that result in the hysteresis phenomenon. First, the imbalance between electron and hole flux in a device, attributed to lower electron mobility of TiO_2 can lead to severe hysteresis. Secondly, shallow trap states close to the conduction band increasing the charge recombination. As a result, carrier pathway between the perovskite active layer and the electron extraction layer (EEL) and smooth contact interface with the perovskite active layer play critical roles in charge transportation. Previous studies have investigated metal doped TiO_2 as EEL, such as Mg, W, Co, Zn, Ag, and Sn, in depth. With the suitable dopant, it could tune the band alignment between the EEL and perovskite active layer. That contributes to improve charge transportation in a device. Typically, the inferior contact between planar EEL and perovskite layer and low conductivity of pristine planar TiO_2 EEL deteriorate the hysteresis phenomenon in a perovskite solar cell. Therefore, mesoporous structure TiO_2 being intimate contact between perovskite layer allow perovskite to infiltrate into mesoporous microstructure and to provide large contact area for electron transportation. Also, the intimate contact can reduce the defect density between an interface. As mentioned above, we believed that developing metal doped meso-TiO_2 EEL is promising for improving electron properties and passivating defects. In this study, we adopted three metals (Ag, Zn, Sn) as dopants into the planar or mesoporous TiO_2 to compare the difference between planar and mesoporous EEL. In the planar PSCs series, a promising Sn-doped TiO_2 PSC showed an average PCE of 14.4%. In the mesoporous PSCs series, the device with optimized 1.0 mol% Sn-doped meso-TiO_2 achieved an average PCE of 19.51%. Further characterization revealed that the absorption edge of Sn-doped TiO_2 red shifted along with the increased doping concentration. Also, the defect density in EEL can be passivated by Sn doping. The upper shift of the conduction band and valance band edge made the energy level alignment in devices much more appropriate. That facilitates electron injection into the EEL with minor recombination. Finally, the champion device with 1.0 mol% Sn-doped meso-TiO_2 EEL delivered a PCE of 20.55%, a high fill factor (*FF*) of 81.72%, and a minor hysteresis index of 0.03.

Demystifying Voltage-Induced Halide Segregation in Mixed-Halide Perovskite Devices Zhaojian Xu[1], Ross Kerner[2], Steven Harvey[2], Kai Zhu[2], Joseph J. Berry[2,3,4] and Barry P. Rand[1,5]; [1]Princeton University, United States; [2]National Renewable Energy Laboratory, United States; [3]Renewable and Sustainable Energy Institute, University of Colorado Boulder, United States; [4]University of Colorado Boulder, United States; [5]Andlinger Center for Energy and the Environment, Princeton University, United States

Mixed-halide perovskites, owing to straightforward bandgap tuning through halide stoichiometry variation, have been considered in many optoelectronic devices. However, unwanted halide segregation under operational conditions, including light illumination and voltage bias, restrict practical applications. While light-induced halide segregation has been heavily studied, voltage-induced halide segregation still lacks in-depth investigation and the mechanism behind remains unclear. Herein, we systematically study the impact of voltage bias on mixed bromide/iodide perovskite devices across the full range of bromide/iodide ratios by conducting a series of long-time voltage biasing tests, and observe three voltage thresholds for an optically stable, mixed-halide perovskite composition with a low bromide ratio, and assign them, in order of increasing voltage, as the hole transport material doping threshold, halide segregation threshold, and degradation threshold, respectively. These empirical threshold voltages are minimally affected by composition until very Br-rich compositions, revealing the dominant role of iodide/triiodide/iodine electrochemistry in voltage-induced halide separation in mixed-halide perovskite devices. Furthermore, voltage-induced halide redistribution is directly visualized by cross-sectional scanning transmission electron microscopy–energy dispersive X-ray spectroscopy (STEM–EDX). By changing the metal electrodes (Au and Ag) and testing different voltage polarities (forward and reverse bias), we demonstrate the mechanism of voltage-induced halide segregation: iodide oxidation at the anode initiates unbalanced bromide, iodide, and oxidized iodine mass transport fluxes, resulting in vertical halide redistribution. The suppression of halide segregation by Ag anode indicates that halide perovskite devices operate as solid-state electrochemical cells when threshold voltages are exceeded, and the species/reaction with the lowest oxidation potential and the species/reaction with the lowest reduction potential in the metal halide device dictate the stability behavior under voltage bias.

5:00 PM EL02.09.27
Stabilizing the Surface of Metal Halide Perovskite Nanocrystals for Grafting Functional Charge Carrier Acceptors and Polymer Matrixes Aaron S. Malinoski[1,2], Hua Fu[1] and Chen Wang[1,2]; [1]Queens College, City University of New York, United States; [2]The Graduate Center, The City University of New York, United States

Protecting the vulnerable surface of perovskite nanocrystals (PNCs) while creating facile charge carrier migration pathways across the ligand interface is a dilemma that is confronted by researchers in many scenarios of applications. Previous work from our group demonstrated that the overabundant synthetic ligands required for passivating the PNC's dynamic surface in the colloidal phase were a major obstacle to establishing strong electronic coupling between the perovskite core and external molecular acceptors. We therefore devised a strategy where we first reconstruct the surface ligand layer of PNCs using small molecule zwitterion ligands (ZLs), and we then investigate various surface functionalization methods. By carefully selecting the binding affinity of the initial reconstructing ZLs, we not only successfully stabilize the PNC surface in solution with a low ligand loading, but we also facilitate quantitative grafting of various functional structures via bidentate coordination anchoring motifs. Functional species that can be tightly anchored to the PNC surface using this strategy include molecular charge carrier, organic semiconductors, and precursors that can carry out photopolymerization reactions. We illustrate the surface functionalization process step by step using NMR and steady-state optical spectroscopy. The rapid migration of photogenerated electrons and holes between the PNC and the grafted functional molecules is observed with time-resolved photoluminescence and transient absorption spectroscopy, confirming that the functionalization strategy can establish strong electronic coupling. The molecular charge carrier acceptors grafted on the PNC surface do not create surface trap states but can serve as routes for extracting the excitonic energy. By inducing the photopolymerization of precursors anchored in the PNC ligand shell, we generate a polymer matrix that tightly wraps the PNC core to enhance their stability. We monitor the dynamics of charge carriers shuffling through the polymer layer using time-resolved optical spectroscopy and adjust the polymerization condition to achieve balanced protection and charge transport mobility.

Understanding Structural Differences in Completely Dry-Processed $MAPbI_3$ Thin Films by Detailed Analyses of Temperature-Dependent Optical Spectroscopy Christina Witt, Konstantin Schötz, Meike Kuhn, Nico Leupold, Simon Biberger, Philipp Ramming, Anna Kohler, Ralf Moos, Eva M Herzig and Fabian Panzer; University of Bayreuth, Germany

In recent years, halide perovskites have attracted much attention due to remarkable increase in associated solar cell efficiencies, which were achieved by processing high quality thin films. Here, even small differences in film morphology seem to be relevant for optimized optoelectronic functionality and stability. However, a detailed understanding of how small morphological differences in perovskite films affect related structural and optoelectronic properties has not yet been fully developed.
Here, we investigate the influence of small morphology differences induced in $MAPbI_3$ thin films by (hot-)pressing, characterized by small increase in crystallographic orientation and grain size, on the structural properties phase transition, defects and energetic disorder. To this end, we perform detailed analyses of temperature-dependent absorption and PL measurements between 300 K and 5 K. We use $MAPbI_3$ thin films prepared by a completely dry processing approach, comprising film formation based on mechanochemically synthesized $MAPbI_3$ powder via powder aerosol deposition method [1,2], followed by (hot-)pressing. The latter has emerged as an attractive method for manufacturing and post-treatment of perovskite films [3,4]. Detailed temperature-dependent absorption and PL analyses reveal lower strain, decreased defect density and less energetic disorder in films with higher out-of-plane orientation and grain size. To resolve even small differences in static energetic disorder, suitable, powerful analysis methods of the Urbach energy are presented.
Our results demonstrate the importance of considering even small morphology differences in halide perovskite films regarding related structural and optoelectronic film properties. The gained knowledge will facilitate identifying structural differences in halide perovskites to further optimize their functionality and stability.

Perovskite/Graphene Sandwiches—Halide Perovskite Heterostructures with Blocked Anion Diffusion Matthew Hautzinger, Steven Harvey, Matthew C. Beard, Joseph Luther and Jeffrey Blackburn; National Renewable Energy Laboratory, United States

Halide perovskites exhibit notoriously fast anion diffusion. This intrinsic material property has hindered advancements in the growth of halide perovskite heterostructures $APbX_3/APbX'_3$ (where X and X' are different halide species), as the halides quickly diffuse across the heterojunction forming an alloy. This inability to grow heterostructures severely limits the utility of halide perovskites as semiconductors, as they are not at parity with the complex heterostructures accessible with traditional semiconducting materials. Here we present the growth of such halide perovskite heterostructures by depositing single layer graphene in between two perovskite layers, $CsPbBr_3$ and $CsPbI_3$. The heterostructure shown, $CsPbBr_3$/Graphene/$CsPbI_3$, shows no anion diffusion after being stored in ambient conditions over long periods of time. In contrast, $CsPbBr_3/CsPbI_3$ deposited sequentially rapidly form alloys of $CsPb(Br_{3-x}I_x)$. A suite of characterizations convincingly demonstrate that the heterojunction formed is sharp and no apparent halide diffusion occurs. DFT calculations, UPS, and TA spectroscopy show there is a type I band alignment between the perovskites in this system and that the graphene has little effect on the interactions of the two perovskite materials. Furthermore, the deposition process for integrating graphene with halide perovskites is extremely facile and does not require expensive laboratory equipment. As such, we believe this can enable numerous advances in halide perovskite research, across many research groups, including more advanced heterostructure architectures, graphene enhanced perovskite device stability, and fundamental studies on halide perovskite/2D materials research.

5:00 PM EL02.09.30
Effect of Light Soaking on the Charge Extraction and Recombination Dynamics of Perovskite Solar Cells Abasi Abudulimu[1,2], Agustin M. Ontoria[2], Zhaoning Song[1], Iwan zimmerm[3], Jose Santos[2], Juan Cabanillas[2], Nijiati Aimaiti[2], Manoj Rajakaruna[1], You Li[1], Lei Chen[1], Sheng Fu[1], Adam Phillips[1], Michael J. Heben[1], Mohammad K. Nazeeruddin[3], Nazario M. Leon[4,2], Yanfa Yan[1] and Randy Ellingson[1]; [1]University of Toledo, United States; [2]Imdea Nanociencia, Spain; [3]EPFL VALAIS, Switzerland; [4]Universidad Complutense de Madrid, Spain

Through a decade of intensive research and development, over 25% of power conversion efficiency has been achieved in perovskite solar cells, placing it in direct competition with silicon-based solar cells. Further improvement toward theoretical limits relies on a better understanding of the charge dynamics in the device under operational conditions. Charge carrier recombination and extraction rates are key parameters that directly define the device performance. However, there are notable variations among the values reported for the device made with the same material and device stacks. Here, we study the charge extraction and recombination dynamics in perovskite solar cells based on the most common compositions, including prototypical methylammonium lead iodide ($MAPI_3$), formamidinium (FA)-cesium lead iodide ($FA_{0.95}Cs_{0.05}PbI_3$), triple-cation lead halide ($[(FAPbI_3)_{0.87}(MAPbBr_3)_{0.13}]_{0.92}[CsPbI_3]_{0.08}$), and mixed tin-lead iodide ($FA_{0.7}MA_{0.3}Sn_{0.5}Pb_{0.5}I_3$) perovskites via transient photovoltage and photocurrent (TPV/TPC) techniques under various illumination intensities and light soaking conditions. We also investigated the effect of a hole transporting layer (Spiro-OMeTAD derivative referred to as HTM3) on $MAPI_3$-based devices under the same experimental conditions. We found that the TPV and TPC traces vary significantly with light soaking in terms of TPV/TPC amplitudes and lifetimes of the fast and slow components, depending on both perovskite and HTM. On the triple-cation lead halide perovskite-based device, the effect occurs on the TPC, while on the $MAPI_3$-based device with HTM3, it appears on the TPV. Careful analysis of the data, including the reproduction of short-circuit current densities and open-circuit voltages of each device measured at various light intensities using the parameters extracted from TPV/TPC, revealed that the variation in TPV/TPC of the light-soaked devices relates to the changes in perovskite composition and perovskite-HTM interface.

5:00 PM EL02.09.31
Top-Down Approach Using Laser Ablation to Achieve High-Performance Semitransparent Perovskite Solar Cells Mayank Kedia[1,2], Monika Rai[1] and Michael Saliba[1,2]; [1]University of Stuttgart, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Semitransparent perovskite solar cells (ST-PSCs) act as promising candidates for building-integrated photovoltaics (BIPVs) as windows and facades. An optimum balance between the power conversion efficiency and transparency in the visible range is required to satisfy these requirements. Amongst many ways to increase the transmittance of halide perovskite thin films, decreasing the absorber thickness by spin coating with the diluted solution is the most

common way. However, these ultrathin films are discontinuous and have often pin-holes due to low concentrations of precursor ink. Thus, achieving a uniform and continuous ultrathin film with reliable scalability is of pressing need.
Here, we employ a top-down approach where a pulsed UV laser is used to etch a thick pre-crystallized film till the desired transparency is achieved without any structural damage. A regressive decrease in the perovskite film thickness from ~500 nm up to ~100 nm is achieved by controlling the laser fluence and exposure time. To obtain an average visible transmittance (AVT) of >22%, the perovskite film is laser ablated to ~ 250 nm. The developed semitransparent devices without any additives have shown a high PCE of > 14%. Additionally, a remarkable PCE of >11 % is achieved for a ~ 100 nm thick perovskite solar cell with ~ 30 % AVT. The results highlight an innovative fabrication method of laser thinning together with patterning to improve high-efficiency semitransparent PSCs while maintaining their transparency.

5:00 PM EL02.09.32
Structural and Electronic Studies on the All-Inorganic $CsPb(I_{1-x}Br_x)_3$ Perovskite in Terms of Light Soaking, Interfacial Layers and Crystallization Kinetics for Efficient and Stable Solar Cells Xiao Wu and Xinhui Lu; The Chinese University of Hong Kong, Hong Kong

Organic-inorganic hybrid perovskites have shown promising applications in optoelectronic devices. However, the volatile nature of organic cations such as methylammonium (MA^+) and formamidinium (FA^+), imposes intrinsic thermal stability issues. To this concern, inorganic $CsPbX_3$ ($X=I^-$ or Br^-) perovskites have attracted rising interest in recent years, owing to their excellent thermal stability and suitable bandgap for tandem applications with narrow-bandgap solar cells such as crystal silicon and CIGS. However, on one hand, the efficiencies of inorganic perovskite solar cells (PSCs) are still lagging behind the hybrid counterparts, demanding fundamental studies on the crystallization mechanisms for high-quality films and the interfacial modifications for efficient charge collection. On the other hand, operational stability under light illumination has always been a concern for solar cells, especially for the halide perovskites with easily mobile halide ions. **Here, we will first present a remarkable light soaking (LS) induced performance enhancement of $CsPb(I_{1-x}Br_x)_3$ PSCs.**[1] **We clarified the impact of light and radiative heating on the crystal structure via in situ grazing-incidence wide-angle X-ray scattering measurements (GIWAXS)** and elucidated the common LS phenomenon in $CsPb(I_{1-x}Br_x)_3$ with various Br/I ratio, which is related to ion migration. Also, we proposed an effective means to suppress the LS effect for obtaining more stable and efficient $CsPb(I_{1-x}Br_x)_3$ PSCs. **Second, we report an efficient low-temperature processed ZnO electron transporting layer engineered by incorporating PbX_2 ($X=I^-$, Cl^- and $CH3COO^-$).**[2] This method could tune the oxygen vacancies in ZnO, promote the growth of the perovskite layer with improved morphology and orientational order, and form a favorable energy level alignment with the perovskite layer, thus facilitating charge extraction and suppressing charge recombination. **Finally, we elucidate the phase transition mechanism of inorganic $CsPb(I_{1-x}Br_x)_3$ from precursor state to perovskite film via GIWAXS measurement and DFT calculations.** It was discovered the phase transition was not a simple conversion from the room-temperature stabilized yellow δ-phase to the high-temperature stabilized black phase. Instead, a multistage phase transition of the γ-δ-γ regime was found throughout the annealing process, resulting in poor film quality. To address this issue, we proposed a method to suppress the transition to δ-phase during heating and achieved efficient (20.1%) and stable $CsPb(I_{1-x}Br_x)_3$ solar cells.

Metal halide perovskite solar cells (PSCs) are an emerging photovoltaic technology with the potential to disrupt the mature silicon solar cell market. Great improvements in device performance over the past few years, thanks to the development of fabrication protocols, chemical compositions and phase stabilization methods, have made PSCs one of the most efficient and low-cost solution-processable photovoltaic technologies. However, the light-harvesting performance of these devices is still limited by excessive charge carrier recombination. Despite much effort, the performance of the best-performing PSCs is capped by relatively low fill factors and high open-circuit voltage deficits (the radiative open-circuit voltage limit minus the high open-circuit voltage). Improvements in charge carrier management, which is closely tied to the fill factor and the open-circuit voltage, thus provide a path towards increasing the device performance of PSCs, and reaching their theoretical efficiency limit. Here we report a holistic approach to improving the performance of PSCs through enhanced charge carrier management. First, we develop an electron transport layer with an ideal film coverage, thickness and composition by tuning the chemical bath deposition of tin dioxide (SnO_2). Second, we decouple the passivation strategy between the bulk and the interface, leading to improved properties, while minimizing the bandgap penalty. In forward bias, our devices exhibit an electroluminescence external quantum efficiency of up to 17.2 per cent and an electroluminescence energy conversion efficiency of up to 21.6 per cent. As solar cells, they achieve a certified power conversion efficiency of 25.2 per cent, corresponding to 80.5 per cent of the thermodynamic limit of its bandgap.

5:00 PM EL02.09.36
Vacuum Deposition of Thermally Stable Perovskite Solar Cells Qimu Yuan[1], Kilian Lohmann[1], Robert Oliver[1], Alexandra Ramadan[1,2], Siyu Yan[1], James Ball[1], Greyson Christoforo[1], Nakita K. Noel[1], Henry Snaith[1], Laura Herz[1] and Michael Johnston[1]; [1]University of Oxford, United Kingdom; [2]University of Sheffield, United Kingdom

Vacuum deposition is a solvent-free method which has proven suitable for growing thin films of metal-halide perovskites (MHPs) [1] and charge-transport layers. Vacuum-based methods offer a diverse array of advantages, including precise control of layer thickness, excellent uniformity and homogeneity of the formed thin film, choice over a wide range of materials and compositions, and the flexibility to grow multi-layer structures and larger-scale modules without the need to rely on complex choices of “orthogonal solvents”. In particular, we have elucidated a multi-source co-evaporation process of formamidinium-caesium (FACs)-based perovskite thin films. Excellent device performance was obtained when such vapour-deposited perovskite intrinsic layer was incorporated into an “inverted” p-i-n solar cell architecture, owing to reduced defect density and improved charge-carrier lifetimes [2].

However, most reports of high-efficiency solar cells based on vacuum-deposited MHP films often utilise solution-processed hole transport layers (HTLs) such as PTAA or Spiro-OMeTAD. Not only are these HTLs relatively expensive, and the additional solution-processing step complicates the overall fabrication process, but also more critically, materials such as Spiro-OMeTAD are prone to degradation under different environmental stressors of temperature and humidity, and thus curtailing the operational lifetime of these devices.

We investigated organometallic copper phthalocyanine (CuPc) and zinc phthalocyanine (ZnPc) as alternative, low cost, and durable HTLs in all-vacuum-deposited solvent-free $[CH(NH_2)_2]_{0.83}Cs_{0.17}PbI_3$ ($FACsPbI_3$) perovskite solar cells. We reveal that the vacuum-deposited CuPc HTL demonstrated improved compatibility in a photovoltaic device with p-i-n configuration, in comparison with ZnPc. Furthermore, we thoroughly examined the long-term stability of these all-vacuum-processed devices under a range of testing conditions. Importantly, unencapsulated devices as large as 1 cm^2 exhibited outstanding thermal durability, demonstrating no observable degradation in efficiency after more than 5000 hours in storage and 3700 hours under 85 °C heat-stressing in N_2 atmosphere [3].

In addition, we uncover the striking differences in the sticking, adhesion, and nucleation of the organic perovskite precursor, formamidinium iodide (FAI), to various HTLs. We highlight the impact of varying sticking characteristics to the stoichiometry of co-evaporated perovskite films and the importance of optimising growth parameters specific to individual charge transport layer if FAI is to be used as a precursor in co-evaporated perovskites [3].

Engineered Negative Pressure in Nanoscaffolded $CsPbI_3$ Imparts Thermodynamic Stability and Optical Tunability to the Perovskite Phase Arkita Chakrabarti and Aaron Fafarman; Drexel University, United States

Strain at heterointerfaces in functional composite materials is inevitable and has in 2D geometries been intentionally engineered to improve superconductivity, ferromagnetism, and phase stability. As an example, tensile strain generated due to the mismatch in thermal expansion coefficients between thin-film $CsPbI_3$ and its substrate (so called substrate-clamping) has been shown to impart metastability of the otherwise unstable perovskite phase at room temperature. However, such substrate-induced stress is biaxial, resulting in an opposing strain in the third, orthogonal axis. Herein, we extend such engineered interfacial strain to all three dimensions to approximate the condition of 'negative pressure,' i.e., 3D tensile stress. Using a generalizable approach, we show negative pressure stabilizes the symmetric, low density, cubic perovskite phase of $CsPbI_3$, which is a promising absorber material for photovoltaic devices. In this work, we crystallized $CsPbI_3$ in the perovskite phase inside rigid oxide scaffolds at elevated temperatures and quenched them. Given the extremely low modulus of $CsPbI_3$, when it is synthesized within a rigid, ordered metal-oxide nanoscaffold at high temperature and then rapidly quenched, a tensile interfacial stress is generated. The three-dimensional tensile strain generated by this thermally induced stress differs from its biaxial counterpart in that it can thermodynamically favor high symmetry crystal phases i.e., the functional perovskite phase. We used X-ray diffraction and high-resolution transmission electron microscopy to identify the phase and estimate lattice expansion as a function of thermal excursions imposed on the $CsPbI_3$-scaffold composite. Furthermore, photoluminescence studies showed bandgap tunability as a consequence of negative pressure. Such an experimental materialization of 3D-interfacial stress or "negative pressure" to access the thermodynamically forbidden phases and tune optoelectronic properties of a perovskite material has been demonstrated for the first time in this work.

5:00 PM EL02.09.38
Stability Enhancement of Ambient Fabricated Perovskite Film Using Ionic Liquid Dopant Supawinee Chaosukho[1], Sorrawit Meeklinhom[2], Sasiphapa Rodbuntum[2], Nuttaya Sukgorn[2], Anusit Kaewprajak[2], Pisist Kumnorkaew[2] and Paiboon Sreearunothai[1]; [1]Sirindhorn International Institute of Technology, Thammasat University, Thailand; [2]National Science and Technology Development Agency, Thailand

The stability of the perovskite film is a crucial factor that challenges the commercialization of Perovskite solar cells (PSCs). It can be affected by factors such as moisture, oxygen, light, and temperature. Another critical factor in the fabrication of PSCs is the ability to deposit the perovskite film in ambient conditions rather than in an inert atmosphere (N_2). To address these issues, this study aims to improve the stability of the perovskite film by adding ionic liquid, such as 1-butyl-3-methylimidazolium tetrafluoroborate ($BMIMBF_4$) and 1,3-dimethyl-3-imidazolium hexafluorophosphate ($DMIMPF_6$), to the perovskite precursor using a two-step deposition method in ambient air. The degradation of the perovskite film was observed under high relative humidity (around 70-80% RH) without encapsulation.
Results from UV-visible spectroscopy showed that the best stable perovskite film with the $BMIMBF_4$ ionic liquid additive achieved 144 hours of α phase perovskite film without changing absorbance and also prolonged the perovskite structure for over 240 hours before being entirely degraded into the undesirable δ phase. $DMIMPF_6$ also showed potential for longer stability than the control film without an ionic liquid additive and could be doped into both the PbI_2 layer (step one) and the FAI/MAI layer (step two). Adding ionic liquids also improved the hydrophobicity of the perovskite film. X-ray diffraction results showed that the film with an ionic liquid dopant could suppress residual PbI_2 compared to the one without an ionic liquid. Overall, this study presents promising results for the large-scale fabrication of stable PSCs.

Approaches to Enhancing Efficiency of Tin Based Perovskite Solar Cells Shuzi Hayase; University of Electro-Communications, Japan

Tin based perovskite solar cells (Tin perovskite solar cells (Sn PVK PV) and Tin-Lead alloyed perovskite solar cells SnPb PVK PV) have attracted attention for Pb free PVK PV and narrow band gap PVK PV working as the bottom cells of PVK/PVK tandem solar cells, respectively. At the beginning of the research, these Tin PVK PV efficiencies were low, compared with those of the Pb PVK PVs, because of the presence of the high carrier trap density associated with various lattice defects including the grain boundary and carriers due to the formation of Sn4+ (self-doping)(1). We have reported that the formation of Sn4+ was suppressed by the addition of small amount of GeI2 (2) and the grain boundaries defects were decreased by ethylenediamine passivation (3). In addition, the ethylene diamine passivation made the Fermi level of the Sn-PVK surface shallower, which causes the band bending near the grain boundary. Because of the band-bending, electron injection from the Sn-PVK layer to n-type layer (fullerene) was accelerated by around 10 times and the charge injection of the holes (from Sn-PVK to hole transporting layer (HTL)) and that of the electrons (from Sn-PVK to electron transporting layer (ETL)) were balanced. By combining these defect suppression engineering, the efficiency of Sn-PVK PV with inverted structure was enhanced to 13.2%

(4). PEDOT-PSS is commonly employed for the HTL of the Sn-PVK PV. From the viewpoint of the stability, inorganic HTLs have advantage over organic HTLs. We found that SnOx (x=1.7-1.8, 10 nm thickness) prepared by plasma-oxidized Sn metal layer is worked for the HTL of the Sn-PVK PV. In addition, the electron injections from the Sn-PVK to fullerene is accelerated by inserting ultrathin plasma-oxidized Sn metal layer (1 nm thickness). These heterointerface engineering enhanced the efficiency of the Sn-PVK PV to 14.1%(5). These defect suppression methods were effective for enhancing the SnPb-PVK PV with narrow bandgap (around 1.2 eV). By introducing mixed monolayer HTL which probably increases the efficiency of the SnPb-PVK PV was enhanced from 23.3%(6).

8:45 AM *EL02.10.02
Structure and Mechanism of Crystallization in 3D and 2D Sn-Based and Mixed Sn-Pb Perovskites Giuseppe Portale; University of Groningen, Netherlands

Three dimensional (3D) perovskite materials with an ABX_3 structure (where A is either an organic or an inorganic cation, B is a divalent metal cation, and X is a halide anion) have demonstrated superb properties as light absorbers in photovoltaic devices. Lead (Pb) based hybrid perovskite solar cells (HPSCs) have achieved an impressive power conversion efficiency (PCE) up to a certified 25.5%.[1] Despite these outstanding achievements, the toxicity of lead causes concerns for the health and the environment. Therefore, attention has recently turned towards lead free HPSCs with the idea of replacing lead by less toxic metals. Among the various alternatives to lead, tin (Sn) has great potential as the Sn based hybrid perovskites display excellent optical and electrical properties such as high absorption coefficients, small exciton binding energies, and high charge carrier mobilities.[2] However, much less is known about Sn-based perovskites, especially about their crystallization mechanism from solution.
Another important aspect is the stability of the perovskite systems when exposed to light and to environmental conditions different than inert atmpsphere. An efficient way to improve HPSCs' stability, is to use the so-called miced dimensional systems, where an amount of 2D perovskite material is added to the 3D perovskite.
For instance, the addition of different amounts of low-dimensional PEA_2SnI_4 perovskite to $FASnI_3$ to form a 2D/3D composed system increases the stability against humidity and improves the performances to a value of PCE as high as 9.0 %.[3] Recently, the efficiency of Sn HPSCs is increased to 14%.[4] Similar approaches were also used to improve the properties of mixed Sn Pb systems.
Key of the reported performance and stability improvement is the formation and distribution of highly aligned structure that occurs during the perovskite solution deposition.
In this contribution, I will report our findings in understanding the formation mechanism during spin coating of this aligned structure in some of these mixed 2D/3D systems. In particular, our approach is to use in-depth structural analysis by ex-situ and in-situ gracing incidence wide angle X-ray scattering (GIWAXS). The ex-situ analysis is performed in a depth resolved manner in our laboratory, while the in-situ data are gathered using a custom-made spin coating device interfaced with 3rd generation synchrotrons.[5]
Our structural findings reveal that the vertical distribution of the 2D phase is crucial to the HPSC performances and stability, but most importantly, the presence of the long cations from the 2D precursor material alters the crystallization pathways during drying, promoting surface nucleation that drives guided crystallization of 3D-like crystals with preferred orientation.

Improving Efficiency and Stability of Wide-Bandgap Perovskite Solar Cells Through $PEABF_4$ Passivation Layer Jaehyuk Koh, Daehan Kim and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In order to realize perovskite-based tandem solar cells that can overcome the theoretical efficiency of a single junction solar cell, active research efforts are being conducted on wide-bandgap (WBG) perovskite solar cells (bandgap ~ 1.7 eV). However, WBG perovskite solar cells still lag behind the current state-of-the-art single junction solar cells based on regular bandgap (1.5 – 1.6 eV) perovskite in both efficiency and stability, mainly due to halide segregation and incomplete passivation of grain boundaries and interfaces which act as a recombination center. To overcome these issues, a passivation strategy using two-dimensional (2D) perovskite, which preferential forms at grain boundaries and interfaces, has been used and shown to suppress halide segregation and passivate defects at the internal and external surfaces. In this study, double passivation strategy were proposed where grain boundaries of WBG perovskite, $(FA_{0.65}MA_{0.2}Cs_{0.15})Pb(I_{0.8}Br_{0.2})_3$, are passivated with 2D layers formed by PEAI and PEASCN while electron transporting layer (ETL)/perovskite interface is passivated by $PEABF_4$. Steady-state and time-resolved photoluminescence confirmed that the introduction of $PEABF_4$ reduced non-radiative recombination, and space-charge-limited current measurement for electron-only device revealed a reduce trap density compared to a reference without the $PEABF_4$ passivation. With our comprehensive passivation approach, we have achieved a very high V_{OC} of 1.21 V along with the champion efficiency of 19.5%. We have also demonstrated a shelf lifetime stability of 1400 hours and 240 hours under N_2 atmosphere and ambient air (RH: 30~40%), respectively.

Ultrafast Dynamics in 2D and Mixed 2D/3D Hybrid Metal Halide Perovskites Rebecca L. Milot; University of Warwick, United Kingdom

Two-dimensional hybrid metal halide perovskites have been investigated for use in optoelectronic devices including photovoltaic cells due to their increased stability as compared to their 3D counterparts. However, quantum and dielectric confinement effects increase the exciton binding energies in these materials to as much as 100s of meV.[1] These increased binding energies correspond to an increase in exciton population at ambient temperatures, and the presence of a large population of excitons can greatly alter the optoelectronic properties. Optical Pump/THz-probe (OPTP) spectroscopy measurements have revealed decreased effective charge-carrier mobilities and significantly shortened charge-carrier lifetimes for 2D perovskites.[2] We further investigate 2D perovskites by analyzing the fundamental properties of $PEAPbI_4$ (PEA = phenylethylammonium) and evaluating a mixed phase Pb-Sn and FA-PEA perovskite using both OPTP and visible transient absorption spectroscopy. Through these investigations, we see similar fast charge-carrier cooling and exciton formation in timescales of about 300 fs in all compositions, which result in decreased effective charge carrier mobilities at later times. However, mixed-phase materials exhibit increased charge-carrier, but these lifetimes are sensitive to morphology and preparation method.

10:30 AM EL02.11.02
Understanding Factors that Induce Static and Dynamic Stress in Metal Halide Perovskites Gabriel McAndrews[1,2], Boyu Guo[3], Benjamin Lefler[3], Aram Amassian[3] and Michael D. McGehee[1,1]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States; [3]North Carolina State University, United States

The operational stability of metal halide perovskite devices hinders their commercial viability despite promising, competitive initial efficiencies. Mechanical stress in perovskites is often overlooked but significantly influences degradation as the presence of tensile stress has been shown to accelerate undesirable PbI_2 formation.[1,2] In addition, the brittle nature of polycrystalline metal halide perovskite films leaves them susceptible to fracture and delamination.[3] Therefore, it is crucial to identify and reduce sources of residual tension that arise from film formation processes. For one, several studies have highlighted the coefficient of thermal expansion (CTE) mismatch between the perovskite and rigid substrates, such as glass, which can induce tension.[2,4] Thermal annealing is essential to promote crystallization for solution processed perovskites, but during the cooldown the crystallites are confined to the substrate and unable to contract with their intrinsic CTE.

Strain engineering approaches to reduce tension or induce compression in perovskites have been primarily focused on molecular precursor or antisolvent additives. However, many strategies lack explanations grounded in thin-film mechanics.[5] Here, we demonstrate perovskite residual stress dependent on composition that cannot be explained solely by variations in CTEs. For example, with standard processing conditions a tin-containing narrow bandgap perovskite ($Cs_{0.25}FA_{0.75}Sn_{0.5}Pb_{0.5}I_3$) exhibits a residual stress of ≈100 MPa whereas the heavily studied “Triple Cation” perovskite ($Cs_{0.05}MA_{0.16}FA_{0.79}Pb(I_{0.83}Br_{0.17})_3$) has near zero stress. Additional sources of stress beyond the CTE mismatch are identified in connection with film formation kinetics to explain the varied stresses in perovskites. Specifically, grain coalescence, adatom/impurity insertion into grain boundaries, phase transitions, and partial attachment of crystallites to the substrate are likely contributors to stress.

We present a broadened perspective on stress engineering and propose new connections between stability and stress. For example, moisture and oxygen uptake can induce compression in perovskites that could be explain the accelerated PbI_2 formation with tension. Finally, the impact of temperature cycling on stress and mechanical stability for perovskite photovoltaics in both terrestrial and space applications are discussed. Due to the CTE mismatch, biaxial tensile stress can be substantial at subzero. Using strategies to have the stress be near zero or compressive at room temperature will be essential to avoid cracking at low temperature extremes.

10:45 AM EL02.11.03
Effective Surface Passivation by *In Situ* Thermal Phase Transition for Highly Efficient Perovskite Solar Cells Dohyun Kim, Seung Un Ryu and Taiho Park; Pohang university of science and technology (POSTECH), Korea (the Republic of)

In this work, we investigated an effective interfacial engineering of perovskite solar cells (PSCs) by adopting in Situ thermal phase transition of alkylammonium formates (AAFos). AAFo, which consists of large organic cation with pseudo-halide anion, can participate in passivation proced as liquid phase at relative low temperature due to the weak coordination between the cations and anions. Thanks to this property, AAFo can give several advantages for the interfacial engineering: (1) Increase of liquid-like behavior of AAFo can effectively passivates into the grain boundaries to reduce trap densities of perovskites. (2) formate anion has relatively higher affinity with iodide vacancies than other halides, leading effective passivating at iodide vacancies for improved thermal stability. (3) Long alkyl chain of decylammonium cations improve moisture stability by preventing the moisture permeation into the perovskite layer. As a result, we achieved 25.0% of power conversion efficiency (PCE) with dodecylammonium formate and superior thermal stability maintaining over 92% of initial effieciency under 85°C N_2 condition. Finally, we achieved a high efficiency of 20.82% will superior fill factor (80.77%) in module PSC with an active area of 23.75 cm^2, proving the suitability of the strategy for manufacturing large-area devices.

11:00 AM DISCUSSION TIME

11:15 AM EL02.11.06
Visualizing Voltage Losses in Highly Efficient and Stable Perovskite-based Tandem Solar Cells Esma Ugur[1], Jiang Liu[1], Erkan Aydin[1], Michele De Bastiani[1], Mingcong Wang[1], Sam Teale[2], Bin Chen[2], Randi Azmi[1], Hao Chen[2], Aidan Maxwell[2], Edward H. Sargent[2], Frédéric Laquai[1] and Stefaan Dewolf[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]University of Toronto, Canada

To achieve higher electricity generation at low cost, the most substantial impact on the energy generation from solar cells is to make existing technologies more efficient per area. This forms the focus of tandem solar cells, which utilize different photoactive materials with different bandgaps, allowing to benefit from a broader range of the solar spectrum. To make efficient and stable perovskite-based multi-junction (e.g. perovskite/silicon and perovskite/perovskite tandem) solar cells – also single-junction ones –, it is important to understand the losses under device operational conditions.[1] To do so, we used absolute (photo- and electro-) luminescence imaging techniques with high spatial resolution.
On the device level, recombination losses could occur either in the bulk of the perovskite or at the adjacent transport layer interfaces. Here, we visualized the interfacial recombination losses using hyperspectral imaging system by analyzing the data with home-built MatLab code. We investigated how the different passivation routes affect the quasi Fermi level splitting (QFLS) of the samples together with device performance, also the stability under different external stressors. In the case of single junction perovskite devices, the focus was on 2D perovskite layers at the electron-selective interface that passivate the trap states and suppress the ion migration. Also, the alternative passivation routes for wide bandgap perovskites such as ammonium-based passivation molecules were studied. These molecules regulate this interface that results in absolute 90 meV enhancement in QFLS. Finally, we further investigated the p-i-n perovskite/silicon monolithic tandem solar cells. Reducing the trap states at perovskite/C_{60} interface both for single-junction and tandem solar cells not only enhances the device performance but also the stability of the devices after damp-heat testing (85°C at 85% relative humidity).[2, 3] Further, origin of the perovskite top cell degradation in perovskite/silicon tandem devices after field test experiments was demonstrated via PL imaging.[4]

SESSION EL02.12: Perovskite Solar Cell
Session Chairs: Xuedan Ma and Yuanyuan Zhou
Thursday Afternoon, April 13, 2023
Moscone West, Level 3, Room 3002

1:30 PM *EL02.12.01
The Origin of Moisture Instability in Perovskite Solar Cells Chunqing Ma[1], Felix T. Eickemeyer[2], Sun-Ho Lee[1], Dong-Ho Kang[1], Seok Joon Kwon[1,1], Michael Grätzel[2,1] and Nam-Gyu Park[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]École Polytechnique Fédérale de Lausanne (EPFL), Switzerland

Since the seminal work on 9.7% efficient solid-state perovskite solar cell in 2012, its power conversion efficiency reached over 25% within a decade. Organic lead halide perovskite as a light absorber for PSCs, however, is unstable under moisture, where the moisture instability was assumed to be due to its ionic nature without in-depth understanding. Although a preponderance of methodologies have been proposed to improve the moisture stability of perovskite films, the origin of moisture instability is still unveiled. We found for the first time that a specific facet in perovskite film was responsible for the moisture instability. Among three facets of (100), (110) and (111) in a cubic structured film, a certain facet was unstable but a certain facet was quite stable under moisture. Experimental combined with theoretical studies revealed that a crystal facet with moisture instability provided a strong water adhesion via the hydroxylation of Pb atoms, leading to phase transformation. Perovskite film where moisture-tolerant crystal facet is abundant was designed and successfully prepared, which showed exceptional stability against moisture without additional surface passivation.

2:00 PM EL02.12.02
Encapsulation of Perovskite Solar Cells Robert Witteck[1], Tobias Abzieher[1], Xiaopeng Zheng[1], Ashley Gaulding[1], Min Chen[1], Brian Habersberger[2], Joseph Luther[1] and Lance M. Wheeler[1]; [1]National Renewable Energy Laboratory, United States; [2]Dow, United States

We study the effect of varying encapsulation polymers and vacuum lamination processes on the electrical properties of perovskite (PSK) solar cells with varying hole transport layer (HTL). In order improve the performance and long-term stability of perovskite solar cells (PSC) it requires a suitable encapsulation material. Yet there is very little work done for understanding what appropriate materials and processing conditions for PSC are.
In this work we investigate PSC with pin architecture, which consists of a glass/ITO/HTL/PSK/LiF/C60/BCP/Ag structure. We employ four different HTL

materials to investigate the effect of the high temperature lamination process on the PSC performance. The PSC are encapsulated at varying lamination conditions with a peak lamination temperature of 125 or 150°C and a total process duration of 12 or 20 min. We employ different polymers for the encapsulation using a conventional peroxide-cured ethylene-vinyl acetate (EVA) and polyolefin elastomers (POE) as well as a low and high crystalline silane and anhydride grafted POE. Subsequent to the lamination we test the long-term stability of the encapsulated PSC in thermal cycling (TC) tests in N_2 atmosphere, where the environmental temperature is varied between -40°C and 85°C holding each temperature for 25 min. Besides *IV* characteristics we perform time resolved electroluminescence (EL) and photoluminescence (PL) imaging measurements.
Our results show that samples with 2PACz HTL yield the highest cell efficiency of 20.0% on average for all samples. Further these cells show the best process stability when comparing the pre and post lamination *IV* parameters. The lamination of the PSC with varying process durations and temperatures reveal that all PSC show a loss in power conversion efficiency, when measured immediately after the lamination. The efficiency loss correlates with the thermal budget of the lamination process, i.e., the hotter and longer the lamination process the higher the efficiency loss. All samples show a recovery in efficiency when stored in N_2 atmosphere after the lamination. However, only samples laminated with a cool and short process show a full recovery back to the initial efficiency. EL and PL images show the formation of dead areas after the lamination, where the size of the dead area grows with increasing thermal budget. We hypothesize that a dead area of a certain size may be able to recover when stored at RT in N_2 atmosphere, while for a dead area above a certain size the recovery is irreversible. A comparison of the various encapsulation materials shows no significant differences when comparing the *IV* parameters before and after lamination. However, we observe slight advantages in stability for the silane grafted POE after 40 TC. At the conference we will present further details on our lamination experiments and the various TC tested encapsulation polymers with up to 200 TC.

2:15 PM EL02.12.03
2D Pb-Halide Perovskites Can Self-Heal Photodamage Better Than 3D Ones Sigalit Aharon[1], Davide R. Ceratti[2], Naga P. Jasti[3], Llorenç Cremonesi[4], Yishay Feldman[1], Marco A. Potenza[4] and David Cahen[1]; [1]Weizmann Institute of Science, Israel; [2]Institut Photovoltaïque d'Ile-de-France, France; [3]Bar-Ilan University, Israel; [4]University of Milan, Italy

Adding a 2D character to halide perovskite (HaP) active layers in ambient-protected cells can improve their stability drastically, which is not obvious from the hydrophobic large cations that force the HaP into a 2D structure. We report now, using two-photon confocal microscopy to study the interior of single crystal, inherent photo-stability of pure 2D Pb iodide HaPs. Compared to 3D HaP crystals, the 2D ones have higher photo-stability and, under conditions equivalent to a few suns, they self-heal efficiently after photo-damage. Using both photoluminescence (PL) intensities (as function of time after photo-damage), and spectra, we compare the self-healing dynamics of 2D HaPs with n=1 or 3 ($(C_4H_9NH_3)_2PbI_4$, $(C_4H_9NH_3)_2(CH_3NH_3)_2Pb_3I_{10}$) and 3D $MAPbI_3$. We find differences between the 2D HaPs in their response to photo-damage and ability to self-heal from different degrees of photo-damage. Based on our findings we suggest a possible chemical mechanism for photo-damage and self-healing of these 2D HaPs: the layered lattice arrangement limits out-diffusion of degradation products, facilitating damage reversal, leading to increased 2D HaP photo-stability, also improving self-healing uniformity. One of the implications of the layered structures' resilience is transfer of their increased stability to devices, based on them, such as photovoltaic solar cells and light-emitting diodes.

2:30 PM BREAK

SESSION EL02.13: Mechanism and Characterization II

3:30 PM *EL02.13.01
***In Situ* and *Operando* Scattering Studies on Perovskite Solar Cells** Peter Muller-Buschbaum; Technical University of Munich, Germany

The first application of hybrid organo-metal halide perovskites as sensitizer in hybrid solar cells marked the cornerstone for what has now become a broad field of extensive research. After overcoming initial challenges, power conversion efficiencies (PCE) of hybrid perovskite photovoltaics strongly increased to above the 25 % mark and now outperform many conventional inorganic thin film technologies for solar cell fabrication. The easy and versatile processing towards an improved stability and reproducibility further increases the massive interest in this type of material. The abundance of precursor materials in combination with the wet chemical processing are rendering hybrid organo-metal halide perovskites as candidates for a low-cost, mass-production photovoltaic technology. However, still the limited reproducibility of the device fabrication and the limited device stability impose challenges to bringing perovskite solar cells to real world applications.
With advanced in-situ x-ray and neutron scattering methods, the perovskite film formation is followed with a very high temporal and spatial resolution. In particular, with multi-modal grazing incidence small- and wide-angle X-ray scattering (GISAXS and GIWAXS) studies, we gain information on the kinetics of inner structures forming during processing. From these data, models about the morphology evolution are extracted and these models guide the fundamental understanding to increase reproducibility in the solar cell fabrication. [1]
Extensive studies have focused on improving the operational stability of perovskite solar cells, but few have surveyed the fundamental degradation mechanisms. One aspect overlooked in earlier works is the effect of the atmosphere on device performance during operation. Here, we investigate the degradation mechanisms of perovskite solar cells operated under vacuum and under a nitrogen atmosphere using synchrotron radiation-based operando GISAXS and GIWAXS. [2]

4:00 PM *EL02.13.02
Light-Induced Structural Dynamics in the Hybrid Perovskites—From Femtoseconds to Seconds Aaron Lindenberg; Stanford University, United States

I will describe recent results focused on elucidating the atomistic response of the hybrid perovskites to light, probing both the ultrafast dynamics that potentially underlies their unique optoelectronic functionalities and the dynamical processes that underlie how these materials degrade. In the first part of the talk I will focus on time-resolved x-ray and electron scattering approaches as applied to a range of material systems including single crystals, thin films, and nanocrystals and describe how these efforts enable new understanding of electron-phonon coupling processes. In the second part I will describe new efforts using cryo-electron microscopy coupled to light to capture structural intermediates during the phase segregation process in mixed-halide perovskite films.

4:30 PM EL02.13.03

Using Multimodal *In Situ* Spectroscopy to Understand the Influence of the Ionic Liquid BMIMBF$_4$ on the Film Formation and Optoelectronic Properties of MAPbI$_3$ Thin Films Simon Biberger, Konstantin Schötz, Nico Leupold, Philipp Ramming, Maximilian Spies, Ralf Moos, Anna Kohler, Helen Grueninger and Fabian Panzer; University of Bayreuth, Germany

Today, metal halide perovskite solar cells are one of the most promising emerging photovoltaic technologies. A key to such highly efficient devices is to realize high-quality perovskite layers, which requires a deep understanding about the perovskite formation and good process control. In-situ experiments have been proven to give important insights into the formation process of the perovskite absorber layer. We use multimodal optical in-situ spectroscopy to further develop an understanding of the thin film formation of the model halide perovskite methylammonium lead iodide MAPbI$_3$ during the one-step processing and the solvent engineering approach. Further, we investigate how the identified formation processes change when we mix a passivating additive, the ionic liquid (IL) BMIMBF$_4$ into the perovskite precursor solution.

One-step processing experiments reveal that IL in the precursor solutions does not affect the formation of perovskite–solvent complexes, but higher IL contents delay the perovskite transformation and decrease growth rates. For solvent engineering, the perovskite growth rate decreases with later anti-solvent (AS) dripping as the properties of PbI$_4^{2-}$ species in the precursor solutions change during drying. Here, the IL also affects the evolution of the PbI$_4^{2-}$ properties, as the IL cation interacts with the PbI$_4^{2-}$. This interaction appears to reduce the perovskite crystallite growth rates after initiating perovskite formation by AS dripping.[1]

Thus, this work shows the sensitive interconnection between precursor properties, film formation process, and final optoelectronic properties of perovskite thin films and how small amounts of additive can impact this relationship. Further, this work highlights the potential of optical in-situ spectroscopy to facilitate more tailored solution processing strategies in the future.

4:45 PM EL02.13.04

Backscattered Electron Imaging for the Instability Analysis of the Structure and Composition of Perovskite Device Cross Sections Abigail Carbone, Mathilde Fievez, Austin Flick, Omar Elsafty, Robert Sinclair and Reinhold H. Dauskardt; Stanford University, United States

The primary obstacle to commercialization of organic-inorganic lead halide perovskites is instability of device performance under operational conditions. Ongoing research efforts are focused on understanding degradation mechanisms of the perovskite absorber, where the structure and chemistry of charge transport interfaces and diffusion of metal species are of particular interest. What has been lacking in these efforts is the application of electron microscopy to directly image and quantify compositional variations and microstructural changes. These would greatly enhance our understanding of phenomena like iodine ion migration, undesirable PbI$_2$ formation, and diffusion of species from adjacent charge transport and electrode layers, all of which lead to diminishing power conversion efficiency.

The goal of this research is to use high-resolution electron imaging techniques to address the fundamental mechanisms that underpin perovskite instability. Scanning electron microscopy (SEM) is a powerful tool for making direct connections between microstructure, composition, and overall device properties. However, using SEM to its full potential is particularly difficult for perovskites because they readily degrade upon incident electron irradiation; they are susceptible to cracking along grain boundaries caused by inelastic-scattering radiolysis of the electron beam[1,2] as well as phase transformations due to localized heating effects[2]. Acquiring compositional information in the SEM using energy dispersive X-ray spectroscopy (EDXS) is not ideal because of diminished elemental sensitivity at the low accelerating voltages and currents required to prevent beam-induced perovskite damage. Additionally, the interaction volume of EDXS is larger than the length scales of our device cross sections.

We circumvent these limitations by employing backscattered electron (BSE) imaging with meticulously optimized beam conditions (e.g., accelerating voltage and beam current), a rigorous set of controls, and delicate sample preparation. We use a low-energy argon mill to create a flat cross-sectional face of photovoltaic cells deposited via a Rapid Spray Plasma Process[3] with the following architecture: ITO/NiO/CsFAPbI$_3$/C$_{60}$/BCP/Ag. We acquire BSE images of as-fabricated devices and devices subjected to accelerated aging conditions to probe the effect of aging on perovskite layer composition. Monte Carlo simulations are implemented to understand the interaction volume of the backscattered electrons generated at our specified beam conditions, and therefore informs the intensity of our subsequent BSE images. We generate intensity profiles along the device cross section using ImageJ. These intensity profiles are compared to a set of controls, which are analyzed in tandem with nano-SIMS depth profiling data to correlate change in BSE image intensity with chemical profiles obtained by SIMS. We studied the correlation of lighter intensity regions on the BSE images to the formation of PbI$_2$ on accelerated thermal aging. These results elucidate the limiting degradation mechanisms of perovskites by leveraging the full potential of SEM imaging in a unique way, and therefore inform direct process engineering solutions for bulk manufacturing of perovskite modules. Additionally, developments in sample preparation of device cross-sections contribute to the ongoing effort to image perovskites using transmission electron microscopy and related analytical techniques.

SESSION EL02.14: Poster Session II

Sub-Diffraction Limited Measurement of Carrier Recombination Dynamics on Lead Halide Perovskite Semiconductors Madeleine Breshears, Rajiv Giridharagopal and David S. Ginger; University of Washington, United States

Traditional optical methods of measuring the spatial heterogeneity of carrier lifetimes—such as fluorescence lifetime imaging (FLIM)—are diffraction-limited, whereas perovskite materials of interest exhibit grain structure at lengthscales far below the diffraction limit. Here, we use time-resolved electrostatic force microscopy (trEFM) to achieve nanoscale spatial resolution of carrier dynamics. trEFM captures the response of the scanning probe cantilever to a perturbation of the electrostatic force gradient between the tip and sample; by monitoring the cantilever oscillation during photoexcitation as a function of wavelength and intensity, we can measure carrier recombination with sub-microsecond temporal resolution. Using this method, we observe slower recombination dynamics in $FA_{0.83}Cs_{0.17}Pb(Br_{0.15}I_{0.85})_3$ on a phosphonic acid-based hole transport layer (HTL) as compared to indium tin oxide substrates, which we correlate these findings with bulk lifetime measurements and FLIM. Finally, we apply trEFM to investigate the spatial heterogeneity in carrier dynamics of a $FA_{0.83}Cs_{0.17}Pb(Br_{0.15}I_{0.85})_3$ when passivated with (3-aminopropyl)trimethoxysilane (APTMS), demonstrating that APTMS-passivation extends carrier recombination lifetimes in perovskite.

5:00 PM EL02.14.05
Additive-Enhanced Aerosol Treatment for Improved Nanoscale Homogeneity, Efficiency and Stability of Perovskite Solar Cells and Photodetectors Joe Briscoe[1], Tian Du[1], Sinclair R. Ratnasingham[1], Thomas J. Macdonald[1], Felix Kasasih[2], Ruoxi Yang[3], Meng Li[4], Zhongyao Jiang[5], Lokeshwari Mohan[1], Adriana Augurio[1], Huda Ahli[5], Shengda Xu[5], Weidong Xu[5], Zhenhuang Su[6], Xingyu Gao[6], Richard Whiteley[1], Chieh-Ting Lin[5], Ganghong Min[5], Saif Haque[5], Kristin Persson[3], Caterina Ducati[2], James Durrant[5] and Martyn A. McLachlan[5]; [1]Queen Mary University of London, United Kingdom; [2]University of Cambridge, United Kingdom; [3]Lawrence Berkeley National Laboratory, United States; [4]Henan University, China; [5]Imperial College London, United Kingdom; [6]Shanghai Institute of Applied Sciences, China

We have previously demonstrated a new approach to solvent-based post-treatment of perovskite films that achieves excellent reproducibility and uniformity by exposing a perovskite film to vapourised solvents delivered via an aerosol-assisted chemical vapour deposition system [1]. Using this process we achieved enhancement of both photovoltaic power conversion efficiency (PCE) and stability in a range of perovskite compositions and device architectures, which we have linked to improvements in both the nanoscale and macroscale uniformity of the material, including a reduction of defects and associated trap states.
Here I will discuss our more recent developments of this process to include organo-halide salts in the solvent aerosol, such as MACl, leading to substantial enhancement of the post-crystallisation grain growth and recrystallisation process [2]. This leads to films that are comprised of ultra-large grains (~1-5 µm) where local traps are almost completely eliminated, as confirmed at the nanoscale via photoconductive atomic force microscopy. The large grains have also allowed us to visualise local variations in photoluminescence (PL) emission at the grain boundaries using hyperspectral PL mapping. Finally, the substantial reduction in trap states and increase of film homogeneity leads to photodetectors that can operate at ~1.5 orders of magnitude lower light levels than those made with conventional spin-coated films.
Expanding beyond solvent post-treatment, we have also applied this technique to pure formamidinium lead iodide ($FAPbI_3$) [3]. Using aerosol-assisted crystallization (AAC) of the $FAPbI_3$ films enhanced by Lewis base additives in the solvent aerosol we are able to crystallise pure black-phase α-$FAPbI_3$ in only 2.5 minutes at 100°C, compared to 20 minutes at 150°C for conventional thermal annealing. Not only does this open up wider processing options for the material, but we demonstrate improvement in PCE and, importantly, phase stability of pure α-$FAPbI_3$ compared to thermally annealed control samples. Using X-ray diffraction, X-ray scattering and density functional theory simulation, we identify that relaxation of residual tensile strains due to the lower annealing temperature and post-crystallization crystal growth during AAC are key factors that facilitate the formation of phase-stable α-$FAPbI_3$.

Highly Stable Inorganic 0D and Quasi-2D Perovskite/Cellulose Nanocrystal Luminescent Films Chih Hao Chiang and Meng Lin Tsai; National Taiwan University of Science and Technology, Taiwan

In the past two decades, 0D perovskite quantum dots (PQDs) attract a lot of attentions in optoelectronic industry and academia due to the narrow emission full width at half maximum (FWHM), tunable bandgap, and high photoluminescence quantum yield (PLQY). Owing to these advantages, PQDs are regarded as the new blue ocean for developing next-generation displays. However, the poor stability of PQDs is the most serious drawback for the further application and commercialize. In order to overcome the stability issue, we developed a strategy to stabilize PQDs by applying surface functionalized cellulose nanocrystals (CNCs) to replace traditional ligands and successfully synthesized the highly stable and color-tunable PQDs/CNCs luminescent films. Nevertheless, the PLQY of the PQDs/CNCs luminescent films is limited due to large crystals formed during the synthesis process. After investigation, we incorporate phenethylammonium halide (PEAX, X = Cl, Br, and I) during the synthesis process to format quasi-2D perovskite structures instead of the PQDs and the PLQY of $CsPbBr_{1.5}Cl_{1.5}$, $CsPbBr_3$, and $CsPbBr_{0.5}I_{2.5}$ films with PEAX passivation can be enhanced more than 10 (from 1.2% to 10%), 3 (from 22% to 69%), and 18 (from 3% to 55%) times, respectively. Moreover, the stability of PEAX passivated inorganic perovskite/ CNCs luminescent films also slightly increase. By combining the advantages of CNC and PEAX, this study demonstrates highly stable light emission/conversion films with largely enhanced PLQY, and it holds the potential for developing full-color, stable, and high PLQY displays in the future.

5:00 PM EL02.14.08
Thermally Stable and Efficient Perovskite Solar Cells employing an IDTT-Based Organic Semiconductor Additive Hyuntae Choi, Dohyun Kim and Taiho Park; Pohang University of Science and Technology, Korea (the Republic of)

Perovskite solar cells (PSCs) have received a lot of attention because of their fascinating optoelectronic features and solution processability, but they still have shortcomings that limit their efficiency and stability. Here, a new small molecule additive (IDTT-ThCz) based on indacenodithieno[3,2-b]thiophene that can interact with perovskite layers is designed. In particular, IDTT-ThCz is introduced into the perovskite layer to significantly suppress the perovskite defects through anti-solvent treatment. In addition, this facile surface passivation greatly improves the charge extraction ability, preventing perovskite degradation. As a result, IDTT-ThCz-treated PSCs showed enhanced power conversion efficiency (PCE) of 22.5% and superior thermal stability by maintaining 95% of the initial PCE after storage for 500 hours under thermal conditions (85°C).

5:00 PM EL02.14.09
Minimizing Energy Loss via Perovskite Heterostructure Fabricated by Transfer Printing Technique for Efficient Perovskite Solar Cells Chih Wei C. Chu, Anisha Mohapatra and Anjali thakran; Academia Sinica, Taiwan

Despite the efficiency of perovskite solar cells (PSCs) has been increased rapidly from 3.9% in 2009 to 25.7% in 2022, the conversion of solar energy into electricity is still not efficient enough due to the energy loss originates from the non-absorption of low-energy photons and thermalization losses of high-energy photons ascribed to the Shockley-Queisser limit. As a result, stacked perovskite architectures including tandem, heterostructure, and prismatic configurations have been proposed to minimize non-absorption and thermalization losses. However, fabricated multi-layer heterostructure through solution process suffers from the dissolution problem in which bottom layer will be destroyed by subsequently deposited perovskite layers. In this work, a grafting-assisted PDMS transfer process was demonstrated for constructing heterostructure perovskite layers for solar cell devices. As a proof of concept, an layer $MAPbSnI_3$ was stacked on top of an $MAPbBrI_2$ layer to fabricate a cascaded heterostructure-based cell. The $MAPbBrI_2/MAPbSnI_3$ heterostructure showed power enhancement of ∼15% as compared to single-layer films MAPbBrI2 (∼13%) and $MAPbSnI_3$ (∼10%), presumably because of minimized thermodynamic and non-absorption losses. Such printed heterostructures suggest a new pathway for minimizing thermalization and non-absorption losses in PSCs and resolving the bottleneck of solution-processable perovskite heterostructures for the realization of efficient perovskite optoelectronics.

5:00 PM EL02.14.10
Hidden Structural Characteristics of Metal Halide Perovskites Monty R. Cosby[1], Nutifafa Y. Doumon[2], Amy E. Louks[2,3], Minh T. Nguyen[4], Michael D. Irwin[4], Joseph J. Berry[2], Laura T. Schelhas[2] and Kevin Stone[1]; [1]Stanford Synchrotron Radiation Lightsource, United States; [2]National Renewable Energy Laboratory, United States; [3]Colorado School of Mines, United States; [4]CubicPV, United States

Formamadinium lead idodide, $FAPbI_3$, is at the forefront of metal halide perovskite (ABX_3) research boasting an impressive 25% efficiency (as of this writing). The structural makeup of an $FAPbI_3$ thin film has been presumed to be primarily the $FAPbI_3$ cubic structure with potentially a low percentage of PbI_2. Using comprehensive powder and grazing incidence diffraction methods, we have characterized these perovskite thin films in great detail to determine the subtle structural parameters which play a role in the material performance. Performance differences in the literature are typically ascribed to changes in processing conditions while the level of characterization is insufficient to determine if there are accompanying structural changes. Our work seeks to address this open question as to whether there are structural differences which correlate to the observed differences in material performance.

5:00 PM EL02.14.12
Monolithic All-Perovskite Tandem Solar Cells with Minimized Optical and Energetic Losses Kunal Datta[1], Junke Wang[1], Dong Zhang[1], Valerio Zardetto[2], Bruno Branco[1], Willemijn H. Remmerswaal[1], Christ H. Weijtens[1], Martijn M. Wienk[1] and Rene A. Janssen[1]; [1]EIndhoven University of Technology, Netherlands; [2]TNO-Solliance, Netherlands

Solution-processed all-perovskite tandem solar cells present an effective device platform to maximize power-conversion efficiencies by combining complementary wide-bandgap mixed-halide perovskites and narrow-bandgap lead-tin perovskites in monolithic architectures to minimize the loss in chemical potential observed in single-junction solar cells due to thermalization and transmission losses.[1] Currently, the open-circuit voltage of such devices is limited by the low radiative yield in the wide- and narrow-bandgap sub-cells. Furthermore, optical losses reduce short-circuit current density contribution of the narrow-bandgap sub-cell, which increases the current-mismatch between sub-cells, thereby decreasing the effective short-circuit current-density of the tandem device.

This work, firstly, identifies sites of non-radiative recombination in the wide-bandgap ($E_g \sim 1.77$ eV) top-cell using absolute photoluminescence spectroscopy and pinpoints the interface between the perovskite and the electron transport layer (C_{60}) as a dominant surface for energetic losses.[2] Using surface treatment strategies based on the use of quaternary ammonium salts, the non-radiative loss is recovered, leading to high open-circuit voltages in single-junction, wide-bandgap solar cells. Compositional engineering, such as potassium substitution, is further used to improve the photostability of devices against light-induced halide segregation. Similarly, in narrow-bandgap ($E_g \sim 1.23$ eV) single-junction solar cells, the interface with the C_{60} layer is improved, as confirmed by electroluminescence spectroscopy, by compensating for sublimed halide ions at the surface, leading to an improvement in the open-circuit voltage. At the same time, high short-circuit current density is ensured by using thin, optically benign, hole-transport layers, such as self-assembled monolayers,[3] that minimize parasitic absorption, and by reducing external quantum efficiency losses due to optical interference by optimizing the perovskite layer thickness.

The monolithic tandem combining the wide-bandgap and narrow-bandgap sub-cells is integrated using a dense, atomic layer deposition-based SnO_x recombination junction that improves stability against solvent ingress during processing. A thin gold monolayer is used to maintain high conductivity across this interface.[4]

Free-carrier absorption in the front electrode of the tandem device is reduced by opting for hydrogenated indium oxide (IOH) instead of commonly used indium tin oxide (ITO),[5] which increases the near infrared response of the narrow-bandgap sub-cell, reducing the current-mismatch between sub-cells. Further decreases in parasitic absorption by using thin hole-transport layers and highly transparent interfacial layers additionally ensures improved light absorption in the narrow-bandgap sub-cell, which leads to current-matched tandem devices. A key highlight of this work is the effective light management strategy that ensures a high NIR response of the narrow-bandgap cell, despite using a low active layer thickness (600 nm). Collectively, these pathways to limit non-radiative recombination and reduce optical losses ensure 23% – 24% efficient tandem solar cells in small (0.09 cm^2) and large (1 cm^2) device areas which mark a > 7% (abs.) and > 6% (abs.) gain in the power conversion efficiency compared to the performance of single-junction wide- and narrow-bandgap solar cells.

5:00 PM EL02.14.14
***In Situ*, High-Throughput Optical Monitoring of Spray-Coated Perovskite Photovoltaics Under Thermal Stress** Mathilde Fievez, Jessica Huxel, Alan Liu, Thomas W. Colburn, Austin Flick and Reinhold Dauskardt; Stanford University, United States

Hybrid organic-inorganic perovskite thin-film solar cells are of great interest as the light-absorbing perovskite layer can be easily deposited via simple solution processing, allowing for low-cost photovoltaic manufacturing. Under operation, prolonged exposure to UV light and elevated temperatures are known to cause premature device failure. Failure mechanisms include the degradation of the perovskite absorber itself and chemical reactions between device layers. Current research focuses on tracking device performance over time which provides an estimate of the degradation timescale. This approach is slow and requires numerous tedious measurements. Therefore, a high throughput characterization method is needed to quantify rapidly the thermal stability of perovskite devices. Optical imaging is an efficient method to screen for stable perovskite absorber compositions but has not yet been applied at a device or module scale.

In this work, we developed an optical imaging platform inspired by previous work [1] to monitor the thermal aging (85°C) of unencapsulated spray-coated perovskite solar cells ($glass/ITO/NiO/CsFAPbI_3/C_{60}/BCP/Ag$) in an inert atmosphere. The importance of studying full cell structures that include all charge transport and electrode layers, together with the constraint on both sides of the cell are included. Our primary goal is to identify the device structures and processing parameters of scalable deposition methods such as spray-coating that minimize photovoltaic devices degradation under thermal stress. This work includes the design of the system and the development of an automated Python image processing algorithm. During aging of devices at 85°C, the RGB and LAB (lightness, red-green and yellow-blue scales respectively) color space values were extracted and averaged over the device active area. This analysis was applied to time series of images acquired during thermal aging to determine the evolution of RGB and LAB values over time.

Upon aging, we observed an overall device lightening and yellowing in certain areas with rates quantified by the respective increase of the L and B mean values. X-Ray diffraction (XRD) confirmed that the yellowing was linked to an increased quantity of lead iodide (PbI_2) or of the non-photoactive $FAPbI_3$ tetragonal (yellow) phase. The monitoring of the L and B distributions over each active area also informed us of the spatial homogeneity of the degradation process. We distinguished homogeneous degradation and defect-induced degradation using the distribution skewness values. We compared the color evolution of devices fabricated using different plasma curing parameters (height, duty cycle), as well as the effect of including additional barrier layers (e.g. phenylammonium iodide) in the device structure. Finally, we demonstrated the scalability of our imaging method through the thermal aging of perovskite mini-modules. This work provides a high throughput optical imaging platform to quantify the effect of thermal stress on perovskite photovoltaics. The resulting high-fidelity visual data set provides insights on perovskite degradation mechanisms with high temporal and spatial resolutions.

5:00 PM EL02.14.15
Multi-Objective Optimization of Open-Air Spray-Plasma Processed Perovskite Solar Cells Austin Flick[1], Mathilde Fievez[1], Thomas W. Colburn[1], Qiaohao Liang[2], Alexander E. Siemenn[2], Tonio Buonassisi[2] and Reinhold H. Dauskardt[1]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, Afghanistan

Rapid spray plasma processing (RSPP) has been demonstrated as a successful method to deposit and rapidly cure homogeneous metal halide perovskite thin films over large areas in open-air conditions.[1] An ultrasonic spray coater accompanied by an atmospheric pressure nitrogen blown-arc discharge plasma dynamically moves over the substrate to rapidly form a compact perovskite film in under a second. One of the key challenges towards optimizing the processing space of the RSPP system is the high-dimensional processing space and the complex relationships between input variables (coating and curing distances, speed, etc.) and output film morphology and optoelectronic properties. Furthermore, developing a pathway for commercialization of perovskite technologies using the RSPP system requires a multi-objective approach to achieve both high power conversion efficiency and long-term stability.

In previous work, a sequential learning framework using Bayesian optimization was adopted to evaluate the initial performance of RSPP perovskite films in a p-i-n photovoltaic device architecture (glass/ITO/NiO/$CsFAPbI_3$/C_{60}/BCP/Ag). This optimization study focused on six individual processing parameters: substrate temperature, linear process speed, spray flow rate, plasma gas flow rate, plasma height, and plasma duty cycle.[2] Probabilistic knowledge constraints built from prior knowledge with the RSPP system informed a regression-based model to refine the high-dimensional processing space towards an optimal regime; however, this initial optimization lacked the complementary stability characterization for a multi-objective approach.

In this work, we advanced the multi-objective optimization through a complementary evaluation of the long-term stability of the previously explored six-dimensional processing space. Over 400 unencapsulated RSPP perovskite devices spanning a broad range of initial power conversion efficiencies were aged for over 400 days in inert atmospheric conditions and evaluated for their performance retention. Within the previously refined processing space, optimal device stabilities were found to retain >90% initial power conversion efficiency, up to 100% performance retention in devices with initial efficiencies of >15%. Furthermore, continued exploration within the refined processing space, incorporating optimization studies of previously fixed processing parameters, enabled further increases in device efficiency >19%. The long-term stability and elevated performances of the RSPP perovskite devices demonstrate a strong foundation towards developing a pathway for commercialization of RSPP perovskite technologies.

5:00 PM EL02.14.16
Structural and Size Effects on $CsPbI_3$ Nanocrystals Luminescence—A Temperature and Pressure Dependent Study Giulia Folpini[1], Olivera Vukovic[1,2,3], E Laine Wong[1], Luca Leoncino[4], Giancarlo Terraneo[5], Annamaria Petrozza[1,6] and Daniele Cortecchia[1,7]; [1]CNST@IIT, Italy; [2]Eindhoven University of Technology, Netherlands; [3]Université de Pau et Pays Adour, France; [4]Istituto Italiano di Tecnologia, Italy; [5]Politecnico di Milano, Italy; [6]King Saud University, Saudi Arabia; [7]Università di Bologna, Italy

Metal halide perovskite nanocrystals (NCs) are promising for photovoltaic and light emitting applications thanks to the tunability of their optoelectronic properties and high photoluminescence quantum yield [1,2]. NCs’ size plays a critical role not only by affecting the optical and electronic characteristics through quantum confinement, but also by changing the surface-to-volume ratio and consequently the structural properties[3]. The soft nature of the metal halide lattice can result in a wide range of structural distortions and defects that also impact the material optoelectronic properties [4], [5], particularly for $CsPbI_3$ where the perovskite g-phase is only stable at room temperature due to the strain induced by the small NC size. Therefore, accurate size-dependent study of perovskite NCs is required to single-out the complex contribution of particle size, quantum confinement, structural distortions, defect losses and phonon scattering, retrieving fundamental structure-property relationships that allow a more precise material’s design.
The size-dependent investigation of perovskite NCs optical and structural properties are limited by the poor size selectivity of the standard hot injection synthesis [3]. We employ the hot injection synthetic method and adapt a size-selective precipitation strategy [6] to controllably isolate $CsPbI_3$ NCs with sizes ranging between the strong and weak quantum confinement regime (7-17 nm), and combine photoluminescence (PL) spectroscopy and X-Ray diffraction (XRD) characterization to elucidate their size-dependent structural and photophysical properties under different thermodynamic conditions controlled by temperature and pressure.
Using temperature dependent PL measurements, we identify the role of exciton-phonon coupling and surface defect passivation by the organic ligands: we find that the level of surface coverage not only directly affects the availability of nonradiative loss channels but also the NPs luminescence through more subtle phonon coupling effects, stressing the need for the careful consideration of the chosen ligands. Pressure on the other hand is an ideal post-synthesis method to investigate the structure-properties relationship by adjusting interatomic distances, lattice deformation and band to band electronic overlap, controlling these parameters independently from NC size [7]. We perform pressure dependent PL and XRD measurements up to 2.5 GPa, observing changes in recombination dynamics and PL quenching at high pressures, as well as a size dependent solid-solid phase transition from the γ-phase to the non-perovskite δ-phase. The relationship between size dependent pressure effect and PL quenching further demonstrate that the lattice deformation

mechanism strongly affects the material's bandgap and recombination dynamics, stressing the importance of the structural engineering of these class of soft semiconductors. By highlighting the key role of particles' size, our findings shine light on a fundamental relationship between structural and optoelectronic properties of CsPbI$_3$ NCs that can likely be applicable to a wide range of perovskite systems.

Investigating the Formation Dynamics of Mixed 2D/3D Perovskite Films via Multimodal *In Situ* Analysis Meredith Goudreau[1], Mahdi Malekshahi Byranvand[2], Tim Kodalle[1], Michael Saliba[2] and Carolin M. Sutter-Fella[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of Stuttgart, Germany

Within the current landscape of solar energy materials, hybrid metal halide perovskite thin films have rapidly emerged as an extremely interesting photovoltaic technology due to their continually improving power conversion efficiencies and ease of fabrication [1]. However, instability under conditions of thermal stress or high humidity still remains a significant obstacle to the production of optimized, high-quality hybrid perovskite solar cell devices [2]. The deposition of bulky, organic cations onto the 3D perovskite layer during or after thin film synthesis generating 2D perovskites has recently emerged as a potential solution for this lack of stability [3]. As the method of incorporating these bulky molecules into the 3D hybrid perovskite film has yet to be optimized [4], and considering the known impact that varying properties of these bulky cations and their counterions have on the formation of the 2D layer [3], it is thus of significant interest to gain mechanistic insights into the formation dynamics and the influence of the concentration of the bulky molecules used on these mixed 2D/3D perovskite thin films.
In this study, in-situ transmission, photoluminescence (PL), and grazing incidence wide angle X-ray scattering (GIWAXS) measurements were employed during spin-coating and annealing of the perovskite films to investigate the evolution of the optical and structural properties.The deposition of the 2D material was combined with the antisolvent (AS) drop in lieu of the typical two-step process in which the 3D perovskite layer is completed prior to deposition of the 2D material to reduce both the processing time and the complexity of the deposition process. By varying the concentration of phenethylammonium chloride (PEACl) being deposited during the AS-step we find that the 2D-treated samples exhibit slower and smoother formation dynamics across all growth stages with nucleation and growth rates inversely proportional to the PEACl concentration. For concentrations higher than 1.5 mg/ml, we see a slight shift in the diffraction peaks of the precursor-solvent phase towards larger q-values, indicating that the intermediate solvate-phase has smaller lattice parameters than in the reference case. In the PEACl-treated samples, the PbI2-related diffraction peak temporarily disappears upon attainment of the maximum annealing temperature, and diffraction peaks corresponding to the n=1 and n=2 phases of the layered 2D-structures emerge. The duration of interruption of the PbI$_2$ signal is longer with increasing PEACl concentration, which we propose derives from consumption of excess PbI2 via reaction with PEACl during formation of the n=1 2D-layer. In addition, the GIWAXS images acquired for the 2D-treated samples indicate strongly pronounced crystal orientation, demonstrating that the simplified combined antisolvent and PEACl drop promotes the formation of 2D-structures. Our results demonstrate the utility of in-situ techniques for obtaining a detailed mechanistic understanding of the 2D layer formation and its subsequent interaction with the 3D triple cation perovskite.

Chloride Gradient Renders Carrier Extraction of Hole Transport Layer for High *Voc* and Efficient Inverted Organometal Halide Perovskite Solar Cell Kai-Chi Hsiao[1], Ting-Han Lin[1], Wei-Fang Su[2,3] and Ming-Chung Wu[1]; [1]Chang Gung University, Taiwan; [2]Ming Chi University of Technology, Taiwan; [3]National Taiwan University, Taiwan

A carrier transport layer and its interfacial effects on an organometal halide perovskite light harvesting layer play an influential factor in either photovoltaic performance or long-term stability of a perovskite solar cell (OHPSC). Although the understandings of the carrier transport layers and interfacial effects on regular structured OHPSCs have been explored, knowledge of an interface between hole transport layer of NiO$_x$ and perovskite in an inverted OHPSC is still necessary to be developed. Here, we performed a universal NiO$_x$ film with the sequential passivation strategy of NiCl$_2$ (SPS-NiCl$_2$ treatment) for either wide bandgap or narrow bandgap of OHPSCs. The SPS-NiCl$_2$ treated NiO$_x$ film not only implements the passivation at the perovskite layer/NiO$_x$ film interface but also confers itself a gradient energy level of valance band inducing by chloride. Comprehensive characterizations reveal that the SPS-NiCl$_2$ treated NiO$_x$ film suppresses non-radiative recombination at the interface and enlarges the splitting of the quasi-Fermi level at the interfaces. The photoconversion efficiency (PCE) of the champion device comprised of the SPS-NiCl$_2$ treated NiO$_x$ film can achieve 19.53% with a record *Voc* of 1.16 V, the lowest *Voc* deficit of 390 mV in NiO$_x$ based inverted OHPSCs. The corresponding devices with encapsulation also exhibit superior long-term stability, and over 80% of initial PCE can be maintained after 1500 h damp-heat test. This study sheds the light on managing the interfacial issues of an inverted OHPSC and offers a feasible path to develop a universal hole transport layer for perovskite layers with different energy bandgap.

Realize the Counterbalance between Sustainability and Photovoltaic Performance of Organometal Halide Perovskite Solar Cell Jia-Mao Chang, Kai-Chi Hsiao, Shun-Hsiang Chan, Kun-Mu Lee and Ming-Chung Wu; Chang Gung University, Taiwan

The containing toxic Pb in perovskite solar cells may obstacle the pace of its further progress. Based on appropriated ionic radius and stable valence electron, barium is the most suitable alkaline earth element for lead substitution in perovskite material. To enhance the tolerance of lead substitution in perovskite material, a bulky cation of phenylethylammonium (PEA$^+$) was induced into the perovskite to serve as A-site cation. The bulky size and dipolar intrinsic properties render it to simultaneously induce a quasi 2D/3D structure ($n>40$) and to passivated the ionic defects in such perovskite material. Herein, we induced PEA$^+$ into perovskite to enlarge the limitation of barium substituted ratio. In addition, the optoelectronic properties and morphology were also improved as 1 mol.% of PEA adopted into the lead reduced perovskite. Taking these advantage, the ratio of barium substitution in dual cation perovskite system can reach to 10 at.% and the corresponding photovoltaic performance can attain 19.1% in a n-i-p configuration. These results shed the light on how to delineate a framework for lead reduction in organometal halide perovskite solar cell and guide a direction for counterbalancing sustainability and photovoltaic performance of perovskite solar cells.

5:00 PM EL02.14.22

Isoelectronic Cations: A Toolset to Study Hydrogen-Halide Interactions in Lead Halide Perovskite Excluding Other Variables Yunping Huang[1,2] and Christine Luscombe[3,2]; [1]University of Colorado Boulder, United States; [2]University of Washington, United States; [3]Okinawa Institute of Science and Technology, Japan

Cations in lead halide perovskite (LHP), though at first considered to merely charge balance the PbX_6 octahedra, have been revealed to have significant impacts on device efficiency and stability. Cs ion, methylammonium, and formamidinium are the common cations in LHP materials. These cations have different sizes and varied numbers of hydrogen atoms interacting with the surrounding PbX_6 octahedra, and so far there are no experimental studies that investigate how LHP properties in correlate with hydrogen-halide interaction independently. To bridge this knowledge gap and provide more fundamental understanding of LHP materials, we designed two ligands based on guanidinium ($C(NH_2)_3^+$) and uronium ($C(NH_2)(OH)^+$), and studied their differences in efficacy and mechanism in LHP thin-film passivation. Guanidinium and uronium are a pair of isoelectronic cations and therefore of nearly identical sizes, while guanidinium has one more hydrogen atom interacting with the PbX_6 octahedra. In addition, these two ligands share the same counter ion (methanesulfonic group) and the same alkyl chain attached to cations ($-C_{12}H_{25}$). These deliberate designs allowed us to exclusively investigate the effects of hydrogen-halide interaction in LHP without other inferences.

After passivating wide-bandgap LHP films ($(Cs_{0.17},FA_{0.83})Pb(I_{0.75}Br_{0.25})_3$) with the alkylated guanidinium ligand (GA), we observed a 12-time increase in photoluminescence (PL) intensity along with the PL lifetime improved from 134 ns to 337 ns compared to the untreated film. On the other hand, the passivation efficacy of the alkylated uronium ligand (UA) is less pronounced, with a 5-time enhancement in the PL intensity and a slight improvement of the PL lifetime (134 ns to 176 ns). In solar cell devices, the GA increased fill factors of the solar cells from 72.37 % to ~80 % and power conversion efficiency from 15.48 % to 17.71% compared to the untreated devices, while the UA passivated devices showed little improvement. These drastically different results indicate that guanidinium and uronium adopt different mechanisms in LHP thin-film passivation despite their nearly identical sizes.

X-ray diffraction and atomic force microscopy suggested a formation of a crystalline guanidinium-rich 3D perovskite phase at the original grain boundary after GA treatment, supported by the (110) diffraction peak shifting to lower angles and an increase in Young's modulus in the GA-treated film. Compared to the original amorphous phase at the grain boundary, the newly formed crystalline phase significantly reduces surface trap density and facilitates charge extraction, leading to a boost in fill factors. On the other hand, the lower passivation efficacy of the UA suggested UA passivates LHP thin films via filling cation vacancies at the amorphous grain boundary. In addition, we observed a slightly reduced open circuit voltage in the GA-treated device, indicating a reduced bandgap of the guanidinium-rich phase, which is consistent with previous theoretical simulations that show hydrogen-halide interactions reduce LHP bandgaps through enhancing spin-orbit interaction and modulating octahedral tilting. The interaction between hydrogen and the PbX_6 octahedral was further confirmed by nuclear magnetic resonance, as we observed all hydrogen signals from guanidinium broaden after filling in the cation sites in the LHP lattice.

In conclusion, by using a pair of isoelectronic organic cations, we excluded other variables to exclusively study how the hydrogen-halide interactions between cations and PbX_6 octahedra affect the surface passivation and the optoelectronic properties of LHP materials, meanwhile providing a novel approach for LHP passivation via surface recrystallization. This project also underlines the value of in-depth interdisciplinary collaborations between the organic and inorganic communities in unfolding the fundamental aspects of LHP materials.

5:00 PM EL02.14.23

Deposition of Conformal Perovskite Films on 100cm^2 Textured Silicon Surface Using Sequential Dry Process Jae-Keun Hwang[1], Sang-Won Lee[2,1], Wonkyu Lee[1], Solhee Lee[1], Seok-Hyun Jeong[1], Sujin Cho[1], Donghwan Kim[1], Yoonmook Kang[1] and Hae-Seok Lee[1]; [1]Korea University, Korea (the Republic of); [2]Stanford University, United States

Perovskite solar cells are currently recording an efficiency of 25.7%, achieving an efficiency close to that of silicon solar cells. Recently, in order to overcome the theoretical limit efficiency of single-junction solar cells, research on tandem solar cells has attracted great interest, especially silicon/perovskite tandem solar cells have reported an efficiency of over 30%. In order to fabricate high-PCE silicon/perovskite tandem solar cells, it is important to maintain the pyramid shape of the textured silicon surface for maximizing the current density. However, it is difficult to deposit conformal perovskite film along a pyramid shape of ~μm on a textured silicon surface through a conventional solution process. Therefore, the dry process is necessary for the fabrication of high-efficiency silicon/perovskite tandem solar cells.
In this study, a uniform perovskite film was conformally deposited on a 100 cm^2 textured silicon surface using two-step sequential sputtering and chemical vapor deposition processes. In addition, a perovskite solar cell with a glass/FTO/TiO_2/$MAPbI_3$/spiro-MeOTAD/Au structure was fabricated to analyze the device characteristics.

5:00 PM EL02.14.24

Sputtered Nickel Nitride on p-NiO_x Stabilizes Halide Perovskite, p-i-n Solar Cells Anat Itzhak[1], Xu He[2], Adi Kama[1], Sujit Kumar[1,3], Michal Ejgenberg[1], Antoine Kahn[2] and David Cahen[1,3]; [1]Bar Ilan University, Israel; [2]Princeton University, United States; [3]Weizmann Institute of Science, Israel

Stability is one of the significant barriers to commercialize halide perovskite, HaP, devices. Interfaces between inorganic selective contacts, preferred in terms of stability, and HaPs are one of the greatest challenges for making stable and reproducible devices. Nickel oxide (NiO_x) is an attractive hole-transport layer as it fits the electronic structure of HaPs, is highly durable, and can be produced at low cost. We demonstrate RF sputtering of NiO_x as a hole transport layer, followed by *in situ* deposition of an ultra-thin nickel nitride (Ni_yN) passivation layer. The Ni_yN coating protects Ni^{3+} (in the oxide) from being reduced to Ni^{2+} during Ar plasma cleaning, thus maintaining NiO_x conductivity.
Additionally, the Ni_yN forms a buffer layer that passivates the interface between NiO_x and the HaPs, protecting the HaP from the reactive Ni^{+3} species. This double effect improves the perovskite solar cell efficiency from an average of 16.5% (with 17.4% record) to 19% average (with 19.8% record) and increases the device stability, as shown by measurements over several days. We conclude that RF sputtering to deposit inorganic passivation layers is an innovative and viable step towards a scalable process of stable HaP-based solar cells.

Insights From the Perovskite Database Project. What we Can Learn From Data Collected From 45000 Perovskite Solar Cells Reported in the Literature T. Jesper Jacobsson; Nankai University, China

The recent development of halide perovskite solar cells has been impressive, both in terms of increased performance and in the number of published papers. The sheer number of papers does, however, make it increasingly difficult to get a good overview of the field. It is also difficult to truly take advantage of all device data generated when it is inconsistently formatted and scattered over thousands of papers. We therefore initiated the Perovskite

Database Project, which is an open-source communal bottom-up effort to gather all generated perovskite device data in one place, provide consistent formatting, and make it adhere to the FAIR data principles. So far, we have collected device data for around 45000 photovoltaic devices with up to 100 parameters per device. In this talk I will introduce the Perovskite Database Project and give examples of insights gained from analyzing the present dataset. Specific examples will include a quantitative discussion about a discrepancy between short circuit currents extracted from JV and EQE measurements, and a reflection about herd behavior in experimental design. I will also discuss what we can expect from the future in terms of follow up studies, challenges, opportunities, and how we can continue to make as good use as possible of our collective research efforts.

5:00 PM EL02.14.26
Exploring the Origin of Degradation at the NiO-Perovskite Interface and its Impact on Perovskite Solar Cells Hye Ri Jung, Hanseul Lee, Namhee Kwon, Soohyung Park and Gee Yeong Kim; Korea Institute of Science and Technology, Korea (the Republic of)

Nickel oxide (NiO_x) has been widely used as a hole transport layer in inverted perovskites solar cells owing to its high-mobility, low cost, and superior stability. Unfortunately, NiO_x tends to form unpleasant reactants in contact with perovskite depending on the valency of nickel ion. Reactants formed by de-protonizing with cationic ammonium and oxidizing iodide species act as hole extraction barriers in the NiO_x-perovskite interface [1]. These reactants lower the V_{OC} and promote device degradation, especially when operating the device. In previous studies, various insertion layers have been proposed to alleviate the interfacial reaction at the NiOx-perovskite. However, the origin of the reaction process depending on the surface state of NiO_x and its effect on perovskite solar cell's stability has not been fully understood. Therefore, in this study, we fabricated perovskite solar cells and investigated the reaction process and decomposition mechanism with different surface states of NiO_x (one is for nanoparticle NiO layer the other one is for sputtered NiO_x thin-film). The origin of this reactant is identified through *in-operando* XPS, TEM and electrical measurements. From *in-operando* XPS, we observed compositional changes and carrier transport in NiO_x-perovskite by applying an external voltage to elucidate charge transfer and decomposition mechanisms in real-time device operation. The result shows that two different types of NiO_x displayed a significant difference in the Ni^{3+}/Ni^{2+} ratio, which in turn affects the stability of the device. The decomposition is induced by the reactants in NiO_x-perovskite and the insertion layer retards the decomposition of perovskite solar cell. We also measured the formation of reactants and the morphology variation of the NiO_x-perovskite interface through TEM over time. As a result, our experiment suggests that the proper insertion layer can control interface degradation and improve hole extraction, thereby efficiently promoting charge separation and suppressing recombination. These results provide insight into the origin of degradation at the NiO_x-Perovskite interface.

5:00 PM EL02.14.27
Ionic Effects on Space Charge Formation at Halide Perovskite Interfaces with Contact Materials Mina Jung, Davide Moia and Joachim Maier; Max-Planck-Institute, Germany

Understanding interfacial effects, such as charge recombination and injection, is a crucial issue to improve the photo conversion efficiency of hybrid perovskite solar cells (PSC) [1,2]. The space charge equilibrium at the interface between hybrid perovskites and contact layers is commonly interpreted according to electronic equilibration only. However, it has been shown that halide perovskites are mixed ionic-electronic conductors and that ionic adsorption at their interface with oxides can have a critical role in the determination of the space charge situation[3]. The resulting ionically-induced charge carrier redistribution may have significant repercussions on device behavior. Therefore, it is important to understand whether such ionic effects are relevant to interfaces involving other materials that are commonly used in high-performance solar cell applications, and how they can be controlled.
In this study, we discuss experimental investigation of ionic effects at the interface between $CH_3NH_3PbI_3$ (MAPI) and a number of insulating, electron or hole transporting oxide materials. We use zeta potential measurements to establish the expected ionic interaction on the surface of oxide particles. We then perform electrical measurements to quantify the ionic and electronic conductivities of composite films, where nanoparticles of the oxide material are embedded in MAPI, as well as of structures where a mesoporous oxide film is infiltrated with MAPI. We study the iodine partial pressure dependence of ionic and electronic conductivities in these films, allowing us to extract the sign of the space charge potential in MAPI when in contact with the oxide phase. Secondly, we demonstrate that molecular functionalization can successfully modify the space charge behavior at the oxide-MAPI interface in both composite and mesoporous films.
With this study, we aim to provide a complete model including both ionic and electronic effects to describe the equilibrium space charge situation at the interface between halide perovskites and contact materials. Our results will help the design of photovoltaic architectures and the interpretation of experimental data accounting for the mixed conducting properties of halide perovskites.

Regulated Lattice Structure of Quasi-2D/3D Tin-Perovskite Absorbers by Fluorinated Phenethylammonium Cation for Stabilized Lead-Free Perovskite Solar Cells Donghan Kim and Jae Woong Jung; Kyung Hee University, Korea (the Republic of)

Lead-free perovskite solar cell is a promising next-generation eco-friendly photovoltaic technology. Particularly, much effort has been devoted in tin-based perovskite solar cells due to idealtical outer electric and ionic radius configuration of Sn^{2+} to Pb^{2+} cation. However, there remains a detrimental oxidation issue of Sn^{2+} to Sn^{4+} causing accelerated self-doping within the interface or grain boundaries of the perovskite absorber layer in ambient conditions. In this work, a fluorinated phenethylammonium iodide (4FPEA) was introduced in a typical quasi-2D/3D tin-perovskite absorber layer to enforce strong hydrogen bonding in the octahedral lattice, which can effectively passivate the defective antisites and retain enhanced oxidation resistance of the perovskite absorber layer. As a result, 4FPEA could contribute to enhancing the oxidation stability of tin-perovskite absorbers and resulting perovskite solar cells. The optimized 4FPEA-based tin-perovskite solar cells achieve promising photovoltaic performance of >4% PCE as the trap state density within defective grain boundaries were successfully passivated. Moreover, the optimized concentration of 4FPEA demonstrated antioxidation properties that were being worked over 1,000 hours under the atmospheric condition of 25 °C and RH 17%.

5:00 PM EL02.14.31
Tailoring the Grain Boundaries Grooves for High-Performance Perovskite Solar Cells Mingwei Hao and Yuanyuan Zhou; Hong Kong Baptist University, Hong Kong

Grain-boundary groove (GBG) is an inherent microstructural feature of grain boundaries in metal halide perovskites, which has not been quantitatively studied. In this work, we leveraged high-resolution characterization methods to qualify the characteristic GBG angles and revealed their impact on properties of perovskite heterointerface and performance of PSC devices. We showed that flattening GBGs can lead to significantly enhanced optoelectronic properties, chemical stability, and most importantly opto-mechanical reliability of perovskite heterointerfaces. Highly efficient and stable perovskite solar cells are thus fabricated via the GBG optimization.

5:00 PM EL02.14.33
Deuteration Improved Stable and Efficient Perovskite Solar Cells Yu Gao[1], Xin Hong[2], Man-Chung Tang[2] and Guodan Wei[1]; [1]Tsinghua-Berkeley Shenzhen Institute, China; [2]Tsinghua University, China

Traditional solution-processed perovskites often suffer from defects-induced nonradiative recombination, which has severely hindered the improvement of device performance, especially the fill factor (*FF*). Herein, we have successfully applied a deuterated precursor as a facile additive not only to improve the perovskite multigrain size with high crystalline order, but also passivate the surface defects. Time of Flight Secondary Ion Mass Spectrometry shows that this deuteration has successfully induced an intermediate to the $CsFAPbI_3$ crystal and exhibiting an increase in grain size and in phase crystallinity. Suppressed iodide ion migration was observed in the deuterium additive-treated devices after aging tests, indicating improved structural stability of perovskite crystals. As a result, these translation into a high fill factor of 83.85% and a power conversion efficiency of 23.45% based on an inverted planar heterojunction device. Also, the devices operate for over 1,000 h at the maximum power point under simulated AM 1.5 illumination, possess a better light soaking stability.

5:00 PM EL02.14.34
Effect of Electrical Bias in the Dark on the Flexible Perovskite Modules Jiyeon Nam, Wonkyu Lee, Hae-Seok Lee, Donghwan Kim and Yoonmook Kang; Korea University, Korea (the Republic of)

In this study, the electrical bias stability of the perovskite flexible module was conducted in the dark state. In general, the solar cell is maintained in the MPP state, but when the module is disconnected during illumination, a voltage close to Voc is applied. Electrical bias causes module degradation by ion migration, charge carrier accumulation, and trap generation, so it is necessary to study the electrical bias stability when the perovskite module is operating and disconnected. The perovskite module was fabricated on a PEN/ITO flexible substrate. The structure of this module is a standard n-i-p structure and uses SnO2 as the ETL material and Spiro-OMeTAD as the HTL material. Au was deposited as the top electrode and all patterns were scribed using a laser and connected monolithically. The cell width is about 0.5cm wide with 5*5cm2. Module A was biased with voltage at the maximum power point(MPP) under 1sun and Vmpp was applied to module B in the dark.
The initial efficiency of module A was 12.82% (Voc: 9.89V, Jsc 2.04mA/cm2, FF: 63.58%) Maximum Power Point (MPP) is tracked in ambient air. The temperature was maintained at approximately 33°C and the humidity was kept below 40%. Modules encapsulated with a diffusion barrier were placed under 1 sun. After 3h MPPT, the efficiency decreased to about 75% of the initial efficiency. The biggest cause of the decrease in efficiency is the decrease in Jsc, which is most likely caused by the decomposition of the perovskite layer, which is a light absorption layer, at a specific location. When the perovskite layer decomposes, Jsc appears to decrease because light absorption and carrier generation decrease. The distribution of elements in the module along the depth direction was measured through SIMS analysis. Measurements were performed on fresh, 25-hour working modules. The intensity of Au near the pattern was higher than that of the neat area. This shows that Au diffused from P2 and the top electrode. In addition, the I2 peak broadened as a result of perovskite decomposition. We obtained electro-luminescence (EL) images before and after MPPT and the intensity of EL decreased around the P2 pattern. Non-radiative recombination sites can be distinguished from EL images in which the perovskite layer disintegrates after ion migration has occurred. Series resistance increased significantly due to the increase of non-conductive materials such as PbI2, which is a by-product of perovskite layer decomposition. Also, the shunt resistance decreased slightly, showing a similar trend to LIT (Lock-in Thermography) results. A thermal imaging camera attached to the LIT system detects Joule heating in the shunt. The number and temperature of hot spots increased.
In the case of module B, the initial efficiency was 14.11% (Voc: 10.43V, Jsc: 2.24mA/cm2, FF: 60.44%). Vmp was applied in the dark state. The temperature was maintained at 24.9°C and the humidity was kept below 50%. Modules are encapsulated in the same way as module A. After 16 hours of application, the efficiency decreased to 11.73(Voc: 9.97V, Jsc 2.17mA/cm2, FF: 54.11%). The biggest change is the reduction of Voc and FF. When a voltage is applied in the absence of light, ions are expected to move along the direction of the electric field, creating non-radiative recombination centers. The result is a decrease in Voc due to recombination. However, ions migrate in the opposite direction when the electric field disappears. When the recovery characteristics were measured again 3 days after the end of the voltage application of the module, the efficiency was 15.23% (Voc: 10.72V, Jsc: 2.23mA/cm2, FF: 63.84%), similar to before voltage application. In the perovskite module, electric bias causes ion migration, creating non-radiative recombination centers, resulting in Voc losses, and light causes decomposition, resulting in Jsc losses.

5:00 PM EL02.14.35
Fully Dry-Processed and Powder-Based Halide Perovskite Solar Cells by Powder-Aerosol-Deposition and Hot-Pressing Christina Witt, Konstantin Schötz, Simon Biberger, Nico Leupold, Meike Kuhn, Philipp Ramming, Eva M Herzig, Ralf Moos, Anna Kohler and Fabian Panzer; University of Bayreuth, Germany

The lifetime and stability of halide perovskite solar cells is well known to be reduced by high internal strain, which correlates with a high degree of energetic disorder. Here, we present a novel method to prepare perovskite solar cells with a low level of internal strain and disorder using a fully dry processing approach suitable for upscaling.
For this, we first prepared perovskite powder with remarkable stability by dry mechanochemical synthesis. Subsequently, this powder is deposited by a dry powder-aerosol-deposition method and pressed at elevated temperatures. This hot-pressing approach increases the grain size and reduces the disorder and strain in the films. Strain and disorder are analyzed using XRD as well as detailed Urbach analyses of temperature dependent photoluminescence and absorption spectra. These detailed Urbach analyses enable us to accurately determine even low static disorder values. We find values as low as 3.7 meV for the dry-processed, pressed films. Moreover, hot-pressing improves the surface roughness and compactness of the films to such an extent that their integration into a solar cell configuration becomes feasible. We demonstrate fully working dry-processed powder-based perovskite solar cells - the first of their kind.
The solvent-free approach allows to separately optimize the synthesis of the material, and the processing of the film. This contrasts with the currently used approaches where the perovskite forms only as the film is formed. Our results thus pave the way for a novel fabrication method of thin-film perovskite solar cells that is suitable for upscaling and that has strong potential to advance the stability of perovskite-based devices.

5:00 PM EL02.14.36
Bulk and Micro-Photoluminescence Studies of Perovskites Stuart Thomson and Matthew Berry; Edinburgh Instruments Ltd., United Kingdom

Perovskite based solar cells are the subject of intense research interest due to the attractive properties of perovskite; high carrier mobilities, large absorption coefficients, tuneable bandgaps, and long carrier diffusion lengths. One of the challenges in any solar cell design is how to get the charge carriers efficiently out of the device. To aid charge extraction, electron and hole extraction layers are routinely incorporated into the device stack.

One promising material being investigated as a hole extraction layer are vertically aligned carbon nanotubes (VACNTs). The VACNTs can be grown in a grid pattern of 'towers' atop the ITO electrode in order to achieve improved charge extraction while maintaining high optical transmission through the ITO/VACNTs. Photoluminescence response from perovskite materials is proportional to the number of charge carriers in the layer and therefore sensitive to charge extraction into adjacent layers. This makes photoluminescence based techniques invaluable for investigating the performance of new extraction layers. In this work steady-state and time-resolved confocal photoluminescence microscopy and photoluminescence quantum yield studies were used to quantify hole transfer efficiency into the VACNT towers.

Additives Engineering for High-Performance All-Inorganic Cs Based Perovskite Solar Cells Gulzhan Bizhanova, Vladimir Pavlenko, Zhuldyz Yelzhanova, Gaukhar Nigmetova, Damir Aidarkhanov, Hryhorii Parkhomenko, Askhat Jumabekov, Mannix Balanay and Annie Ng; Nazarbayev University, Kazakhstan

The emerging perovskite solar cells (PSCs) have made a breakthrough in the photovoltaic community. To date, the power conversion efficiencies (PCEs) of the single junction PSCs have been increasing from 3.8% in 2009 to the latest record of 25.7%. Despite the impressive PCEs of PSCs, the material instability and short device lifetime are the major obstacles of future commercialization. For conventional organic-inorganic hybrid PSCs, the presence of methylamine ions (MA^+), formamidine ions (FA^+) and other organic components causes poor thermal stability of the perovskite thin films due to the volatile nature of the organic components at 80 – 100 °C. The preparation of all-inorganic perovskites such as $CsPbX_3$ (X = I, Br) can prevent the use of the volatile organic components, which is believed to be the potential solution for enhancing the thermal stability of perovskite thin films. However, the photovoltaic performance of all-inorganic Cs based PSCs is still below the conventional type of organic-inorganic hybrid PSCs. The quality of the all-inorganic perovskite film is one of the important factors in determining the device efficiency and stability. In this work, the ionic liquids (ILs) are used as the additives during the preparation of $CsPbI_2Br$. It is found that the crystallization of $CsPbI_2Br$ and its surface morphology are significantly enhanced by using the controlled amount of ILs. A systematical investigation has been performed on the materials and devices. The experimental results show that incorporation of ILs is an effective method to fabricate high-performance $CsPbI_2Br$ based solar cells.

Towards Standardization of Accelerated Stress Testing Protocols for Metal-Halide Perovskite Photovoltaic Modules Laura T. Schelhas; National Renewable Energy Laboratory, United States

Metal-Halide Perovskite (MHP) photovoltaic (PV) modules are at the cusp of commercialization. One major hurdle that remains is establishing confidence in long-term field performance and durability of MHP modules. A lot of progress has been made in addressing many performance stability issues in MHP cells and modules; however, in the absence of established protocols for MHPs, many of the studies have been conducted using the International Electrotechnical Commissions 61215-series (IEC61215) of standardized tests. IEC61215 lays down requirements for the design qualification of terrestrial photovoltaic modules suitable for long-term operation in open- air climates and test results are not construed as a quantitative prediction of module lifetime. While some of the testing protocols outlined by IEC61215 are likely to be relevant to MHPs and do provide some insight to potential degradation mechanisms, they should not be used to infer any estimation of durability or field performance without a more rigorous understanding of how those test conditions affect the MHP and whether those conditions are even relevant. In addition, counterpart field-exposure and a thorough analysis of the degradation pathways introduced by external stressors will be needed to validate any accelerated stress testing conditions. Here I will discuss an initial accelerated stress testing protocol that can be used as the foundation for the development of a standardized test procedure for qualification of commercial MHP modules. We apply the protocol to different MHP module architectures to identify the critical degradation pathways that will inform future testing development. In addition, the modules are exposed to outdoor environments such that a cross- examination with indoor results can be used to verify the relevance of the indoor stress conditions. This work is part of the recently established Perovskite PV Accelerator for Commercializing Technologies, PACT, program.

Blade Coated Inverted Perovskite Solar Cells and Minimodules with Vacuum Assisted Nucleation Approach He Wang and Xinwen Zhang; University of Miami, United States

Solar cells using metal halide perovskite as the absorber are attracting significant attention due to their high power conversion efficiency, and potential low fabrication cost. A key obstacle to commercialization is represented by the difficulty in fabricating highly efficient and stable large area solar cells. As such, to bridge the gap between laboratories and industry for perovskite solar cells, it is crucial to develop devices in an ambient environment using materials and methods that can be scalable. One of the key steps is to control the nucleation and crystallization of perovskite on a large area. Antisolvent can be used to quickly extract the solvent during the spin coating process for nucleation and crystallization, but it is inherently limited to small areas, making it a poor candidate for large area. In addition, the fast and crucial nucleation process is very sensitive to the time when the antisolvent is added, greatly hampering its reproducibility.

We utilize a vacuum assisted approach to obtain mirror-like, pinhole-free, crystalline and uniform blade-coated perovskite films.[1] The vacuum replaces the antisolvent to quickly remove the solvent to initiate the nucleation process and produce the intermediate phase. We have conclusively proven that this method can be applied to many perovskite compositions. In order to improve thermal stability, MA^+ (methylammonium) is substituted by FA^+ (formamidinium) or a mixture of cations. One difficulty is that FA ink is not straightforward to develop, since $FAPbI_3$ favors the yellow phase at room temperature in air. Our solution involved using solvent N-methyl-2-pyrrolidone (NMP) to replace the conventional co-solvent dimethyl sulfoxide to fabricate perovskite film under ambient environment, since NMP exhibits a stronger interaction with PbI_2 and FAI.

Besides the perovskites layer, hole transport material (HTL) is also of importance for efficient and stable device. Organic HTL poly[bis(4-phenyl)(2,4,6-trimethylphenyl)amine (PTAA) has been the premier choice for the p-i-n device architecture. One drawback is that PTAA is hydrophobic, limiting the choice of solvents for perovskite precursors. Therefore, we choose an inorganic semiconductor NiOx as the HTL in our work. It exhibits high photostability with a hydrophilic surface, and can be easily scalable. On the other hand, NiOx has relatively low open-circuit voltage caused by the surface traps. Based on the physical properties of NiOx, we optimize it by tuning the composition in perovskite precursors to improve the device efficiency. In addition, the passivation effect with phenethylammonium iodide at the top and bottom interfaces of perovskite layer based on p-i-n structure has been studied. The optimized device blade coated under an ambient environment exhibits an efficiency of 20.7%. The encapsulated solar cells exhibit long-term photostability, keeping 96% of the original efficiency after 648 hours under one sun, 45°C, 50%-60% RH.[1] Our work demonstrates a highly scalable process, promising for manufacturing, and we have also applied the blade coating followed by vacuum quenching approach to minimodules.

8:45 AM EL02.15.04
Stabilization of Formamidinium Rich Halide Perovskites for Highly Efficient and Stable Perovskite Photovoltaics Satyawan D. Nagane; University of Cambridge, United Kingdom

Halide perovskite-based solar cells have achieved record-breaking efficiencies of 25.7% in single junction and 32.5% in tandem configurations [1]. Formamidinium (FA) lead triiodide ($FAPbI_3$)-based single junction solar cells are the most efficient single junction devices to date. However, the conversion of the black-phase $FAPbI_3$ perovskite phase to unwanted non-perovskite phase of $FAPbI_3$ has hindered its widespread acceptance as an absorber for photovoltaic applications. Cation alloying is one of the most efficient routes to stabilize the FA-rich halide perovskite phase. The outstanding example of this is the triple cation, $Cs_{0.05}FA_{0.78}MA_{0.17}Pb(I_{0.83}Br_{0.17})_3$, composition which has delivered highly reproducible photovoltaic devices with improved ambient stability [2]. Even though this composition delivers highly reproducible devices, this approach is non-ideal as it compromises the bandgap and the mixed-cation and mixed-halide nature can lead to spatial compositional heterogeneities [3]. Here I will reveal the role of functional organic molecule in stabilization of corner-sharing photoactive black phase of pure $FAPbI_3$. A functional organic molecule-based approach allows us to stabilize $FAPbI_3$ perovskite phase without the issues associated with cation alloying. By introducing functional organic molecules into the perovskite precursors, we can template black-phase perovskites that are highly stable in a variety of operational conditions even without any other cation alloying [4]. I'll step through the mechanism of this additive-assisted stabilization approach and outline the road map from here on to go towards highly efficient, highly stable $FAPbI_3$ based PV devices.

A Look into a Sustainable Future by Understanding Perovskites Stability Laura Miranda Perez and Severin Habisreutinger; Oxford PV, United Kingdom

Perovskite PV has been at the center of photovoltaic discussions during the last ten years for a variety of reasons. In one hand, it is the major breakthrough on PV in the last decades, it has achieved efficiencies unseen before, without having reached its full potential yet. On the other hand, the technology is questioned based on the intrinsic stability of the material and sustainability factors, as the presence of hazardous elements. Oxford PV has been focused on the integration of perovskite PV in tandem configurations with silicon since 2014, holding the world record in large area at 26.8%. Our results show that it is possible to have a reliable product meeting the industry standards, as well as proving it to be the most sustainable option at hand. The perovskite-on-silicon technology is a technological disruption without a business disruption. In this presentation, I will show the Oxford PV advances on materials, device integration, and product designs that had led to the success of a sustainable and reliable new technology, ready for its market entry.

10:00 AM *EL02.16.01
Bi-Functional Inorganic Interlayers via Low-Temperature Atomic Layer Deposition Toward Highly Stable and Efficient Perovskite Solar Cells (>23%) Hyoungmin Park[1], Sooeun Shin[1], Pronoy Nandi[1], Dipayan Pal[1] and Hyunjung Shin[1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]SKKU Institute of Energy Science & Technology, Korea (the Republic of)

Power conversion efficiency (PCE) of Perovskite solar cells (PSCs) is over 25.7%. Despite PSCs' high PCEs, their operational as well as environmental instability remains to be solved and restrict PSCs' commercialization. Currently, the state-of-the-art PSC is used almost pure α-$FAPbI_3$ (Formamidinium lead tri-iodide) as an absorber and 2,2',7,7'-tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9'-spirobifluorene (Spiro-OMeTAD) as hole transporting layer (HTL) in the *n-i-p* normal structure of PSCs. A chemical-deriven phase transition from photoactive α-$FAPbI_3$ to non-photoactive δ-$FAPbI_3$ is pointed as a significant challenge. In addition to phase transition issue, much lower stability of Spiro-OMeTAD is critical for the device performance degradation. As an interlayer in between top metallic electrodes (i.e., Au and/or Ag) and Spiro-OMeTAD/α-$FAPbI_3$, inorganic HTLs prepared by a low-temperature atomic layer deposition (ALD) technique provide bi-functionality to stabilize the PSCs during operation in ambient. Transition metal oxide (TMO) as an inorganic interlayer can be a strong candidate. Most of TMO layers generally require a high processing temperature and the lack of *p*-type characteristics inhibits application to PSCs as hole-transporting interlayers. In this study, we adopt ALD to fabricate TMO layers at low temperatures (~ 50 °C) and intentionally induce oxygen deficient traps to form empty *d*-bands to induce and further enhance hole transporting properties. With their oxygen deficient trap assisted hole transporting properties, we fabricated n-i-p normal structure PSCs of α-$FAPbI_3$ and Spiro-OMeTAD with ALD grown TMOs (amorphous-TiO_2, MoO_x and V_2O_{5-X}) on top of Spiro-OMeTAD to enhance device stability. During fabrication, we adopt funnel like 2D perovskite passivation layers for defect passivation and enhance perovskite's stability coming from hydrophobic characteristics. [1] As a result, highly efficient PSCs of PCE of over 23%

with TMOs are fabricated with pin-hole free hole transporting and protection bi-functional ALD layers. [2,3] The environmental stability of PSCs with ALD-V_2O_{5-x} interlayers is over 90% initial PCE after ~ 600 hrs, while without the interlayer started to be degraded under 80% of initial PCE just after around 200 hrs without any special encapsulation. In conclusion, this study demonstrates the application of TMOs as hole transport/protective bi-functional interlayers and ALD as an optimal deposition method without damaging the underlying perovskite absorber. Furthermore, this study shows the possibility that ALD TMOs can be also applicable to tandem device fabrication with p-i-n type PSCs and stable PSCs' commercialization.

Refining Perovskite Solution Chemistry—Repurposing Degradation Products for Improved Efficiency and Stability Nakita K. Noel; University of Oxford, United Kingdom

Since the first demonstration of efficient halide perovskite solar cells, there has been sustained and growing research interest in this class of materials. With facile deposition processes and excellent optoelectronic properties, these materials have found applications not only in photovoltaics, but in a myriad of optoelectronic devices. While research into halide perovskites for light emission and X-ray detection is just beginning to surge, perovskites are most well known for their remarkable PV performance, achieving certified power conversion efficiencies approaching 26%. Despite their truly impressive device performance, these materials have not yet reached their true potential. The major obstacle to this is an incomplete understanding of crystallisation processes, as well as defects which exists on surfaces and at interfaces in perovskite thin-films. For solution-processing, arguably the most researched deposition modality, defect control may start with the ability to control precursor ink chemistry. In this talk, I will illustrate how understanding ink chemistry and degradation processes can yield the ability to precisely control crystallisation kinetics and phase transformations; and in particular, how we can use this approach to fabricate halide perovskite films with improved optoelectronic quality, yielding devices with not only enhanced performance, but notable improvements in operational stability.

11:00 AM EL02.16.03
Scalable, One-Step Manufacturing of Robust Perovskite Thin Films in Open-Air with Rheological Modification Nicholas Rolston[1], Carsen Cartledge[1], Muneeza Ahmad[1], Saivineeth Penukula[1], Antonella Giuri[2] and Aurora Rizzo[2]; [1]Arizona State University, United States; [2]CNR Nanotec - Institute of Nanotechnology, Italy

Metal halide perovskites hold the potential for making the next generation of high-efficiency, low-cost solar cells through solution processing of Earth abundant materials. The U.S Department of Energy has identified four major challenges facing PVSKs: stability, scalability, manufacturability, and accelerated test protocols for reliability validation. Typical processing utilizes an antisolvent or gas quenching step.

Unmodified perovskite inks designed for spin coating produce pinholed, uneven, and shunted films when processed in air or with scalable processing methods. Novel polymeric modifiers have recently been used to improve film uniformity and density. These additives not only act as rheological modifiers by increasing ink viscosity, thus allowing longer periods for crystallization and smooth films, but the long chains of the polymer create an organizational scaffold that increases resistance to humidity. Furthermore, additives from the food industry, such as cornstarch, have been found to enhance mechanical integrity and the operational lifetime of devices in addition to inducing spherulitic domains that can be tuned in size by temperature and precursor concentration to increase performance.

In this work, the effects of gellan gum, a nontoxic polymeric modifier from the food industry, are studied on improving PVSK stability using scalable, one-step processing in open air. The use of a nontoxic solvent system further extends the wetting period, thus improving crystallization control. We measure the film stress to be tunable and compressive based on the additive concentration. We find that the additive enables reproducible and scalable perovskite devices to be produced in ambient conditions that match state-of-the-art performance on areas >25 cm^2 with efficiencies exceeding 15%. The devices are stable under both thermal cycling and continuous operation (1000 hours). We attribute the compressive stress in the films along with significantly reduced ion migration based on impedance spectroscopy and transient photocurrent measurements as key reasons for the improved device stability. We validate the effect through aging perovskites with different film stresses and additive concentrations for mechanistic understanding of how film stress influences ion migration and device stability.

11:15 AM EL02.16.04
Iodine Exchange and Spontaneous Self-Doping in Iodide Perovskite Semiconductors Julian A. Vigil[1], Nathan Wolf[1], Adam Slavney[1], Nicholas J. Weadock[2], Michael Toney[2] and Hemamala Karunadasa[1]; [1]Stanford University, United States; [2]University of Colorado Boulder, United States

The successful incorporation of lead-halide perovskites and lead-free halide double perovskites in various optoelectronic devices has spurred remarkable discoveries and innovation in recent years. Research-scale perovskite-based devices boast efficiencies competitive with more established technologies, including as thin-film solar absorbers and light-emitting diodes. However, despite these impressive efficiencies, areal scale-up and long-term stability continue to lag and present outstanding questions. Indeed, many of the recognized limitations are intrinsic to the perovskite crystal, including thermodynamic phase instability, mobile ions, and an abundance of point defects. These characteristics manifest in many ways in devices, including moisture and temperature sensitivity and current-voltage hysteresis, underscoring the necessity for investigations of the perovskite structure and defect chemistry.

Here, we highlight the predominant role of halogen vacancies and present our characterization of spontaneous iodine exchange in iodide double perovskites. This unique type of external defect reaction is mostly appreciated for its role in oxide crystals at high temperature; we show that the analagous exchange between iodine vacancies and gaseous iodine is spontaneous at room temperature and directly influences the electronic charge carrier concentration. We provide evidence that the iodine vacancy is a shallow electron donor, leading to striking *n*-type self-doping effects by manipulating the external pressure of iodine. Furthermore, single-crystal measurements allow for analysis of the thermodynamics of the exchange equilibrium and modeling of the diffusion-limited kinetics associated with transport of vacancies and iodide anions in the bulk crystal. Finally, we introduce complementary *in situ* X-ray diffraction and single-crystal diffuse X-ray scattering studies to correlate defect chemistry with the structural response at various length scales. A broad and critical evaluation of the mixed ionic-electronic conductivity and defect chemistry of the halide perovskites is discussed in the context of this underappreciated external defect equilibrium.

11:30 AM EL02.16.05
Highly Efficient and Stable Perovskite Solar Cells with Exceptional Thermal Cycling Performance Min Chen and Joseph Luther; National

Renewable Energy Laboratory, United States

We have witnessed the rapid development of perovskite solar cells from initially reported 3.8% to the 25.7%. However, the current perovskite solar cells still suffered from the low stability especially in the thermal cycling test. The layered structure of perovskite solar cells will experience continuous mechanical stress/strain during the thermal cycling, resulting in the failure of the photovoltaic performance. Herein, we reported an improved thermal cycling performance by adding the large organic cations molecules during the deposition of perovskite layers. As a result, the stress state of the perovskite thin films could be relieved, and the modified perovskite solar cells dropped to 85% of initial efficiency of 23.5% after 500 cycles. This approach will lead to an new avenue in improving the thermal cycling performance and have great potential in space engineering.

11:45 AM EL02.16.06
Vapor Deposited Wide Bandgap Metal Halide Perovskite Semiconductors for Multijunction Photovoltaics Jay Patel, Siyu Yan, Laura Herz, Nakita K. Noel and Michael Johnston; University of Oxford, United Kingdom

Hybrid perovskites semiconductors provide an opportunity to create highly efficient low-cost, lightweight, photovoltaics that have a high power-to-weight ratio. Physical vapor deposition is the technique that enables the creation of a multilayer heterostructure that contains hybrid perovskites semiconductors, small-molecule organic and metal oxide semiconductors. However, to develop such an intricate architecture that can reach close to the theoretical limit, the metal-halide perovskite semiconductors need to have minimal defects and phase stability. We have shown that by manipulating, the substrate material [1] the temperature [2] and the addition of additives [3] can aid in growing highly crystalline, low defect density perovskite thin films.
In this study, using physical vapor deposition, we develop an all-inorganic 2eV perovskite semiconductor which is phase stable and has minimal voltage losses. We then use X-ray diffraction analysis to show how and why the material is phase stable. We then use this technique to create the phase stable perovskite composition and integrate it into a solar cell.

Monolithic Perovskite-Silicon Tandem Solar Cells for Continuous Solar-Assisted Water Splitting Kunal Datta[1], Bruno Branco[1], Yifeng Zhao[2], Valerio Zardetto[3], Nga Phung[1], Andrea Bracesco[1], Luana Mazzarella[2], Martijn M. Wienk[1], Mariadriana Creatore[1], Olindo Isabella[2] and Rene A. Janssen[1]; [1]Technische Universiteit Eindhoven, Netherlands; [2]Delft University of Technology, Netherlands; [3]TNO-Solliance, Netherlands

Photovoltaic (PV)-driven hydrogen (H_2) evolution through electrochemical (EC) water splitting is an effective method to store energy and compensate for the intermittency of solar irradiation.[1] However, the high cost of present-day concentrated inorganic multijunctions used in such systems undermines their future commercial competitiveness. Solution-processed perovskite-based multijunctions, on the other hand, present cheap, easy-to-process alternatives that can deliver high current without light concentration and, when coupled to a flow EC system, can provide an efficient method for H_2 generation.[2]

This work describes the design and development of 1 cm^2 monolithic perovskite-silicon tandem solar cells that are well-suited for this application. First, compositional engineering strategies (cationic and anionic substitution) are used to tune the optical bandgap of the perovskite layer and to stabilize it against light-induced halide segregation. By introducing bromide to replace iodide in the perovskite lattice, the optical bandgap (E_g) is widened to ~ 1.7 eV, ideal for multijunction applications. Potassium substitution is then used to stabilize the crystal against photo-instability, that can decrease the long-term performance of devices.[3] Thereafter, the polymeric hole transport layer (PTAA) is substituted for a self-assembled monolayer (2PACz), whose favorable energetic alignment with the valence band of the perovskite minimizes energetic losses and increases the open-circuit voltage of devices.[4] Using absolute photoluminescence spectroscopy, the perovskite/C_{60} interface is further found to dominate non-radiative recombination; choline chloride or LiF interfacial layers are used to improve radiative yield and open-circuit voltage.

The perovskite top-cell is then integrated with a silicon heterojunction (SHJ) bottom-cell to build the monolithic tandem device. Here, an interfacial atomic layer deposition-based NiO layer is used to increase the surface hydroxyl content, characterized by X-ray photoelectron spectroscopy, which benefits the binding of the self-assembled hole transport monolayer.[5] As a result, tandem devices with low voltage losses are developed using a perovskite top- and a SHJ bottom-cell.

Optical simulations are then used to optimize the light incoupling and the current-mismatch between subcells. Specifically, the role of anti-reflective coatings (MgF_2) in minimizing reflection losses, and parasitic absorption in interfacial layers (ITO, C_{60}), is explored in order to identify materials and layer thicknesses that maximize absorption in the active layers of the device. Subsequent experimental development based on the optical simulations yield current-matched tandem solar cells with a power conversion efficiency of over 25%; a voltage loss of < 70 mV compared to the sum of the open-circuit voltages of single-junction perovskite and SHJ solar cells emphasizes the lossless recombination junction based on NiO. The efficiency represents > 6% (abs.) gains compared to the efficiencies of both perovskite and SHJ single-junction solar cells.

Lastly, the fabricated tandem solar cell is coupled to a flow EC cell using RuO_2 and Pt for O_2 and H_2 evolution respectively. The polarization curve of the EC cell overlaps with the current density-voltage curve of the PV cell close to the maximum power point indicating minimal additional losses in the coupled PV-EC system during operation. As a result, a stable solar-to-hydrogen (STH) conversion efficiency of > 21% is recorded both in continuous (18 h) and day-night cycling (72 h) operation.

2:00 PM EL02.17.04

Transparent Conductive Composites—A New Class of Encapsulants for Durable Perovskite Photovoltaics Kai C. Outlaw-Spruell[1], Jackson Xu[1], Qi Jiang[2], Kai Zhu[2] and Nicolas Gaillard[1]; [1]University of Hawaii, United States; [2]National Renewable Energy Laboratory, United States

Since the first report of perovskite solar cells (PSCs) in 2009, tremendous research efforts on absorber chemistry have boosted the power conversion efficiency of this material class from 3.9% to 25.7%. Although impressive, this attribute alone cannot guarantee the commercial success of PSCs, as any emerging technology must also meet the 20-25 yrs. stability already achieved by other mature photovoltaic (PV) classes. To date, the durability of best performing PSCs is limited to few months at best, constituting an important roadblock in their deployment.

In this communication, we report on our efforts with using transparent conductive composites (TCCs) as gas-barrier to repell moisture and oxygen while preventing out-diffusion of volatile species in PSCs. Unlike most conductive flexible polymers, where media are coated on top providing only *in-plane* conductivity, TCCs innovate by allowing simultaneous high optical transparency (%T>90% in the 370nm-2000nm region) and high *out-of-plane* electrical conductivity (R<0.2 W.cm^2). This unique characteristic is permitted by highly conductive 50-micron Ag-coated PMMA spheres protruding out of a transparent non-conductive polymer host.

To demonstrate that TCCs can effectively isolate PSCs from the outside environment while permitting electrical current to pass through, we will first report on an experiment in which PSCs were immersed in a 0.5M sulfuric acid electrolyte solution (pH0.3) and used as photocathodes to drive photoelectrochemical water splitting. Under such harsh conditions, unprotected PSCs discolored within seconds upon immersion and were unable to produce any appreciable photocurrent. In contrast, PSCs coated with TCCs were able to sustain continuous water splitting for over 5 hours at a steady photocurrent density of 20 mA/cm^2. The fact that PSCs protected by TCCs were able to drive an electrochemical reaction for such extended period in highly corrosive aqueous solution is a testament of TCCs' potential to protect PSCs when operating under less strenuous ambient conditions.

To further validate this novel protection concept, we will report on the effect of weathering on TCCs made of various polymer hosts, including polyepoxy, EVA, and polyolyflin. We will present optical transparency and electrical conductivity data measured periodically on TCCs during 1,000+ hrs. exposure to outdoor Hawaii climate (tropical semi-arid climate with average annual temperature, insolation, and relative humidity of 23.5^{o}C, 5.4 kWh/m^2 and 68%, respectively). Finally, we will discuss durability data of high-efficiency PSCs coated with TCCs and measured under accelerated testing conditions (50^{o}C, ambient air with 40-60% RH, 1-sun illumination).

8:00 AM *EL02.18.01

Intrinsically Stable and Versatile Co-Evaporated Halide Perovskites Solar Cells Annalisa Bruno; Energy Research Institute @ Nanyang Technological University (ERI@N),, Singapore

Metal-halide perovskites (MHP) are one of the most promising low-cost optoelectronic materials, due to their excellent optoelectronic properties and fabrication versatility. Since the advent of the first perovskite solar cells (PSCs) in 2009, their power conversion efficiency (PCE) has now reached 25.6% [1], for active areas smaller than 1 cm^2 and their operational stability is constantly improving [2-4]. The interest in transferring the existing technology into large-area perovskite modules using industrial-compatible techniques is exploding.

In this talk, I will show why thermal evaporation is a promising MHP fabrication technique to bring this technology closer to reliable and extended production, relying on excellent size scalability, promising stability, fine composition control, and surface adaptability [5]. The co-evaporated perovskite thin films are uniform over large areas with low surface roughness and a long carrier lifetime. I will present our highly efficient, large-area, PSCs where the $MAPbI_3$ perovskite is deposited by thermal co-evaporation. Developing optimization strategies customized for n.i.p [6-8] and p.i.n [9] architectures the PSCs achieved PCEs above 20% in both configurations and with different perovskites compositions. Moreover, the co-evaporated $MAPbI_3$ is formed intrinsically strain-free, and the PSCs showed remarkable structural robustness and impressive thermal maintaining over ≈80% of their initial PCE after 3600 under continuous thermal aging at 85 °C without encapsulation [8].

Extrapolating the optimization strategies over large areas, the co-evaporated mini-modules achieved record PCEs of up to 18.7% for active areas larger than 10 cm^2. Looking toward building-integrated photovoltaics we have also developed colored semi-transparent PSCs and mini-modules with a wide range of colors.

I will further discuss how these results represent a significant step toward the commercialization of the perovskite technology in comparison with other vacuum-based and hybrid technologies.

Bias-Free Solar to Chemical Conversion using Perovskite Photocathodes Rashmi Mehrotra, Dongrak Oh, Yuri Choi, Sang-Hak Lee, Sung-Yeon Jang, Jungki Ryu and Ji-Wook Jang; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Considering the increasing consequences of climate change, utilizing fuels synthesized by mere use of solar flux, water, and ambient air seems to be advanced option for the simultaneous capture and storage of vast amounts of solar energy at ambient temperature and pressure. Solar hydrogen production is one of ultimate technologies needed to realize a carbon-neutral, sustainable society [1]. However, an energy-intensive water oxidation half-reaction together with the poor performance of conventional inorganic photocatalysts have been big hurdles for practical solar hydrogen production [2]. In first part of work, we present a photoelectrochemical cell with a record high photocurrent density of 19.8 mA cm^{-2} for hydrogen production by utilizing a high-performance organic-inorganic halide perovskite as a panchromatic absorber and lignocellulosic biomass as an alternative source of electrons working at lower potentials. Additionally, the system was able to generate H_2 without applying any additional bias while utilising raw waste itself [3].

To further draw the application of perovskite photoelectrodes, we applied the photocathode to generate bias-free hydrogen peroxide (H_2O_2). It is an eco-friendly oxidant and a promising energy source comparable to H_2. It stands an irrefutable chance due to its wide application for wastewater treatment, the paper industry, and pulp bleaching with numerous in-situ production of other chemicals including propylene. However, currently, more than 95 % of H_2O_2 production relies on the anthraquinone oxidation process [4], which requires a significant energy supply at several steps and numerous organic chemicals. In addition, precious Pd-based catalysts and high-pressure H_2 used during the hydrogenation reaction increase the cost of the process and introduce many safety issues. Therefore, developing single-step oxygen reduction to H_2O_2, with a simple and eco-friendly method can pave a promising route [5]. However, utilising inorganic semiconductors impedes solar-to-chemical conversion efficiency (SCC) lower than 1 % due to several factors including their low absorption coefficient, sluggish kinetics owing to the charge diffusion length, and low stability and selectivity of the H_2O_2 production's electrocatalyst. In second part of work, we utilized an inorganic-organic-based lead halide perovskite photocathode for demonstrating bias-free solar H_2O_2 production without the need for additional bias or sacrificial agents. To further improve the stability and selectivity of this photocathode, we passivated the photocathode with oxidised buckypaper as the H_2O_2 electrocatalyst and the field's metal as an intimate junction for the subsequent transfer of photogenerated electrons towards oxygen reduction reaction. With such an efficient strategy, an SCC of ~1.463 % is attained in such a system, attaining 100 % selectivity toward H_2O_2 for 12 h. Moreover, the integrated photocathode was able to produce a stable photocurrent for 45 h continuously under one-sun simulated conditions [6].

ACI 2D Perovskite Enabled Dual Passivation for Efficient and Stable Perovskite Solar Cells—From Interface to Bulk Pengfei Wu[1,2], Shirong Wang[1,2], Xianggao Li[1,2] and Fei Zhang[1,2]; [1]Tianjin University, China; [2]Collaborative Innovation Center of Chemical Science and Engineering(Tianjin), China

Here, we report an alternating-cation-interlayer (ACI)-phase 2D (n=2) passivation layer modulating the bulk and interfacial defects in the perovskite films simultaneously by the mixed GAI and MAI (MGM) treatment, leading to the suppressed nonradiative recombination, longer lifetime, higher mobility, and reduced trap density. Consequently, the devices' performance is enhanced for both p-i-n and n-i-p structures, with the highest reaching ~24.0%. In addition, the MGM treatment can be applied to a wide range of perovskite compositions, including MA-, FA-, MAFA-, and CsFAMA- based lead halide perovskites, making it a general method for preparing efficient perovskite solar cells. Without encapsulation, the treated devices show improved shelf life (ISOS-D-1 stability) and real-life stability.

Interface Engineering with Polymer Hole Transport Layer for 3D Perovskite Solar Cells Thomas Mather, Ehsan Ghavaminia and Anupama B. Kaul; University of North Texas, United States

Perovskite solar cells have demonstrated impressive efficiency, but their susceptibility to moisture ingress and ion-transport must be reduced in order to attain a lifetime sufficient for a commercially viable photovoltaic technology. New approaches have been used to create PSCs, including with triple cation absorbers, lowering the dimensionality of the absorber or alternate electrode layers, in order to address the stability issue. Another way in which stability is enhanced is via interface engineering to block moisture access to the hygroscopic photoabsorbers used in PSCs. In this work, we explored the use of polymer interface layers between the 3D perovskite absorber and the conventional hole transport layer, Spiro-OMeTAD. Specifically, poly-[bis-(4-phenyl)-(2,4,6-trimethylphenyl)-amin] (PTAA) and Poly({4,8-bis[(2-ethylhexyl)oxy]benzo[1,2-b:4,5-b′]dithiophene-2,6-diyl}{3-fluoro-2-[(2-ethylhexyl)carbonyl]thieno[3,4-b]thiophenediyl}) (PTB7) were examined in the regular structure, but these are mostly utilized as hole transporting layers in an inverted structure. Specifically, the effect of inserting PTAA and PTB7 layers, as buffer layers at the interface between the absorber layer and hole transporting layer in perovskite solar cells is investigated. The power conversion efficiency of perovskite solar cells decreased from 16.49% in case of using PTAA to 12.73% by using PTB7.

Lattice Distortion Suppresses Phase Segregation in Triple-Junction Perovskite Photovoltaics Zaiwei Wang, Lewei Zeng and Edward H. Sargent; University of Toronto, Canada

The tunable band gaps and facile fabrication of perovskites make them attractive for multi-junction photovoltaics. However, light-induced phase segregation limits their efficiency and stability: this occurs in wide bandgap (> 1.65 eV) I/Br mixed perovskite absorbers, and becomes even more acute in the top cells of triple-junction solar photovoltaics that requires a fully 2.0 eV bandgap absorber. We report herein that lattice distortion in I/Br mixed perovskites suppresses phase segregation, generating an increased ion migration energy barrier arising from the decreased average interatomic distance between A-site cation and iodide. Using a ~2.0 eV Rb/Cs mixed-cation inorganic perovskite with large lattice distortion in the top subcell, we fabricated all-perovskite triple-junction solar cells and achieved an efficiency of 24.3% (23.3% certified quasi-steady-state efficiency) with an open-circuit voltage of 3.21 V. The triple-junction devices retain 80% of their initial efficiency following 420 hours of operation at the maximum power point.

9:00 AM EL02.18.07
Unraveling Electron Dynamics in Perovskite Nanocrystals from Milli-to Femtoseconds Fredrik Johansson[1,2], Azmat Ali[2], Birgit Kammlander[1], Alberto García Fernández[1], Mariam Ahmad[3], Elin Berggren[4], Hervé Cruguel[2], Morten Madsen[3], Emmanuel L'Huillier[2], Ute Cappel[1] and Nadine Witkowski[2]; [1]KTH Royal Institute of Technology, Sweden; [2]Sorbonne Université, CNRS, Institut des NanoSciences de Paris, INSP, France; [3]University of Southern Denmark, Denmark; [4]Uppsala University, Sweden

The fundamental understanding of carrier dynamics in- and between photovoltaic materials is of utmost importance for the advancement of material and device engineering. These dynamics includes both transfer of electron and holes through the material and between layers of different materials. The focus herein will be on charge transfer and relaxation of excited electrons in nanocrystals of the lead halide perovskite $CsPbBr_3$. $CsPbBr_3$ is material that has shown promise as absorber layer in devices and it is also relatively stable under x-ray illumination compared to its hybrid cousins. This allows for long measurements that often is a requirement for studies of electron dynamics. Furthermore, nanocrystals allows for efficient tuning of its electronic properties by changing their size and shape [1,2].

Reviewing the timescales in which charge transfer occurs in lead halide perovskites that are similar to our system, it is shown that it varies through several orders of magnitude. For an interface between methylammonium lead iodide and the 2D material WS_2, pump-probe measurements with 45 femtoseconds time resolution did not capture the charge transfer process, indicative that it occurred on a shorter timescale. However, a small fraction of the electrons remained in the perovskite layer for up to 2 ns [3] showing that multiple processes are competing and for nanowires of $CsPbBr_3$ it has been reported that the exciton radiative recombination is in the few nanosecond regime [4]**.**

We have used time resolved x-ray photoelectron spectroscopy on $CsPbBr_3$ nanocrystals to study the longer time scale and specifically recombination processes and have measured a decay constant in the range of 0.5 millisecond for the $CsPbBr_3$ nanocrystals on a gold substrate which can be compared with 20 microseconds that we recorded for a spin-coated $CsPbBr_3$ thin film on TiO_2.

To study the other faster end of the timescale we used two photon photoemission, were the decay of the valence excited state of $CsPbBr_3$ nanocrystals with two different ligands was followed. The technique allows for studies of hot electron cooling and polaron formation, processes that occur in the picosecond range [5]. Our measurement revealed several time dependencies, showing hot electron cooling in the 0.5 picosecond range independent of which ligand was attached to the nanocrystal and a slower component, that could describe trap states, with decay constants in the several picosecond range. However, this slow component is dependent on which ligand is attached to the nanocrystals.

For the truly ultrafast timescale inside the nanocrystals, on the few femtosecond and even attosecond scale, core-hole clock spectroscopy was used [6,7]. This chemically specific, resonant x-ray spectroscopy uses the core-hole lifetime as an internal clock and allows for studies of pure electronic charge transfer *i.e.* tunneling. Our results indicate that charge transfer occurs on the few femtosecond timescale when resonantly exciting both the cesium L_3-edge and the lead M_5-edge.

To summarize, we have measured charge transfer and electron dynamics in $CsPbBr_3$ on timescales spanning twelve orders of magnitude, from femtoseconds to milliseconds using different spectroscopic techniques. Providing a comprehensive review of the electron dynamics in this promising material system.

Emerging Metal-Halides for Energy-Resolving X-Ray Detection and Imaging Yang Yang; Zhejiang University, China

In this talk, I will first briefly introduce the backgrounds of X-ray detection and metal-halide materials, then give a few examples of why metal-halide-based scintillators and semiconductors are very promising candidates for indirect and direct X-ray imagers. Those examples cover several lead-free metal halides scintillators materials, featuring with negligible self-absorption loss and high X-ray light yield. One the basis of those emerging materials, energy-resolving large pannel X-ray imaging are demonstrated in our group.

Electrochromic Transition Metal Oxide Nanocrystals Delia Milliron; The University of Texas at Austin, United States

Transition metal oxide thin films are the active elements of electrochromic smart glass used in commercial building applications and more. Colloidal nanocrystal synthesis can produce and tune structures at both the atomic and nanoscale that are not readily accessible by conventional physical vapor deposition, providing new opportunities to develop structure-property relationships for electrochromic materials. Nanocrystal inks are readily coated to make optical quality films, facilitating spectroelectrochemical analysis and potentially providing a pathway for low-cost manufacturing compatible with flexible form factors. We discovered that the crystal structure and morphology of niobium oxide nanocrystals play a dominant role in controlling their spectral response upon electrochemical reduction. Depending on the atomic scale structure, niobium oxide can darken selectively in the range of visible wavelengths or near infrared wavelengths or both, selectively as a function of the applied bias. The coloration efficiency can also vary by about 5 fold. Combining experimental and computational analysis, we relate these dramatic differences in electrochromic response to the nature of the electronic states populated when ions are electrochemically inserted. The most promising niobium oxide nanocrystals have been incorporated in prototype electrochromic devices.

Plasmonic Electronic Paper Oliver Olsson, Marika Gugole and Andreas Dahlin; Chalmers University of Technology, Sweden

Micro- and nanostructures are widely used by nature to create vivid colors. An example of this is the morpho butterfly with its blue wings created not by a pigment, but by a nano-structure. Adjacent to this, humans have generated colors by plasmonics for thousands of years. An example of this is the metal nanoparticles in old church windows whose resonances create the colorful glasses which still can be seen today.

In our group, we use plasmonic structural colors to create highly reflective pixels in red, green, and blue. We later modulate the reflection with an electrochromic material incorporated inside or on top of the structures.

The plasmonic metasurfaces are made by an evaporated back reflector made of silver or aluminum (~100 nm) and a spacer layer of aluminum oxide (60-110 nm). A thin film (20 nm) of semi-transparent gold is evaporated on top to create a Fabry-Pérot cavity resonator that extinguishes one part of the visible spectra. Patterns such as a nanohole array can be introduced in the gold film by colloidal lithography. This generates a plasmonic effect that scatters red light to further enhance the coloration.
Both tungsten oxide and conjugated polymers are used to modulate the reflection and shut the pixel ON and OFF. The inorganic tungsten oxide gives the best contrast for all three colors[1]. However, the switching speed was faster for the conjugated polymers, under some conditions reaching video speed[2].

By substituting the aluminum oxide spacer layer with an electrochromic material, the metasurface can be dynamically tuned. Tungsten oxide's electrochromism is accompanied by a change in the real part of the refractive index which alters the resonant frequency of the cavity[3]. A similar effect is achieved by the thickness change of conjugated polymers upon doping[4]. Tungsten oxide can alter the colors by shifting the peak reflection wavelength around 100 nm while the polymer alternative (PT34bT) can span the whole visible spectra [3, 4].

To further show how metasurfaces could be incorporated into a reflective display the colored structures were prepared on a commercial flexible TFT backplane. Conjugated polymers can then be selectively polymerized on individual pixels and can be controlled individually without cross-talk.

As an alternative to active matrix addressing, we are also working on a passive matrix that has the potential to greatly simplify the fabrication of pixelated devices. The configuration utilizes an electrochemical reaction on a counter electrode based solely on ITO. The reaction on ITO introduces hysteresis into the electrochromic device which makes it possible to use in a passive matrix configuration. The reaction which occurs is likely associated with trace amounts of water.

Silver Electrodeposition Based Multicolor Electrochromic Device toward Plasmonic Nanophotoelectronics Norihisa Kobayashi, Shun Uji and Kazuki Nakamura; Chiba University, Japan

We reported silver electrodeposition-based electrochromic device (ECD) which exhibited reversible color change from transparent to chromatic color, black and silver-mirror in a single device. This coloration is based on the absorption by localized surface plasmon resonance (LSPR) enhanced by the silver nano deposit. In this paper, we review a relationship between optical properties, deposition process and morphology of silver nanoparticles toward plasmonic nanophotoelectronics as well as color reflective display.

11:45 AM EL03.01.04
Low Power Structural Color Tuning in a-Si Dielectric Metasurface via Li Ion Insertion Elena Kovalik[1], Janna Eaves-Rathert[2], Cary L. Pint[3] and Jason G. Valentine[2]; [1]Vanderbilt University, United States; [2]Vanderbilt University, United States; [3]Iowa State University of Science and Technology, United States

Optical metamaterials allow for wavefront manipulation through the precise geometry of subwavelength scatterers. The incorporation of active materials into these structures enhances functionality by tuning wavefront response with an applied stimulus. However, next-generation device architectures require active elements that are readily available, can be applied at optical frequencies, and consume minimal power. Here, we employ Li-ion insertion into amorphous silicon Fabry-Perot films and metasurfaces, utilizing both change in refractive index and accompanying lattice expansion as tuning mechanisms. We show reversible color change with the application of -0.2 V vs. Li/Li+ for the thin film structure, much less than the 2V required for the previously established electrochromic oxide WO_3. We then pattern the thin film into a metasurface and demonstrate reversible color bleaching and restoration in individual structural-color pixels. These devices show dynamic coloration ability well-suited for novel low-power reflective displays.

SESSION EL03.02: Inorganic and Metal Oxide Devices
Session Chairs: Brandon Faceira and Aline Rougier
Tuesday Afternoon, April 11, 2023
Moscone West, Level 3, Room 3012

1:30 PM EL03.02.02
Novel Approaches of Doped Metal Oxides Nanostructuration and Surface Engineering Towards More Sustainable and Autonomous Plasmonic Electrochromic Systems Anthony Maho; ICMCB - University of Bordeaux, France

Plasmonic nanostructures of doped metal oxides such as indium-tin oxide ITO are well-known for their selective and controlled modulation ability of NIR radiations in advanced electrochromic systems, as a consequence of the capacitive tuning of their carrier concentration through external electrical bias. Such materials are integrable in dynamic heat-filtering smart windows devices, additionally showing extremely fast switching kinetics as well as high optical contrasts, coloration efficiency, and cycling durability.

The present contribution will highlight different colloidal synthesis methodologies of ITO nanocrystals based on Schlenk line thermal decomposition and on hydro/solvothermal protocols, leading to stable and easily-workable dispersions in highly polar and low-toxic media. Such dispersions can then be used as “precursor inks” in wet deposition processes, especially spray coating, leading to uniform and highly-covering electrochromic thin films onto glass substrates. Ultimately, optical and electrochemical properties of the generated NIR-modulating layers are shown to be strongly dependent on the synthetic and post-synthetic treatments and conditions.

The talk will also address the challenge of directly interfacing ITO nanostructured films with pentacene molecular layers, well known as light absorbing, electron donor materials in many optoelectronic and photovoltaic applications in view notably of their spin-allowed singlet fission properties. Practically, ITO and pentacene can be processed into bilayers from consecutive spin coating and organic molecular beam deposition, respectively, allowing for *in-situ* electron generation in pentacene as organic photodonor and transfer towards ITO as inorganic photoacceptor. Materials microstructural and optoelectronic properties are carefully assessed through SEM, AFM, XRD, Raman, VIS-NIR spectrometry and transient absorption spectroscopy TAS, with obtained results highlighting their high-impact potential as self-powered NIR electrochromic filters, all in all targeting more and more materials sustainability and device autonomy.

This work involves research contributions recently achieved and/or under progress by University of Liège – GREEnMat in Belgium (Prof. Rudi Cloots), University of Texas in Austin (Prof. Delia J. Milliron), Imperial College London (Prof. Sandrine Heutz) and University of Bordeaux / ICMCB-CNRS (Dr. Aline Rougier).

1:45 PM EL03.02.03
Hybrid Molybdenum-Tungsten Oxide as Novel Dual-Band, VIS-NIR Selective Electrochromic Material in Advanced Smart Windows Florian Gillissen[1], Jennifer Dewalque[1], Pierre Colson[1], Rudi Cloots[1] and Anthony Maho[2,1]; [1]GREEnMat - University of Liège, Belgium; [2]ICMCB - University of Bordeaux, France

The energy efficiency of smart fenestration devices used in modern buildings could be greatly improved by the integration of advanced electrochromic materials. In particular, the ability to selectively control the amount of visible and near infrared (NIR) radiations transmitted through the windows could allow for independent control of light and heat supplies, offering a better suitability to respond to different climates, seasons, and users comfort. Such advanced smart windows typically involve electrochromic layers made of nanostructured highly doped metal oxides (tin-doped indium oxide ITO, aluminum-doped zinc oxide AZO), in which the selective modulation of NIR independently from the VIS behavior can be supported through localized surface plasmon resonance (LSPR) effects. In that configuration, the electrochromic material is only capacitively charged and discharged through electrochemical bias, with no redox reactions and cation insertion / extraction occurring like in conventional electrochromic metal oxides.

Therefore, there is a strong need to develop novel formulations and/or structures of electrochromic materials coupling conventional and plasmonic behaviors, so to reach a selective, dual-band modulation ability of VIS and NIR. In this context, specific formulations of nanostructured tungsten oxide (Cs-doped WO_3, WO_{3-x}) have already been highlighted as promising. Moreover, the plasmonic optical features of hybrid molybdenum – tungsten oxide have been shown to be strongly enhanced in comparison to the parent oxides, displaying an intense absorption peak around 700 nm. This resonance frequency, coupled with the stronger intensity of the signal, makes this "MoWOx" hybrid oxide a very interesting candidate as dual-band VIS/NIR-selective electrochromic material.

In this work, hybrid Mo-W oxide is successfully synthesized through a one-step hydrothermal route, with the recovered powder being dispersed in low toxic solvent and coated onto glass substrates by spin or bar coating. The morphological, structural and optoelectronic properties of the powders and films are investigated through SEM, XRD, XPS, EPR, UV-VIS-NIR spectrophotometry and electrochemistry. Following the developed protocols, a "parent", non-hybridized WO_{3-x} formulation testifies for a "traditional" dual-band signature between "clear" (62% transmittance in VIS, 82% in NIR), "cool" (61% in VIS, 44% in NIR) and "dark" (42% in VIS, 18% in NIR) states. On the other hand, some of our selected "MoWOx" formulations - typically obtained with initial Mo/W atomic ratios of 2/1 - offers the possibility of a "warm" dual-band commutation mode that implies a darker state in VIS (modulable from 43 to 11% transmittance) and a fully-tunable NIR transmittance (from 76 to 8%). Such behavior can be directly corelated to the ratio of oxygen vacancies and the stoichiometry of metallic elements specifically observed in hybrid Mo-W formulations in comparison with the parent oxides. Preliminary cycling assessments also indicate an improved electrochemical reversibility and durability of the "MoWOx" compounds.

This research is funded by FRS – FNRS (Projet de Recherches PDR "PLASMON_EC" #T.0125.20) and involves collaborations with University of Namur (Prof. Luc Henrard & Dr. Michaël Lobet), ICMCB-CNRS (Dr. Aline Rougier & Dr. Mathieu Duttine) and Université Paris-Saclay (Dr. Mathieu Kociak).

2:00 PM EL03.02.04
Evaluation of All-Solid State Electrochromic-Supercapacitor with Varying Surface Roughness of WO_3 Film; Nanoparticle Deposition System(NPDS) vs Sputtering Jiseon Kim[1], Sungjun Choi[1], Dongwon Shin[1], Diao Xungang[2] and Caroline Sunyong Lee[1]; [1]Hanyang University, Korea (the Republic of); [2]Beihang University, China

Development of energy storage systems is essential since the need of renewable energy arises in order to reduce global carbon emissions. With the demand for lithium-ion batteries still overwhelming, safety of lithium-ion batteries is the issue since explosion of batteries often occur by overcharging or electrolyte leakage. Even though supercapacitors based on metal oxide are promising due to its higher stability compared to batteries, capacity loss of device under overcharging is inevitable. To overcome this problem, there are two-strategies; electrochromism and solid-state electrolyte. In this study, supercapacitor combined with electrochromic technology which can visually check the amount of charge/discharge are studied. From the point of energy storage perspective, WO_3 film is considered to be one of the electrochromic-capacitive bifuncitional material for a pseudo-capacitor. Moreover, solid-state electrolyte is an attractive alternative to prevent explosion. In addition, inorganic solid-state electrolyte has advantages for smaller volume, lighter weight and higher thermal stability compared to those for conventional liquid and gel electrolyte.
Herein, we have investigated the effect of WO_3 deposition methods on evaluating characteristics of electrochromic supercapacitor (ECS). We have used two dry deposition methods to fabricate WO_3 thin film to build ECS along with all-solid state electrolyte. Two types of full-cell ECS were produced by depositing inorganic electrolyte and positive layer such as $LiMn_2O_4$ in a series on WO_3 thin films which was fabricated by NPDS and sputtering method. Deposition methods change surface roughness greatly in WO_3 thin film owing to nanoparticle deposition system(NPDS) and sputtering method. NPDS is a novel dry deposition method which can produce films by accelerating powder to supersonic speed due to its pressure difference within the system. When powders were collided onto the electrode, powders broke and crushed while resulting highly rough surface. Since this method does not require any binder or solvent, it is an eco-friendly process. Moreover, low vacuum and low cost can make this system very attractive for the next generation deposition method. Second, sputtering method was used to deposit WO_3 thin film. Sputtering method is one of the commercialized thin film production method where It can fabricate various films under high vacuum with mass-production of thin films. Moreover, the advantage of high uniformity in film thickness, results in very low surface roughness.
Evaluation of WO_3 films deposited via NPDS vs. sputtering were compared with respect to optical, electrochemical and energy storage properties of full devices in comparison. It was found that the surface roughness of WO_3 thin film using NPDS is almost 10 times higher than that of WO_3 thin film using sputtering method. With high surface roughness of WO_3 film, WO_3 film using NPDS showed larger electrochemical reaction area. Finally, differences in surface roughness have affected device performances such as transmittance, charge capacity and areal capacitance. For instance, initial transmittance of the device with WO_3 film using NPDS was found to be lower than that of WO_3 film using sputtering due to increased light scattering caused by rough surface of WO_3 film using NPDS. However, charge capacity and areal capacitance were improved in the device due to high roughness film owing to its larger reaction area. Therefore, advantageous deposition of thin film for target performance of ECS devices can be selected with varying surface roughness of WO_3 thin film.

Investigation of the Memory Effect in Electrochromic Sputtered WO_3 Thin Films—A Combined Approach of Experiments and Machine Learning Brandon Faceira[1], Lionel Teulé-gay[1], Gian-Marco Rignanese[2] and Aline D. Rougier[1]; [1]Institut de Chimie de la Matière Condensée de Bordeaux, France; [2]Institute of Condensed Matter and Nanosciences, Belgium

Electrochromic materials and devices, able to modify reversibly their optical properties in response to an applied voltage are recognized as one of the key green technologies for sustainability and energy savings. The state of the art of electrochromic oxide is WO_3, which undergoes coloration upon reduction with insertion of small cations (H^+, Li^+ or Na^+) associated with a visual color change from colorless to dark blue. Aiming at low energy consumption applications, the unusual property of so-called the memory effect, known as the persistence of the colored state for electrochromic materials when the applied voltage is withdrawn, has recently received particular attention. This unusual property for electrochromic metal oxides allows to reduce power consumption of devices by avoiding to apply a permanent voltage in order to keep the desired color or optical state. Herein, amorphous WO_3 thin films were grown by Radio-Frequency Magnetron Sputtering (RFMS) using a WO_3 ceramic target. EC properties were estimated by cycling the films in lithium-based electrolyte while the memory effect was characterized by the evolution of the optical transmittance ΔT at 550 nm in 48h of Li_xWO_3 colored films in air-controlled environment (25°C and 50% R.H). By adjusting sputtering parameters such as power density, oxygen and total pressure films with a low

(ΔT_{550nm}~61%) or high color persistence (ΔT_{550nm}~16%) were obtained. Nevertheless, it was found that high color persistence WO_3 films could also present a low electrochemical reversibility (~23%) hence limiting practical applications. In order to optimize the compromise between these two properties, machine learning, ML, was used as a tool to design prediction maps depending on the sputtering conditions. By combining color persistence and reversibility in a single map, high performance WO_3 films with high color persistence and reversibility were targeted. From this ML mapping, WO_3 films with three different electrochromic properties were found : namely, films showing *(i)* an irreversible blue coloration and high color persistence, *(ii)* films with high reversibility but poor color persistence and *(iii)* films with a memory effect which present both high values [1]. As a result from the ML prediction maps, the total pressure during the deposition plays a key role on the memory effect since the three categories of WO_3 films were obtained by varying this parameter. In the meantime, by increasing the total pressure, films progressively go from a compact morphology to a porous one. As the morphology is more open, faster lithium diffusion and switching times are recorded. In return, the duration of the memory effect is shortened. Hence WO_3 films with a high memory effect with good EC properties requires a careful control of the morphology allowing to avoid irreversible coloration or poor color persistence. The relationship between the deposition conditions, morphology, stoichiometry and the memory effect property in WO_3 films will be discussed.

2:30 PM EL03.02.06
Electro-Responsivity in Electrolyte-Free and Solution Processed Bragg Stacks Giuseppe M. Paternò[1,2], Liliana Moscardi[2] and Francesco Scotognella[1,2]; [1]Politecnico di Milano, Department of Physics, Italy; [2]Istituto Italiano di Tecnologia, Italy

Achieving an active manipulation of colours has huge implications in optoelectronics, as colour engineering can be exploited in a number of applications, ranging from display to lightning. In the last decade, the synergy of the highly pure colours of 1D photonic crystals, also known as Bragg stacks, with electro-tunable materials have been proposed as an interesting route to attain such a technologically relevant effect. However, recent works rely on the use of liquid electrolytes, which can pose issues in terms of chemical and environmental stability.
Here, we report on the proof-of-concept of an electrolyte free and solution-processed electro-responsive Bragg stack.[1] We integrate an electro-responsive plasmonic metal oxide, namely indium tin oxide, in a 1D photonic crystal structure made of alternating layers of ITO and TiO_2 nanoparticles. In such a device, we observed a maximum of 23 nm blue-shift upon the application of an external bias (10 V). Our data suggest that electrochromism can be attained in all-solid state systems by combining a judicious selection of the constituent materials with device architecture optimisation.

Flexible Electrochromic Devices—Challenges and Progress Pooi See Lee; Nanyang Technological University, Singapore, Singapore

An electrochromic device (ECD) controls optical properties such as transmittance, reflectance, or emittance in a reversible manner upon electrical bias. This distinctive characteristic enables ECD to be utilized in a variety of applications, including green buildings and electrochromic displays. Flexible electrochromic devices encounter issues on electrolyte sealing, compatible transparent electrodes and cycling stability while subjected to mechanical strain. High performance electrochromic devices (ECD) have been assembled using tungsten oxides (WO_3) and iron-centered coordination polymer (FeCP) electrochromic materials, respectively. The electrolyte applied is based on an in-situ polymerization of poly(ionic liquid) (PIL) solid ionogel.[1] The resultant ECDs are of high color contrast, high thermal stability and cycling stability. Flexible form factor and deformability of the ECDs can be achieved. Meanwhile, we design and synthesis bimetallic oxides $Nb_{18}W_{16}O_{93}$ with tunable intracrystal cavity leading to superstructure motifs and uniform self supported electrochromic film.[2] On the other hand, developing a stable solid electrolyte with wide potential window and high ionic conductivity is desirable for solid-state reversible electrodeposition and dissolution of metal (REDM)-based ECDs. A heat-insulating black ECD based on reversible Ni–Cu electrodeposition and dissolution in a tailored organohydrogel has been achieved. The flexible black ECD fulfills a superior color neutrality and delivers an outstanding cycling stability and mechanical cyclic bendability.

4:00 PM *EL03.03.03
Leveraging the Electrochromic Effect in Soft PhotoElectroChemical Systems (SPECS) Understanding Processes for Solar Fuels and Energy Storage Erin L. Ratcliff; University of Arizona, United States

Highly scalable, durable π-conjugated polymer materials provide control over local environments afforded through synthesis, long-lived charge carrier lifetimes, and flexible, low-cost, and scalable thin film formats which circumvent the shortcomings of inorganic materials (surface states, grain boundaries, challenges in processing, and mechanically unstable platforms). The Center for Soft PhotoElectroChemical Systems (SPECS) is a newly funded Energy Frontier Research Center that focuses on the basic science questions that underpin the development of low-cost, robust energy conversion and energy storage technologies based on new organic polymer (plastic) electronic materials. These materials are predicted to fill a critical position in the U.S. energy portfolio, providing for next-generation fuel-forming platforms (energy conversion) and batteries (energy storage) that cannot currently be achieved with conventional (hard) inorganic materials.

SPECS' mission is to understand the factors controlling charge and matter transport processes that underpin emerging energy conversion (i.e. catalysis) and energy storage technologies across spatiotemporal scales to guide durable soft material development and optimization. The realization of all-organic semiconductor systems that capture light energy and convert it into chemical energy requires a detailed understanding of structure-property relationships governing the interconnected dynamics of photo-generation, transport, and electron transfer across multiple interfaces. Dark electrochemical processes must be understood before increasing the complexity via light-matter interactions. This talk will focus on increasing complex, multiple interface platforms, towards the goal of photons-to-electrons-to-molecules energy conversion processes. A number of *in situ/operando* spectroelectrochemical and photoelectron spectroscopy capabilities will be discussed for this exciting new area of energy conversion.

4:30 PM EL03.03.04
Structure-Property Relationships in Organic Mixed Ion-Electron Transporting Materials Loren G. Kaake; Simon Fraser University, Canada

There are three major classes of models for ion transport in organic electrochromic materials. The first is based on equivalent circuits, the second uses the drift-diffusion equation, and the third emphasizes the morphological heterogeneity of organic electronic materials. Of these models, the drift-diffusion equation provides the appropriate balance of rigor and ease of understanding. A simple model for describing the dynamics of electrochromic devices that accounts for in-situ spectroscopic observations and frequency dependent cyclic voltammetry will be presented. The importance of ion drift versus ion diffusion remains a point of contention. Clearly, including drift is a more general perspective, but it will be shown that ion transport does not depend on the applied field, demonstrating that in at least one common conducting polymer, diffusion alone is the appropriate metric for quantifying the rate of ion movement. As is typical of diffusive processes in solids and liquids, the rate of ion diffusion in organic electrochromic materials depends on the solubility of the ion in the electrochromic material. When the charge density of the organic semiconductor is included in the expression for solubility, quantitative fits can be obtained that describe the voltage (not field) dependence of the rate of ion diffusion. We find that the fastest switching electrochromic materials can be obtained by increasing the solubility of the ion in the electrochromic material, which includes the use of hydrated ions for hydrophilic polymers.

Role of Solvent Composition During Processing of Stimuli-Responsive PNIPAM/Silyl Methacrlyate Copolymers Fabian Rodriguez[1], Jason Linn[2], Diana Zhang[2] and Michelle Calabrese[2]; [1]University of Texas Rio Grande Valley, United States; [2]University of Minnesota, United States

Electromagnetic radiation from the sun, can produce changes in the internal temperatures of infrastructures. Offsetting this increase in temperature requires greater energy consumption. Therefore, the use of smart glass windows has increased, as these windows restrict the passage of solar radiation that enters through exterior windows and thus providing greater energy efficiency. Despite these favorable qualities, implementation of smart windows is limited due to higher production and installation costs since traditional smart windows are pretreated and cannot be processed onto already existing windows. This means that standard windows would have to be removed and replaced with expensive smart windows. Therefore, cost becomes a barrier for businesses, schools, or individuals who are seeking green alternatives. To circumvent these costs while still meeting demands for greater energy efficiency, thermosensitive polymer coatings have been proposed as an alternative to traditional smart windows such as thermal glazes or hydrogel laminates.
In this study, poly(N-isopropylacrylamide-co-3(trimethoxysilyl)propyl methacrylate copolymer (PNIPAM -co-TMA) has been studied as thermal-responsive glass coatings due to optical properties stemming from thermally reversible phase changes. These phase changes result from the abrupt coil-to-globule transition where aqueous solutions shift from clear to opaque with increasing temperature. The thermoresponsive behavior of PNIPAM is favorable for sprayable smart window coatings for their ability to filter out light and heat from solar radiation. However, the presence of TMA, which allows PNIPAM coatings to bind to glass substrates, can lead to irrecoverable opacity due to crosslinking within the copolymer chain.
Cloud point testing was utilized to characterize the optical response of PNIPAM-co-TMA over several thermal cycles as irrecoverable transmittances can be observed when the TMA crosslinks within the copolymer chain. However, systems composed of 95% mol of water and 5% mol of DMSO were able to recover their original clarity across various concentrations of TMA. These results are significant because co-nonsolvency allowed access to the collapsed, opaque, state using solvent mixtures instead of temperature. This may be advantageous for coating processes. Various co-nonsolvent systems were processed into coatings through either spin or drop coating. When processing the co-nonsolvent systems into coatings, the solutions were kept at lower viscosities to better replicate a sprayable coating. This was a critical consideration when optimizing the spin coatings as the viscosity of the solution has a direct impact on the rpm required to spin. Finally, contact angles at 23°C and 60°C were collected for a coated slide. At room temperature, below the cloud point temperature, the coated slide had a contact angle of approximately 21°. When the coated slide was heated to 60°C a contact angle of 52° was measured. These results verify that the PNIPAM-co-TMA solution maintains the characteristic hydrophilic/hydrophobic phase change after the coating grafts onto the glass and subsequently permits this research to impact the use of polymer responsive coatings to improve energy efficiency.

5:00 PM EL03.04.02
Origin of Black Coloration in Reversible Metal Electrodeposition Dynamic Windows Cheon Woo Moon, Nikhil C. Bhoumik, Desmond Madu and Christopher Barile; University of Nevada; Reno, United States

Dynamic windows with electronically controlled transmission are a promising technology to increase the energy efficiency of buildings because they allow for the control of heat and light transmittance from the outside. Recently, our group has investigated dynamic windows based on reversible metal electrodeposition and designed devices that possess high contrast ratios and excellent cycleability. By modulating the structure and reactivity of the electrolyte and the electrode, uniform thin films of metals can be electrodeposited on transparent conducting oxides over a relatively large area, opening up the possibility of using reversible metal electrodeposition for practical smart window applications.[1]
To generate a black opaque state with privacy level transmission (< 0.1%), various metals have been investigated including Ag [2, 3], Cu-Bi [4], and Zn [5]. Reflection and transmission of the electrodeposits must be minimized to generate a dark black appearance. However, a deep understanding of the coloration principle in terms of the micro- and nanostructures of the electrodeposited metals has not been described. For example, Ag is a plasmonic material, and Zn is non-plasmonic material in the visible light region, but both metals can generate black colors. In this work, we explain the origin of black coloration in the reversible metal electrodeposition systems using electromagnetic simulation-based (finite-difference time-domain; FDTD) approaches.
As the size of the window increases, the coloration efficiency (CE) of device tinting is an important issue to consider. We therefore have designed nanostructures that maximize coloration efficiency. By considering the deposits as arrays of isolated nanoparticles, the nanoparticle size effect in terms of transmittance and reflectance is investigated after fixing the amount of metal in a unit cell. Next, optical characteristics are analyzed by modeling the experimentally-determined three-dimensional structure of the electrodeposits. Finally, the effects of metal oxides and other side products in the electrodeposits are carefully examined from the perspective of optical resonance modulation.

Increased Cycleability for Reversible Zinc Electrodeposition for Dynamic Windows Nikhil C. Bhoumik[1,2], Desmond Madu[1], Profulla Mondol[1] and Christopher Barile[1]; [1]University of Nevada, Reno, United States; [2]Jahangirnagar University, Bangladesh

The energy crisis is a grand challenge facing our world. In the U.S., buildings are responsible for ~40% of total energy consumption. Dynamic windows, which switch between dark and clear states upon application of a voltage, can result in an average of 10% energy savings in buildings. In previous research, it has been demonstrated that Zn-containing aqueous electrolytes used on transparent conducting glass electrodes facilitate fast, reversible, and color-neutral Zn electrodeposition over thousands of cycles in dynamic windows.[1,2] However, for commercialization applications, some important challenges still need to be overcome. Common challenges for reversible Zn electrodeposition on dynamic windows are dendritic growth, parasitic H_2 evolution, irreversible Zn-ion loses, and low cyclability.
In this work, we improve the durability of 25 cm^2 Zn dynamic windows to 10,000 cycles and overcome all the above-mentioned challenges by using a unique electrolyte system. To achieve these results, we studied a series of electrolytes in different solvents and found relationships between the electrolyte and solvent compositions and the switching speed and cycleability of the devices. Proper control of the electrode-electrolyte interface results in the suppression of dendrite growth and enhances the reversibility of the Zn electrodeposition and stripping processes. The optimized electrolytes possess high Coulombic efficiency (> 99%) and promote the formation of smooth and compact electrodeposit morphologies that efficiently block light. This study also allows us to design prototype two-electrode 100 cm^2 Zn dynamic windows that switch uniformly to <2% within 30 s. Our results indicate that Zn is a promising metal for future practical dynamic windows based on reversible metal electrodeposition.

Colorful E-Paper Based on Inorganic Nanostructures Marika Gugole; Chalmers University of Technology, Sweden

In recent years, reflective displays have gained a lot of attention due to their low power consumption and excellent visibility in sunlight. The market already offers viable options for reflective displays, mostly based on electrophoretic ink (E-ink). However, this technology has a number of limitations, including poor color quality. Therefore, black-and-white E-ink displays remain the most popular alternative [1].
We have investigated the integration of structural coloration and electrochromic materials for new types of reflective displays in color. We fabricated highly reflective red, green, and blue metasurfaces, based on Fabry-Perót cavities and plasmonics. In order to display dynamic images, we implemented electrochromic materials as on/off shutters [2].
To further improve the overall reflectivity, we aimed to reduce the number of subpixels needed to achieve a wide color gamut. Generally, this subdivision consists of three subpixels, normally red-green-blue. By fabricating a dynamic Fabry-Perót cavity, where one of the layers is made up of electrochromic WO3, we predicted to achieve full color with only two subpixels [3]. In this case, the electrochromic material tunes the resonance of the cavity, which in turn shows several colors depending on the degree of ion intercalation.
Furthermore, commercial alternatives have a slow refresh rate, which makes them unsuitable for displaying videos. To overcome this problem, we have incorporated electrochromic polymers into engineered nanostructures with positive curvature. By optimizing electrolyte and electrode configuration, the switching speed could be improved to the extent needed to enable video display [4].

Oriented Surface-Anchored Metal-Organic Frameworks (SurMOFs) as Electrochromic Active Thin Films Antoine Mazel, Lucas Rocco, Nicolas Penin and Aline D. Rougier; CNRS ICMCB, France

Nowadays, electrochromic thin-films are mostly based on inorganic oxides (WO_3, V_2O_5…) or organic compounds (viologens, polymers…). Hybrid materials, combining inorganic and organic building blocks, are ideal candidates to expand the range of compounds for the development of original and performant EC thin films. Herein, we report the synthesis of novel hybrid EC thin films based upon highly oriented porous materials. The unusual property of the films lead to the design of an original electrochromic device.
Over the past two decades, porous coordination polymers and Metal-Organic Frameworks (MOFs) have emerged as an important family of crystalline materials with a broad range of applications[1]. These unique class of hybrid materials assembled from metal ions or clusters and organic ligands as building units allow the combination of functional ligands in a highly ordered three-dimensional fashion[2]. In these materials, the EC property can either originate

from the organic or inorganic component. Recently, a strategy based on the sequential and controlled immobilization of the key components of the MOFs led to the fabrication of highly homogenous materials where the ligands and the metals present a preferential orientation. These new MOF thin films are called Surface-Anchored Metal-Organic Frameworks (SurMOFs)[3]. Besides the generation of highly oriented and non-interpenetrated materials, this method is compatible with almost every substrates and uses a very small amount of precursors (few mg/cm*cm) making SurMOFs ideal candidates for the integration of highly sophisticated ligands into functional materials.

In this work, we developed novel electrochromic thin films based on oriented SurMOFs. Thin films were synthesized via spray-coating by using zinc acetate and a ligand from the perylene diimide (PDI) family. The electrochromic activity of the SurMOFs was recorded in imidazolium-based ionic liquids. Interestingly, two strikingly different behaviors were observed depending on the electrolyte composition. The as-deposited films switch reversibly from orange to dark blue in a lithium-based electrolyte while they adopt a cyan reduced state in salt free electrolytes. Taking advantages of this unusual property, a bi-color device with an original configuration was designed offering a uniform orange oxidized state and a bi-color cyan and dark blue reduced state. Clearly, two different mechanisms took place and the reduced species responsible of the color were identified. To our knowledge, this work represents the first one regarding the use of SurMOFs for electrochromic applications and opens the doors of a new category of EC materials as the combination between ligands and metals are infinite.

Electrochromic Performance of Silver Nanowires Based Transparent Electrode Films: an Approach to ITO-Free Electrochromic Devices

Ambreen Ambreen[1,2], Brandon Faceira[1], Laetitia Bardet[2], Camilo Sanchez-Velasquez[2], Abderrahime Sekkat[2], David Munoz-Rojas[2], Daniel Bellet[2] and Aline D. Rougier[1]; [1]Institut de Chimie de la Matière Condensée de Bordeaux, France; [2]Laboratoire des Matériaux et du Génie Physique, France

Transparent electrodes (TE) have been widely studied as a key component of many optoelectronic devices such as solar cells, flexible light-emitting devices, transparent heaters and smart windows. Currently, indium tin oxide (ITO) is extensively used as transparent electrode for these devices owing to its high transparency, electrical conductivity and chemical stability. However, the scarcity of indium, the expensive deposition method and brittleness of ITO prompted the search for new flexible, stable and low-cost TEs. Silver nanowire (AgNW) networks appear as a promising alternative thanks to their high optical transparency, excellent electrical properties and mechanical flexibility [1], and are indeed gaining much attention in the last years. In order to improve the integration of AgNW networks into industrial devices, their stability against electrical and/or thermal stresses needs to be enhanced. One of the applications of TE is smart windows that have attracted great attention due to their potential applications in energy-efficient devices. Thanks to electrochromic materials that can alter their transparency as a response to an electrical input, [2] smart windows can decrease the need for energy-intensive heating or air conditioning in buildings. Strong direction of improvement in ECDs consists of replacing the commonly used ITO as transparent electrode with a flexible TE. In this context, AgNW networks are promising candidates however, their stability to oxidation and corrosion in electrolyte remains a key issue for the application. Moreover, the method and experimental conditions of electrochromic oxide deposition on AgNW networks also influence the stability of AgNW networks.

The aim of the present work is to prepare ITO-free electrochromic devices using stable AgNW networks as TE. The network is deposited through spray-coating on transparent glass substrates. To overcome the instability issues, AgNW networks are coated with a thin conformal protective oxide layer using atmospheric pressure spatial atomic layer deposition [3]. The influence of post deposition treatment on the properties and stability of AgNW networks are discussed. The electrochromic oxide is deposited through radio frequency magnetron sputtering (RFMS) technique and the electrochromic performance is determined through cyclic voltammetry and chronoamperometric characterizations. The performance of AgNW based electrochromic film is compared with the ITO based electrochromic film.

Fabrication of Color Visualized Sensing System for NOx Gas Using Dry Deposition Method Sungjun Choi, Haritham Khan, Jiseon Kim, Jin-Goo Park and Caroline Sunyong Lee; Hanyang University, Korea (the Republic of)

As the emission of toxic gas continues to increase, the importance of monitoring the emission of toxic gas through a gas sensor is increasing continuously. Since most of these harmful gases are invisible, a system to give quick information about leakage is crucial. Conventionally, gas sensors should be heated to a high temperature to sense toxic gas by measuring its change in resistance. In this study, a gas sensor operable at low temperature with an electrochromic device that can display its presence of gas by changing its color at low voltage are implemented in one circuit to visualize sensing of toxic gas. When toxic gas is inserted, resistance of sensor is increasing, and the electrochromic device changes its color by changing its current. Therefore, the gas sensor to be used in this study should have high sensitivity at low temperature, while the electrochromic device operates at low voltage.

Ceramic oxides such as WO$_3$, ZnO, and TiO$_3$ are mainly used as active materials for gas sensors. In this study, a thin film was fabricated using a nanoparticle deposition system (NPDS) as a thin film deposition method to fabricate sensing films. NPDS is a method of dry deposition on a substrate by accelerating the powder in the nozzle to supersonic speed due to the pressure difference between the chamber and the nozzle in a low-vacuum atmosphere at room temperature. NPDS can control roughness of thin film to control reactive surface area. In addition, MoS$_2$ was coated on the surface of the thin film using a hydrothermal synthesis method after thin film production through NPDS. Through this, we tried to fabricate a gas sensor that has a highly reactive surface which can be operated even at low temperatures through MoS$_2$ coating.

In this study, three thin films of WO3, ZnO, and TiO3 were fabricated by NPDS method, followed by MoS$_2$ coating on each thin film through hydrothermal synthesis. We have used 200 ppm of NOx gas while we monitor the behavior of gas sensing while we vary temperature. The material with the best sensing sensitivity was selected. Finally, a sensor using the selected material with the highest sensitivity, and an electrochromic device were implemented in one circuit to build color visualized sensing system. We have used electrochromic gel (EC gel) based on mono-heptyl viologen (MHV, 1-heptyl-4-(4-pyridyl) pyridinium) which is capable of color-changing at low voltage for electrochromic device.

5:00 PM EL03.04.08

Modular Electrochromics – Designs for Facile Color-Mixing John M. Toribio, Omer Yassin and Gregory Sotzing; University of Connecticut, United States

Neutral states are quite lucrative in electrochromic design due to their versatile applications in different forms of shading and displays. Color neutrality is typically achieved as a result of subtractive color mixing, using a combination of chromophores having complementary absorption spectra to cover the entirety of the visible region. Several aspects of design should be considered when combining chromophores, including redox potentials, absorption spectra, migration effects during operation, and ease of synthesis or blending. Herein, we present a new system for achieving color neutrality in electrochromic devices by combining a set of complementary chromophores that can either be blended or co-reacted to form a new compound for polymerization that represents its component chromophores. As an example, we highlight a novel multichromophoric electrochromic polymer containing a conjugated 3,4-propylene dioxythiophene (ProDOT) backbone and a reversible redox active small molecule electrochrome tethered to the conjugated chain. The resulting electrochromic device exhibited a 55.7% photopic contrast with bleached and dark state transmittances of 70.4% and 14.7%, respectively. Furthermore, we briefly discuss approaches to develop melt-processable electrochromic polyesters as modular electrochromics.

Dynamic Switching of Optical Contrast in Structural Colors Based on Rayleigh Anomalies by Li-Ion Insertion Kyungnae Baek, Cheon Woo Moon and Jerome Hyun; Ewha Womans University, Korea (the Republic of)

To demonstrate dynamic on/off switching of structural colors, Li ion intercalation of WO_3 in Fabry-Perot cavities and gap plasmon resonators has been explored by many groups. Various structural colors can be prepared by controlling the arrangement or dimension of such resonators while the input and output of Li ions into the resonators can change the colors from dark to bright. One of the challenges has been achieving near 100% optical switching contrast, which can be achieved with a completely black off state. In this study, we prepare vibrant structural color pixels composed of WO_3 nano gratings and demonstrate various colors based on the Rayleigh anomaly (RA) under a cross-polarized excitation and detection configuration. From RCWA calculations, high switching contrast (>80%) between the intercalated and deintercalated states was confirmed at specific grating heights. To experimentally demonstrate these findings, we fabricated an electrochemical cell with a WO_3 grating on a metal working electrode and ITO counter electrode sandwiching an electrolyte including Li ions dissolved in propylene carbonate. The grating was oriented 45 degrees with respect to the input polarized and the refection was viewed with a separate orthogonal polarizer. With the appropriate grating parameters, this configuration enables one to view colors from the RA. With an applied cathodic bias, the Li_xWO_3 gratings appear black. The original colors from different gratings returned with an applied anodic bias. Based on these calculated and measured results, we suggest the use of this structural color pixel in high contrast dynamic reflective displays.

SESSION EL03.05: Organic Electrochromic Molecules and Polymers I

Flipping the Spectra—Optimizing Transmission, Contrast and Color in Anodically Coloring Electrochromes John R. Reynolds[1], Dylan Christiansen[2], Justine Wagner[1], Mason Butt[3], Abigail Dejneka[1], Simone Tennyson[1], Eric Shen[1], John Bacsa[4], Anna Österholm[1] and Aimee Tomlinson[3]; [1]Georgia Institute of Technology, United States; [2]Electrochromic Company, United States; [3]University of North Georgia, United States; [4]Emory University, United States

The ability to tune the electronic transitions of both molecular and polymeric electrochromes provides controlled absorption of ultra-violet, visible and near infrared light. Cathodically coloring conjugated polymers (CCPs) have been developed which exhibit a full palette of primary colors, and can also be mixed to form secondary colors and neutral (brown and black) states. Upon oxidation, light absorption for the these CCPs is moved into the near IR, with concurrent loss of the visible light absorption, yielding transmissive states. While high electrochromic contrasts are accessible with these polymers, a limit is reached as the near IR absorption bands tail in the visible providing some residual red-light absorption, causing the oxidized form to have a light blue or gray hue. Cathodically coloring molecular electrochromes, of which the viologen family is most prevalent, avoid this as the dication state absorbs in the UV, giving rise to a truly colorless state, and can be subsequently reduced to the visibly colored radical cation state with high optical density. Here, we report on our work in developing both unsymmetrically and symmetrically structured molecular Anodically Coloring Electrochromes (ACE). We start with unsymmetrically structured two-ring (EDOT-phenylene) molecules having neutral states that are UV absorbing and colorless with L*a*b* values of 100, 0, 0. The ACE molecules oxidize to vibrantly colored, cross-conjugated, radical cations with absorptions that span the visible spectrum creating green, yellow, and red chromophores. We subsequently extended the conjugation length of the ACE molecules to symmetric three-ring EDOT-Phenylene-EDOT structures, which exhibited varying degrees of hue and saturation within the blue color space in their oxidized form. By functionalizing the central 1,4-phenylene moiety with electron donating methoxy groups, we optimized the system to oxidize at a low potential, exhibit a single narrow radical cation absorbance in the visible region with a saturated blue color, and provide a high electrochromic contrast. As these ACE molecules are soluble, and have similar oxidation potentials, they could be mixed to create transmissive, colorless blends that switch to opaque black solutions. Finally, by functionalizing the ACE molecules with pendant phosphonic acid groups, they could be adsorbed onto nanoITO modified electrodes. Placing the chromophore in intimate contact with the electrode allows for rapid on-demand switching, with our first-generation ACE molecules reversibly switching from 98% transmittance to 30% transmittance within seconds over 100 cycles. These results establish the design strategies needed to further develop a complete palette of high contrast and user controlled molecular electrochromes with a truly colorless state.

9:00 AM EL03.05.02
Ultrahigh Optical Contrast Electrochromic Polymers Zhiyang Wang, Liyan You, Vaidehi Pandit, Jagrity Chaudhary and Jianguo Mei; Purdue University, United States

Electrochromic materials undergo reversible color changes upon application of an external potential bias. P-type cathodically coloring electrochromic materials absorb in the visible region in the neutral state, and the oxidized state absorbs in the NIR to IR region appearing transmissive by eye. However, the oxidized species exhibit an absorbance tailing into the visible region, thus never reaching a fully transparent state. In this work, we report a new concept for the design of p-type anodically coloring electrochromic polymers. The neutral states of these polymers are UV absorbing and completely transparent in the visible region. The color of the polymer in oxidized state is controlled by tuning the conjugation length. These polymers are mixed to create transparent-to-black electrochromic device. The device exhibits an ultrahigh optical contrast up to 95%, the highest value reported in literature.

9:15 AM EL03.05.03
Substituent Influence on Degradation of ProDOT Electrochromes Kuluni Perera, Wenting Wu, Atheena Jenkins, Michael Espenship, Matthias Zeller,

Liyan You and Jianguo Mei; Purdue University, United States

Molecular electrochromes are capable of switching between optically transparent and colored states through redox processes. Although the color of an electrochrome can be readily tuned using substituents, these alterations can also influence reactivity of the molecule, especially when in charged, open-shell forms. Increased susceptibility to undesired side reactions may affect reversibility of the color changes and diminish long-term cyclability of these electrochromic materials. This work focuses on a group of electrochromes designed based on the 3,4-propylenedioxythiophene-phenyl (ProDOT-Ph) π-conjugated core, whose stability in the oxidized, radical cation state is significantly influenced by the number and position of methoxy substituents placed on the phenyl ring. Radical cations were generated using both chemical and electrochemical doping and the subsequent degradation was tracked through a combination of UV-Vis-NIR spectroscopy, mass spectrometry and single crystal XRD analysis. Considerable deviations from expected radical cation characteristics were observed over time, depending on the substitution pattern. Two distinct irreversible degradation processes related to functional group loss and sigma dimerization were identified. Computational calculations reveal a trend in substituent-driven radical localization effects, which helps to explain the observed reactivity of the radical cations. While the judicious placement of substituents could successfully prevent rapid methoxy degradation, eventual radical dimerization could only be overcome by varying the end-capping group. These findings provide insights on the role of substituents in determining electrochrome stability and design considerations for durable redox-active molecular systems.

9:30 AM EL03.05.04
Probing Electron Density Modulation and Steric Interactions to Elucidate Color Control in Anodically Coloring Electrochromes Justine S. Wagner[1,1], Evan Smith[2], John Bacsa[3], Aimee Tomlinson[2] and John R. Reynolds[1,1,1]; [1]Georgia Institute of Technology, United States; [2]University of North Georgia, United States; [3]Emory University, United States

Recently, our group has made a significant contribution to the field of anodically coloring organic electrochromics (ACEs) through the autonomous manipulation of the band gaps of the neutral and radical cation forms. Here, we systematically evaluated the optoelectronic and structural effects of substituent alteration on a tunable centralized phenylene core on a symmetrical three ring conjugated thiomethyl-substituted bis(3,4-ethylenedioxythiphene)-1,4-phenylene molecule. In addition, we revisit the asymmetric EDOT-phenylene bi-aryl structural motif by accessing and modulating the lower energy (LE) radical cation peak position and oscillator strength through the incorporation of a sterically hindered electron rich moiety. We capitalize on the versatility of both constructs to demonstrate how steric interactions and electron density modulation impact the conjugation, torsional angles, and bond distances of both forms. As a consequence, there is an alteration in the optoelectronic properties and redox activity which controls color access and vibrancy of radical cation and dication states. These results, combined with our earlier work, increases our design rules thereby allowing for fine-tuning of the hue and saturation of molecular electrochromes. Ultimately, this work has allowed us to get closer to reaching our goal of developing a complete ACE color palette consisting of a fully transmissive colorless neutral state and a highly absorbing colored charged state.

9:45 AM EL03.05.05
Polyhedral Oligomeric Silsesquioxane Functionalized Viologen Hybrid Materials for Large-Area Flexible Electrochromic Devices Jong Seung Park[1], Fayong Sun[1], Joo Hee Eom[1], Do Yeon Kim[1], Gaurav K. Pande[1], Seung Geol Lee[1] and Sung Kyu Park[2]; [1]Pusan National University, Korea (the Republic of); [2]Chung-Ang University, Korea (the Republic of)

The electrochromic devices (ECDs) exhibit reversible color changes due to electron and ion transfers during the redox reactions. Viologen derivatives have been frequently employed in ECD fabrication due to their electron-accepting capability and facile synthetic routes. However, viologens have often disclosed slow switching speed, poor long stability, and mediocre coloration efficiency. Meanwhile, transparent conducting oxide (TCOs) electrodes are another vital component determining the visual contrast and switching behaviors of ECDs. Indium tin oxide (ITO) has been widely adopted as a TCO material. Still, the ECDs have often suffered from low conductivity and poor uniformity, especially in the case of ITO-PET films. Due to the inevitable voltage drop for large electrodes, the performance degradation has become even more severe.
Herein we present the polyhedral oligomeric silsesquioxane functionalized viologens (POSS-viologens) applicable for large-area flexible ECDs. The structural rigidity of POSS fillers and the synthetic versatility of viologen compounds are manipulated. The active layer formed using ion gel compositions by spray and bar coating methods displays good mechanical stability and high ionic mobility. Depending on the active device sizes, the electrochromic behaviors are investigated in-depth and compared with conventional viologens. Furthermore, the TCO electrodes are treated with semi-conducting nanoparticles to adjust and enhance the distribution in contact resistance. Different electrode patterns and power supply connections are applied for the device preparation. The current results may offer feasible approaches for mass production of large-area flexible ECDs at affordable costs by employing POSS-viologens and modified electrodes combined with the solution coating methods.

Energy Saving Electrochromic Windows Based on Conjugated Polymers with Counter Electrode Modification Eunkyoung Kim; Yonsei University, Korea (the Republic of)

In the quest to reduce energy consumption, smart window devices present a core solution to reduce the massive energy loss through windows. Smart window devices can be designed on the basis of electrochromic (EC) principles, which offer simple integration mechanisms for color switching, optical sensing, and energy storage. An energy saving electrochromic window was explored based on charge-balancing concept and interfacial carrier transport control. A blue or black-to-transparent EC windows were achieved through the combination of EC polymers and a capacitive layer. A porous film was grown from aniline interfaced-graphene flakes, to provide a capacitive layer with a high surface area and electrical conductivity. As prepared EC windows afforded a highly transparent (>75%) and a large color-contrast EC window, which showed a high energy density enough to fuel an electronic clock and LED. A 10 × 10 cm2 size window was demonstrated, to feature the scalability of the electrochromic capacitive window. These electrochromic properties of CPs with counter electrode modification approaches make them very promising candidates for designing functional smart windows. Single cell type multi-functional windows have emerged based on CPs, to deliver electrochromic capacitive windows and photoelectrochromic windows. The progress of these efforts will be highlighted in this talk, along with guiding principles.

11:00 AM EL03.06.02
Optical Dispersion and Dynamic Thermoregulation Metasurface of IR-electrochromic Conductive Polymer Ting-Hsuan Chen[1] and Po-Chun Hsu[2]; [1]Duke University, United States; [2]The University of Chicago, United States

Personal thermoregulation is an energy-efficient innovation to address the need of human body temperature homeostasis. With its variable emissivity, mid-IR electrochromic conductive polymer can act as active material in a device to offer thermal comfort without energy input. Additionally, by incorporating the metal-insulator-metal (MIM) perfect absorber design, dynamic conductive polymer metasurface could provide larger emissivity contrast for personal thermoregulation. However, modelling the optoelectronic behavior of conductive polymer is challenging in the mid-IR due to the coupling of phonon and free carriers. Here, we present the spectroscopic ellipsometry and WAXS studies at various electrical potential and establish the correlation between charge transport properties, complex refractive index, and the morphology. The change in carrier concentration is successfully observed by fitting from various optical dispersion models. As a proof of concept, we also demonstrated the electrochemically dynamic metasurface for emissivity tuning by biasing and switching the structure between a high-emissivity perfect absorber and a metallic reflector.

11:15 AM EL03.06.03
Design Rules for High Contrast Mid-Infrared Electrochromism Eric Shen, Callie Goins, Austin L. Jones, Anna Österholm and John R. Reynolds; Georgia Tech, United States

The ability to modify a material's optical properties by varying the applied voltage is the foundation of the field of electrochromism. To date, most of the new material development is primarily focused on designing chromophores with strong and fast visible light modulation, where materials that can switch between a colored and colorless state, as well as those that switch between multiple colors, have generated opportunities in areas ranging from tinted windows, to color indicators paired with sensors, to user-controlled eyewear. However, the ability to modulate transmission in the mid-infrared (mid-IR) has been far less explored even though it has the potential of making a substantial impact in a range of applications including thermal camouflage and motion sensing. While several material classes can exhibit IR electrochromism, conjugated polymers can be synthetically tuned to readily investigate structure property relationships. This property has been utilized to develop a strong understanding of how their neutral state spectra can be predictably controlled. Their oxidized spectra however are far less well understood.
In this presentation we extend this understanding by evaluating several families of conjugated polymers. Thin films are spray-coated onto IR-transparent substrates and chemically treated to either neutralize the film through exposure to hydrazine or oxidized by exposure to a chemical dopant. In conjugated materials, oxidation gives rise to a rearrangement of bonds to accommodate the charge, accompanied by a shift in absorbance to longer wavelengths starting from the near-IR and continuing well into the mid-IR, arising from the optical signature of radical cations and dications. The intensity and width of the IR absorption is determined not only by the type and number of charge carriers, but also by how effectively they can delocalize along the chain. Theory suggests that the better stabilized the charged state of a conjugated material is, the greater the absorbance in the mid-IR. Here, we will summarize how we have been able to optimize IR switching in solution-processable EC polymers using some simple structural modifications resulting in champion systems exceeding 85% thin film contrast from 3-12 µm, areas where IR sensors commonly operate. This was achieved using a combination of an electron-rich backbone that has the ability to readily planarize and the incorporation of polar functionalities that we hypothesize are able to enhance polymer-electrolyte interactions and stabilize the charged state. The addition of electron-accepting repeat units is a common strategy for red-shifting the neutral state absorption for visible range electrochromism. Here, we find that these electron-deficient acceptor units compromise charge carrier delocalization and the stability of the oxidized state resulting in the mid-IR absorption rapidly tailing off above 3 µm. Replacing the polar functionalities with apolar analogs also does not have a significant impact on the visible electrochromism but, for the systems studied here, the intensity of the mid-IR modulation is noticeably compromised. Finally, we will show examples of IR-reflecting device prototypes and discuss some of the challenges that go beyond the active material, in particular how different device layers must be carefully considered based on their contribution to the mid-IR response.

11:30 AM EL03.06.04
In-situ Measurement of the Swelling, Mechanical Property, Damage, and Doping Kinetics of Poly(3,4-propylenedioxythiophene) Electrochromic Polymers Xiaokang Wang, Jianguo Mei and Kejie Zhao; Purdue University, United States

The doping of electrochromic polymers involves rich coupling between mechanics and electrochemistry. The drastic changes in the microstructure and properties originate from the electron transport and ion intercalation in the polymers. In our recent work, we quantify the breathing strain, the evolution of the mechanical properties, materials degradation and damage, and the doping kinetics of poly(3,4-propylenedioxythiophene) (PProDOT) thin films in-situ using customized environmental nanoindentation and optical microscopy. Upon oxidation, a breathing volumetric strain of 12–33% is persistent in different sets of electrolytes of various solvents, salts, and salt molarities. Also, the elastic modulus, hardness, and yield strength decrease by a factor of two. Heavily cycled PProDOT films show reduced volumetric strain and accumulated mechanical damage of channel cracks and dysfunctional regions of slow and inhomogeneous electrochromic switching. Interfacial engineering techniques are demonstrated to increase the lifetime of thin film electrochromic electrodes by two orders of magnitude. As the swelling-induced stress may bias the doping kinetics, we observe that an applied pressure as low as 2.8 MPa significantly retards the electrochromic switching in a designed moving front setup. Our work presents a systematic characterization of mechanical behavior and doping kinetics in a model electrochromic polymer and informs the mechanical and electrochemical reliability of organic electrochromic devices.

11:45 AM EL03.06.05
Synthesis and Conductivity Optimization of Ladder Polyaniline Featuring Extraordinary Stability, States-Delocalization Mingwan Leng and Lei Fang; Texas A&M University, United States

A highly stable, conductive ladder pernigraniline salts was synthesized. EPR and SQUID test were performed to prove that its conductivity comes from polaron delocalization. By comparing side chains with different electron donating/withdrawing group, parameter basicity is turn into a key design parameter for acid doped quinoidal structures. Meanwhile, the ladder structure enabled it good reversibility in Lithium salt and acid electrolyte, and extraordinary stable performance on electrochromic device. At the end, with assistant of robot and AI, the experiment of exploring acid additive to the polymer proved that liquid acids additive enabled it morphologies fitted for conductivity test.

SESSION EL03.07: Reversible Metal Deposition and Inorganic Electrochromic Devices

Design Factors that Enable High Performance Dynamic Windows Based on Reversible Metal Electrodeposition Michael D. McGehee[1], Andrew Yeang[1], Yuchun Cai[1], Gabriel McAndrews[1] and Christopher Barile[2]; [1]University of Colorado, United States; [2]University of Nevada, Reno, United States

Dynamic windows with adjustable tint give users control over the flow of light and heat to decrease the carbon footprint of buildings and improve the well-being of the people inside them. In this talk we will discuss the design of windows based on reversible metal electrodeposition. Topics will include the choice of metal (Cu, Bi, Ag or Zn), counterion (halides, nitrates, perchlorate), and solvent (water vs DMSO). We will also discuss how intercalation of lithium into nickel oxide or a metal mesh electrode can be used as the counter electrode. We will show how proper design can avoid irising, enable excellent resting stability, provide color neutrality, achieve light transmission below 0.1 % for privacy and result in good cycle life.

2:00 PM EL03.07.02
Investigation and Manipulation of Zinc Electrodeposition Morphology for the Construction of Reversible Zinc Electrodeposition Dynamic Windows Desmond Madu[1], Andrew A. Thompson[1], Madeline J. Leahy[1], Micah V. Lilo[1], Michael D. McGehee[2] and Christopher Barile[1]; [1]University of Nevada, Reno, United States; [2]University of Colorado Boulder, United States

Reversible metal electrodeposition (RME) is an underexplored and promising method for the design of dynamic windows with electronically controllable transmission. RME enables the construction of dynamic windows with fast switching and color-neutral tinting. A variety of metals have been explored, but each has thus far been associated with negative attributes. In this work, we investigate Zn RME due to its ability to produce viable windows despite the negative reduction potential of Zn. By systemically studying the chemical composition of aqueous Zn electrolytes and the structure of Zn electrodeposits on tin-doped indium oxide electrodes, we are able to create high contrast reversible 25 cm2 windows that possess >99% Coulombic efficiency. X-ray diffraction and scanning electron microscopy analyses allow us to link window optoelectronic performance to the electrolytes' composition and Zn electrodeposit morphology. Through the use of polymers such as polyethylene glycol , we are able to manipulate the deposited Zn morphology. This change in morphology allows for a large increase in cycle life from less than 100 cycles to more than 1,000 cycles with retention of other beneficial properties. With this increase in cycle life as well as a high contrast ratio, Zn RME is a viable option for further development of metal-based dynamic windows.

2:15 PM EL03.07.03
Understanding and Improving Mechanical Stability in Electrodeposited Cu and Bi for Dynamic Windows based on Reversible Metal Electrodeposition Gabriel McAndrews[1,2], Andrew Yeang[1], Yuchun Cai[1], Christopher Barile[3] and Michael D. McGehee[1,1]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States; [3]University of Nevada, Reno, United States

Reversible metal electrodeposition (RME) is a growing field with applications ranging from batteries (e.g. Li, Zn) to dynamic glazings for thermal emissivity (e.g. Ag) or windows (e.g. Cu, Bi, Ag, Zn). Dynamic windows based on RME can enhance building efficiency up to 20% due to reduced lighting, heating, and cooling loads while reducing glare.[1] While a reductive potential is applied, RME windows based on Cu and Bi can adjust light transmission from ~ 70 % to < 0.1 % ("privacy state") when ~180 nm of metal is electrodeposited on the transparent conducting electrode.[2] Uniform, smooth, and compact films enable RME windows to reach low transmission states with color neutrality at large scale,[2] and the transparency of the window can be regained by switching the polarity of the potential.[3,4]

We find that films plated to privacy state transmission with a Cu-Bi ratio of ~2:1 fracture and delaminate within 24 hours resulting in a visually unattractive window with lost active metal and a reduced dynamic range. While the Cu-Bi film is stress free upon deposition, after 4 hours of resting 38 MPa of tensile stress develops. Likewise, pure Cu films exhibit 142 MPa of tension after deposition. The tension in Cu-Bi and Cu films combined with the $Cu(ClO_4)_2$ in the electrolyte results in severe, widespread sinusoidal cracks and delamination due to stress corrosion cracking (SCC). In contrast, electrodeposited Bi films have compressive stress, likely due to high self-diffusion and insertion of atoms into grain boundaries during plating. We emphasize the importance of stress characterization in electrodeposited films to identify susceptibility to mechanical failure driven by SCC. In turn, we demonstrate a Bi-based dynamic window with crack-free resting stability that exceeds 9 weeks.

Highly Opaque and Durable Dynamic Windows based on Reversible Zinc Electrodeposition Christopher Barile, Desmond Madu, Nikhil C. Bhoumik and Cheon Woo Moon; University of Nevada, Reno, United States

Dynamic windows harnessing reversible metal electrodeposition (RME) have emerged as a promising technology to enable energy-efficient windows with electronically tunable transmission. Metals are ideal materials for blocking light due to their high opacity and color neutrality. Most previous work on metal-based dynamic windows using aqueous electrolytes relies on the reversible electrodeposition of Ag, Cu, and Bi.[1-3] These metals are more noble than H_2, and thus H_2 evolution can be avoided during device switching.

Recently, we were inspired by work on secondary Zn batteries[4] to develop aqueous Zn electrolytes for reversible metal electrodeposition for dynamic windows. Despite being substantially less noble than H_2 with a standard reduction potential of -0.76 V vs. SHE, reversible Zn electrodeposition can be conducted with high Coulombic efficiency with properly designed electrolytes. We find that H_2 evolution can be kinetically passivated by Zn, ZnO, and $Zn(OH)_2$ electrodeposits. Moreover, because the solubility of common Zn salts in water is much higher than those of Ag, Cu, and Bi, high concentration electrolytes can be designed that results in rapid metal electrodeposition. Zn also can be electrodeposited with a much more compact morphology than other explored metals, which allows for Zn-based dynamic windows to reach privacy-level transmission in less than one minute. We also demonstrate that Zn-based dynamic windows can cycle 10,000 times without significant degradation, and they exhibit excellent bistability. Taken together, these results highlight that Zn is a promising candidate for practical metal-based dynamic windows.

Gel Polymer Electrolyte for Reversible Metal Electrodeposition Dynamic Windows Enables Dual-Working Electrodes for Faster Switching and Reflectivity Control Yuchun Cai[1], Tyler Hernandez[1,2], Andrew Yeang[1], Michael Strand[1,2], Francis M. Yavitt[1], Eldho Abraham[1] and Michael D. McGehee[1]; [1]University of Colorado Boulder, United States; [2]Stanford University, United States

Dynamic windows based on reversible metal electrodeposition (RME) represent an exciting, new class of electrochromic devices. These RME windows function by the electrochemical movement of metallic ions dissolved in a nearly colorless aqueous electrolyte between a transparent conducting working electrode and a metal mesh counter electrode. Metals are ideal light modulators for dynamic windows because they can be color neutral, inert, photostable, and opaque at 20-30 nanometer thicknesses. Our team has demonstrated metal-based dynamic windows that boast a dark state below 0.001% visible light transmittance in less than 10 minutes, an ultrawide range for optical and solar modulation (ΔT_{vis}=0.76 and ΔSHGC=0.56) with uniform and color neutral (C*<5) tinting in prototypes >900 cm^2 [1].

Though aqueous liquid electrolytes often have higher ionic conductivities than ones with high polymer content[2], dynamic windows with liquid electrolytes face problems of leakage and short-circuiting, especially for large-scale windows. Gel polymer electrolytes (GPEs) are attractive due to their ability to act as a physical separator between the two electrodes to help avoid short-circuiting[3,4]. For this study, a porous polyvinyl alcohol (PVA) GPE is synthesized as a physical separator where the polymer backbone provides the mechanical structure, and the pores are filled with BiCu ClO_4 liquid electrolyte. This highly transparent physically cross-linked PVA gel was implemented into RME dynamic windows, and the PVA GPE window can readily be tinted to below 0.1% visible light transmittance, exhibits color-neutral transmittance, and has similar coloration efficiency with liquid windows.

Importantly, the use of PVA GPE in windows provides opportunities for dual-working electrode (dual-WE) windows without short-circuiting. Dual-WE windows are made by incorporating a second piece of ITO-glass and integrating the Cu mesh counter electrode within the electrolytic matrix to the center layer of the window**.** Compared with single-WE windows, dual-WE windows are more susceptible to short circuits with a higher potential for the middle free-standing mesh to touch the WEs. Our dual-WE GPE windows switch about two times faster than single-WE liquid windows, i.e. the dual-WE window reaches the 0.1% transmittance state in 101 s while the single-WE liquid windows take 207 s. Additionally, each side of the dual-WE GPE window can be tinted individually to demonstrate varied optical effects (i.e., more reflective or more absorptive), providing users and intelligent building systems with greater control over the appearance and performance of the windows in single device architecture.

This work demonstrates the first application of GPE in the RME dynamic windows and strides toward commercialization by showing the dual-WE GPE architecture without short-circuiting concerns especially in large-scale windows, along with the benefits of twice the speed of switching and the controllable reflectivity states.

Dual-Band Electrochromic Devices Utilizing Niobium Oxide Nanocrystal Benjamin Z. Zydlewski and Delia Milliron; The University of Texas at Austin, United States

Electrochromic window coatings that can modulate visible and near-infrared (NIR) light independently are important to the development of smart windows which can control solar heating and lighting to improve energy efficiency of buildings. Our work utilizes the electrochromism of monoclinic $Nb_{12}O_{29}$ nanocrystals to develop devices that can modulate the transmittance of NIR and visible light separately. The devices incorporate a secondary ion storage layer that allows for the charge and discharge of the electrochromic material, leading to reversible coloration. The configuration of the device consists of a working electrode composed the niobium oxide nanocrystals coated on a transparent conductive electrode, a non-aqueous gel electrolyte, and a counter electrode. The overall transmittance of the device can be modulated by applying different electrochemical potentials between the two electrodes. The dual-band electrochromic behavior of the niobium oxide nanocrystal allows for selective modulation of the NIR transmittance with low device potentials, along with significant visible modulation at higher potentials. In this work we study the performance trade-offs of varying film thicknesses, transparent conductive electrode materials, and ion storage layers. For optimum transmittance modulation, charge balance between the two electrodes is key. We compare the charge storage capacity and transmittance of NiO nanocrystals, CeO_2 nanocrystals, and amorphous VO_x thin films to determine optimum conditions for charge balance, allowing for full modulation of the electrochromic niobium oxide. We also show that these materials can be solution processed, without high temperature annealing steps, onto both rigid glass and flexible plastic substrates using blade coating. Optimal parameters for device assembly and overall performance will be discussed.

4:00 PM EL03.08.03
Back Injection Molding of Electrochromic Multilayer Films on Polycarbonate Substrates Christopher Johannes; University of Kassel, Germany

The integration/processing of flexible electrochromic multilayer films in common plastic injection molding processes could be advantageous with regard to the possible range of applications and mass production of electrochromic devices (ECDs). Especially light weight, slightly three dimensional formed and optically modulating windows are of interest in the transportation sector. Most optical applications based on amorph plastics, such as plastic windows or headlight coverings, are made of polycarbonate or polymethylmethacrylate (e.g. the well known brands Makrolon® and Plexiglas®). Especially polycarbonate as substrate material for ECDs could be advantageous regarding the optical properties compared to the often used PET substrate, particularly regarding the haze.
Therefore, a battery-type ECD multilayer structure based on polycarbonate substrate was developed aiming at good optical properties, especially a neutral colored and highly transmissive bleached state. For this reason, a neutral counter electrode of TiO2 and a highly transmissive polyurethane based gel electrolyte [1] was chosen. ITO was applied as current collector layer and PEDOT:PSS as working electrode.
Within a funded project an injection mold was developed and manufactured that allows to back mold the multilayer films (active area: 4 cm x 4 cm) and introduces a bending radius (200 mm). The integrated embossing unit leads to drastically lower injection pressure the cavity compared to standard processing. This results in lower shear and compressive stress on the multilayer film as well as reduced orientation and residual stresses in the injected component.
First back injection molding experiments with polycarbonate showed severel problems, especially considering the brittle metal oxide layers. After processing micro cracks all over the surface and macroscopic cracks at the kinks were detectable (beginning and end of radius). Due to different shrinkage of film and injected melt, the half cells partially detached from each other and deformed in most cases. In case of lamination defects at the multilayer films edges melt penetrated between the half cells. Most ECDs showed no function afterwards. Few surviving ECDs showed a non homogeneous coloring, defects, lower current responses and slower switching speed compared to the function before. Due to these findings the above described ECD configuration was adjusted and the brittle metal oxide layers were replaced. Instead of ITO a very conductive PDEOT:PSS formulation was used as current collector layer and TiO2 was replaced by Prussian Blue. The first ECD showed comparable transmittance changes, but considerable slower coloring/decoloring, probably due to lower conductivity of the current collector layer. The bright state was slightly blue colored and the total transmittance in the bright state was pretty low with 49 % compared to the original configuration with almost 70 %. Very promising on the other hand are the results with back injection molding since the major problems did not occur. Neither cracks were visible nor the cell detached. An accompanying peel study revealed that the new configuration had a 2.5 times better adhesion between the half cells (over the electrolyte). The total visible transmittance in the oxidized state at +1.5 V was 49 % before and 50 % after the process. The transmittance in the reduced state at -2.5 V after 60 s was 37 % before and 41 % after the process. So, the transmittance change was 12 % before and 9 % after back injection molding. Increasing the cycle time to 120 s led to a transmittance change of 14 % before and 13 % after the process. Accordingly, the switching speed decreased, but the total transmittance change only decreased little.

Fabric Electrochromics, Spandex and Nonwovens Gregory Sotzing; University of Connecticut, United States

Many advancements in electrochromics have been made over the decades, including adaptation of electrochromics to textiles. Many facotrs come into play when adapting electrochromics applied to rough, high surface area textiles that would bend and stretch. Further, the construction and implementation of such devices needs serious consideration for end use. Implementation of our very low sheet resistance polyethylenedioxythiophene-polystyrene sulfonate (PEDOT-PSS) prepared by our published screen printing and PEDOT/PSS phase segregation onto both spandex and unwoven synthetic leather, coupled with our conjugated polymer precursor technology, along with hole-through PEDOT-PSS connections, allowed for the construction of electrochromic displays on the front side of fabric while having electrical connections on the back. Here, we will discuss our open-air robust electrochromic fabric display technique, and the research necessary to adapt a technology from a relatively low surface area application using flat substrates to a very high surface textile having the ability to stretch and bend. The logic behind the choices made for electrical conductor, electrochromic material, electrolyte, and protective coating to seal the device, yet provide a fabric-feel, will be presented as well.

Tunable Structural Colouration Based on Electrochromic Conducting Polymers Shangzhi Chen[1,2], Stefano Rossi[1] and Magnus P. Jonsson[1]; [1]Linkoping University, Sweden; [2]University of Cambridge, United Kingdom

Precise manipulation of light-matter interactions has enabled various strategies to produce vibrant and non-fading structural colours. However, dynamic tuning structural colours across the visible spectrum with high brightness has proven to be a great challenge. Here, we present a novel method based on electrochromic conducting polymers and Fabry-Perot cavity structures, to create reflective colours that can be tunable throughout the entire visible range and beyond[1,2]. The colour tuning mechanisms *via* electrochemistry can be attributed to the variation of the thin film thicknesses, the polymer's complex refractive index, or a combination of both. In addition, we will demonstrate a novel film patterning techniques based on vapour phase polymerization and ultraviolet (UV) exposure, which could modulate the conducting polymer thin film thickness and refractive index synergistically. Combing this method with a greyscale photomask enables facile fabrication of high-resolution and multi-colour structural color images within single steps. We believe our new proof-of-concept device structure and the UV-patterning method will be highly promising for the future electrochromic displays.

Multicolored Display from Electrochromic PANI/PS-b-P2VP Thin Films Junxin Wang[1], Dashui Zhang[2] and Huiying Qu[2]; [1]University of Cambridge, United Kingdom; [2]Guangxi University, China

We fabricate an adaptive multicolored electrochromic display to tackle the limited color range in electrochromic materials. It is based on the synergetic effect of structural colors generated by polystyrene-block-poly (2-vinyl pyridine) (PS-b-P2VP) thin-film interferences and pigment colors arising from the electrochromic polyaniline (PANI) thin film. The pigment and structural colors are switchable by applying small external voltages ranging from -0.2 V to 1 V in the aqueous electrolyte. In contrast to the traditional coloration mechanism that mainly involves pigment color variations, our method uses pigment and structural color, achieving a wide range of color control and switchable vivid coloration. Evidence indicates that pronounced color changes of the PANI/PS-b-P2VP thin-film depend on the states of PANI, protonation/de-protonation of P2VP, and the thickness of each layer. The low energy consumed and excellent durability also satisfy the demand for applicable portable electronics. Our work provides new insights to design multiple-colored electronic devices with low energy consumption and high durability.

9:30 AM EL03.09.03
All Polymer Electrochromic Matrix Display Inho Song, Ke Chen, Liyan You, Won-June Lee and Jianguo Mei; Purdue University, United States

Emerging see-through display (i.e., transparent display) display is significant in future sophisticated displays such as wearable and portable electronics, augmented and virtual reality, electronic papers/billboards, digitized shopping displays, head-up display, and other new-generation displays. The non-emissive electrochromic (EC) materials and devices have received remarkable attention for use in the display electronics, due to the advantages such as their excellent outdoor readability, low power consumption, wide-viewing angle, and eye-saving features. However, optical signal crosstalk between multi-pixels in matrix display is serious problem, which originated from the unwanted charge transfer in EC components. In addition, the widely used inorganic-based transparent conducting electrodes (e.g., indium thin oxide and fluorine doped tin oxide) suffer from issues such as poor mechanical flexibility and an energetic mismatch between the organic-inorganic semiconductor interface. Thus, reduction of the signal crosstalk is a key factor related to the successful fabrication of matrix EC displays. In this research, we have successfully demonstrated a photolithographic patterning of all-polymeric EC components like matrix electrode, ion storage layer, solid-state electrolyte, and EC active materials. Highly capacitive and conductive conjugated polymers were used as matrix electrodes lines for passive matrix-based display operation. The transparent conductors exhibited low sheet resistance and high transmittance, which leads to fabrication of transmissive matrix displays. Great reduction of the crosstalk was shown by using the direct isolation of highly wettable and crosslinkable electrolyte thin film in high resolution *in-situ* photolithography. Ionic liquid based poly(ethylene glycol) diacrylate precursor solutions can be easily wettable on the ionic storage layers, plastic substrates, and EC polymers due to absence of polar solvent and addition of thiol based monomers. The whole polymer, patterned EC display pixels exhibited transparent/flexible display application with very low power consumption by an electrochemical behavior of the EC polymers in low voltage and their enlarged optical memory by robust electrical double layer in ionic liquid. A subtractive color can be actively tuned in matrix display, along with the laterally stacked subpixels based on micro-patterned EC polymers which have no interference with each other. These findings represent a novel strategy for fabricating flexible, dynamically color-tunable EC displays and are expected to advance the development of future see-through display applications.

9:45 AM EL03.09.04
Scalable Manufacture of Flexible Solid-State Electrochromic Devices by Physical Vapour Deposition Maimouna Diouf, Susan Impey and Adrianus Indrat Aria; Cranfield University, United Kingdom

The fight against climate emergency requires a solution to address the growing challenges of providing cost-efficient carbon emission reduction whilst improving the security of supply. Improving energy efficiency of residential and non-residential (schools, hospitals, shopping centres) buildings is at the heart of this fight due to the large carbon footprint of indoor lighting and thermal management including heating and air-conditioning. Electrochromic smart windows can be darkened or brightened as desired with a touch of a button to improve the energy efficiency of buildings. They allow a full control of visible light from outside, which reduces the dependency on indoor lighting systems, and simultaneously blocks infra-red energy from entering the room, which reduces the dependency on air-conditioning systems. Existing electrochromic smart windows, however, are rigid, bulky, and heavy, thus limiting their applications and consumer uptake. In addition, the commonly used liquid or gel electrolyte is susceptible to breakdown and leakage.

Here, we will present our recent work on the development and scalable manufacture of flexible solid-state electrochromic devices to enable light weight and economical smart windows. All device components, including transparent electrodes, electrochromic elements, and electrolyte, were made of submicron metal oxide thin films. These thin films were deposited on sub-mm flexible polymer substrates and stacked monolithically using physical vapour deposition technique. This allowed us to manufacture devices with active area of >255cm^2 and transmittance modulation of 37% in the visible range. Accelerated and field test were carried out to confirm the stability of the devices without any encapsulation. We will also present some challenges that occurred during device fabrication that resulted in device shorting and heterogeneous colouring.

10:30 AM *EL03.10.01
Metallo-Organic Thin Films Made in Israel Milko van der Boom; Weizmann Inst of Science, Israel

We demonstrate controlled charge trapping and release, accompanied by multiple color changes in metallo-organic coatings. The dual functionality of our metallo-organic materials provides fundamental insight into metal-mediated electron transport pathways. The electrochemical processes are accompanied by distinct, color-to-color transitions. Some of our coatings consist of two elements: 1) a nanoscale gate consisting of a layer of well-defined polypyridyl ruthenium complexes bound to a flexible transparent electrode, and 2) a charge storage layer consisting of isostructural iron complexes attached to the surface of the gate. This gate mediates or blocks electron transport in response to an applied voltage. Combining electrochemistry with optical data revealed mechanistic information: the coloration of the coatings directly relates to the formation of intermediate species, providing evidence for catalytic positive charge release mediated through the gate. These and other coatings can be functional elements in conventional electronic circuits.

11:00 AM *EL03.10.02
Recent Progress on Electrochromic Devices with Metallo-Supramolecular Polymers Masayoshi Higuchi; National Institute for Materials Science

(NIMS), Japan

Metallo-supramolecular polymers (MSPs) are coordination polymers in which metal ions and multitopic ligands are connected alternately with coordination bonds and was found to show reversible electrochromic (EC) properties (Chem. Rec., 7, 203-209 (2007)). The EC changes are triggered by electrochemical redox of the metal in MSPs. Since MSPs have specific colors caused by the metal-to-ligand charge transfer (MLCT) absorption, the color is tunable by changing the metal species and the ligands. Blue, purple, red, yellow, green and black colored MSPs were reported so far. In this presentation our recent research results on (1) design of MSPs and the EC properties, (2) design of EC decices (ECDs) with MSPs and their EC functions and (3) mass fabrication will be reported.

11:30 AM *EL03.10.03
Electrochromic Materials and Devices Based on Metal Coordination Polymers Marco Schott; Fraunhofer Institute for Silicate Research ISC, Germany

A new and exciting class of electrochromic (EC) materials are metal coordination polymers (MCPs) that can be synthesized via self-assembly of metal^{2+} ions (e.g. Fe^{2+}, Ru^{2+}) and bis(terpyridine) ligands resulting in linear polymer chains. By using different metal ions and/or ligands a broad color variation can be obtained. MCPs exhibit a strong absorption in the visible region attributed to a metal-to-ligand-charge transfer (MLCT) transition responsible for the intensive coloration. In particular, iron-based metal coordination polymers (Fe-MCPs) show excellent EC properties in terms of optical contrast, coloration efficiency, switching speed, low operating voltages and cycling stability as compared to inorganic state-of-the-art EC materials, such as tungsten or nickel oxides, used in most of the commercial smart window products. Fe-MCPs as cathodically coloring EC materials switch reversibly from a blue colored (reduced) state (Fe^{2+}) to a highly transmissive (oxidized) state (Fe^{3+}) over thousands of cycles.
MCPs can readily be deposited as thin films on transparent conducting glass or plastic substrates by means of wet-chemical processes, e.g. spin/dip coating, roll-to-roll slot-die coating or ink-jet printing. For Fe-MCPs, the fabrication of thin film electrodes was scaled-up from the laboratory to the pilot scale and their EC properties investigated in detail.
Novel EC device configurations based on Fe- and Ru-MCP thin film electrodes and different counter electrode materials, such as (mixed-) metal oxides or Prussian blue (PB), were realized with a focus on color variation (towards neutral tint), optical contrast, and cycling stability. Within the research project FLAIM, Fe-MCP inks are being investigated towards an automized and AI controlled production and optical characterization of EC thin film glass electrodes in a robotic platform.
Thus, MCPs are very promising materials for the use in future EC applications, such as architectural/automotive glazing, smart labels, sensors, displays, home appliances, and goggles/visors. However, they have to be further tested and validated, in particular under real use conditions, to prove their maturity and qualify them for a next generation EC technology.

SESSION EL03.11: Virtual Session

Session Chairs: Haizeng Li, Jianguo Mei, Fengling Zhang and Anna Österholm
Tuesday Afternoon, April 25, 2023
EL03-virtual

9:00 PM *EL03.11.01
Fabry-Perot-Type Multicolored Inorganic Electrochromic Materials and Devices Zhigang Zhao; Suzhou Institute of Nano-Tech and Nano-Bionics, Chinese Academy of Sciences, China

Tungsten oxide (WO_3) is the earliest discovered, and most widely used inorganic electrochromic material, which can change its optical properties (transmittance, reflectance, or absorption), or colors, induced by an electrical current or voltage. Owing to its high stability, strong weatherability, good adhesion to glass substrates, easy to large-scale production, and so on, the WO_3 material has a high commercial prospect. However, for a WO_3 material in its pure form, this compound only displays a onefold color modulation from transparent to blue, which is very difficult to achieve the utmost goal of full-color tunability for future electrochromic technology. Here, we introduced a Fabry-Perot cavity structure, changed the thickness, refractive index, and repetition period of the dielectric material in the cavities, and modulated the photonic bandgap, for realization of muti-color inorganic electrochromic devices. Such a simply structured device can significantly change to other more brilliant colours by changing the optical indices (n, k) of the tungsten oxide layer through ion insertion under applied potentials. Meanwhile, we emphasized the integration of multicolor electrochromic devices with other advanced energy, environment and electronic technologies to obtain new concept and multi-functional devices of new intelligent energy storage systems, high color purity devices and "Janus" devices.

9:30 PM EL03.11.02
Zinc Anode-Based Electrochromic Devices Haizeng Li[1], Wu Zhang[2] and Abdulhakem Y. Elezzabi[2]; [1]Shandong University, China; [2]University of Alberta, Canada

The development of electrochromic materials has opened the door to the development of numerous devices including smart windows, color displays, optical filters, wearable camouflages, among others. Although the current electrochromic devices do not consume energy while maintaining their colored or colorless states, their bistable operation requires external electrical energy to be consumed during switching. To reduce the energy consumption of an electrochromic device, an emerging Zn anode-based electrochromic device concept was recently introduced to partially retrieve the consumed electrical energy. In this talk, the speaker will introduce the mechanism of zinc anode-based electrochromic devices. The speaker will also introduce their group's research regarding zinc anode-based electrochromic devices.

9:45 PM *EL03.11.03
Bistable Electrochromic Materials and Devices Based on Proton-Coupled Electron Transfer Yumo Zhang; Jilin University, China

Bistable displays are considered a promising solution to reduce energy consumption in applications such as electronic shelf labels, electronic tags and smart windows because of their unique abilities to retain information (in particular images) without power input and their minimal power requirements for information change. Various strategies have been reported to implement bistable displays, including strategies based on cholesteric liquid crystals, e-inks and electrochromism. In particular, bistable electrochromic devices, in which colour change is controlled by redox reactions or the application of an electric field, are advantageous due to their simple structure and easy fabrication. However, unclear material design rules and several technical challenges intrinsic to the electrochromic switching mechanism, including undesirable drab colour, poor retention of bistability and low colour contrast, have hampered the development and widespread commercialization of bistable devices.

Recently, proton-coupled electron transfer (PCET) processes have been used to design ideal bistable electrochromic materials in our work. The PCET mechanism enhances the bistable properties of electrochromic materials by adjusting supramolecular interactions, broadening colour selection with available pH indicators and avoiding high-energy intermediates that may reduce the material's stability. The electrochromic devices show wide colour tunability and good bistable properties, and prototype devices of colourful bistable electrochromic electronic shelf labels, smart glasses, and rewritable e-paper with easy scaleup potential have also been developed.

10:15 PM *EL03.11.04
Investigation on Electrochromism of Transparent to Black Transition via Various Paths Chunye Xu; University of Science and Technology of China, China

Electrochromism is a phenomenon that optical properties of materials change stably and reversibly under an applied electric field. Electrochromic (EC) devices have attracted the attention of scholars because of their advantages of multiple colors, high energy efficiency, environmental friendliness and intelligent adjustment. Blackness of EC devices with high optical contrast is desired in automobiles, electronic displays, anti-glare mirrors, switchable window, etc. We have been investigating several ways to reach this goal as the following.
Firstly, we attempted to obtain transparent to dark black EC materials in a relatively simple process by spraying method. By using green and purple as complementary colors, a mixed solution of polymer was sprayed, and the functional film was obtained. Secondly, using the easy-oxidization properties of N-methyl-phenothiazine (NMP) to match the charge capacity of WO_3 thin films, we prepared a complementary EC device with good optical regulation and high stability. Thirdly, we selected benzothiadiazole viologen and triaminocyclopropene salt to prepare EC devices, which is unpublished yet.
Finally, using Ag as the functioal material, which has a good electrodeposition effect, we utilized electrodepositing Ag on PProDOT-Me_2 to fabric functional devices, which achieve excellent performance of a high optical contrast, a fast coloring speed and a strong cycle stability with colorless, blue and black three-state transition.

Ions and Electrons in Halide Perovskites—Bulk vs Interfaces Joachim Maier; Max Planck Institute for Solid State Research, Germany

The first part of the presentation summarizes parts of our work on bulk ion conductivity in halide perovskites. It deals with identifying the respective ionic and electronic charge carriers, discusses the adjusting screws for changing their concentrations as well as the relevance for polarization phenomena and stability. The surprising finding that light enhances the ion conductivity in the iodides [1] but not in the bromides, offers a simple explanation for the light induced demixing [2]. In the context of stability recent work on ion conduction in "hollow perovskites" [3] and "2D perovskites" [4] will be touched upon. The second part of the presentation refers to interfaces. It is shown that mobility of ions and the significant fraction of ionic charge carriers gives rise to ionically dominated built-in potentials, a point that had not been addressed in the photovoltaic literature and might lead to a paradigm change in the understanding of photoactive interfaces [4,5]. This ionic interaction "enslaves" the electronic redistribution, such that the electrons undergo a "fellow traveler effect".

Molecular Relays in Nanometer Scale Alumina—Effective Protection Layers for Water-Submersed Halide Perovskite Photocathodes Yuval Harari, Chandra Pathak and Eran Edri; Ben-Gurion University of the Negev, Israel

Halide perovskite (HaP) solar cells have an excellent voltage efficiency (>70%) and a low electron-affinity conduction band minimum, making them prospective candidates to be used as photocathodes in integrated low-cost solar fuel generators. However, halide perovskites are notoriously unstable in aqueous solutions and immediately dissolve upon exposure to liquid water. Ultrathin layers (< 10 nm) of Al_2O_3 deposited by atomic layer deposition are suitable encapsulants to prevent water ingression but are also electronically insulating. Embedding linear conjugated organic molecules ('molecular relays') that transverse the insulating layer enables selective electron transport across the insulating encapsulating layer. The electronic functionality of the embedded molecular relays is verified by conductive probe atomic force microscopy and photo-electrodeposition of metal particles (Pt and Ag) from ethanolic solutions. Lastly, the encapsulated HaP photoelectrodes were submersed in a CO_2-saturated aqueous electrolyte and a photocurrent of ~100 $\mu A/cm^2$ (at ~ -0.32 V vs. Ag/AgCl) was measured. This work demonstrates a way for stabilizing semiconductors in polar and protonic electrolytes as photoelectrodes for the generation of solar fuels.

9:15 AM EL04.01.03
Lead-free Bismuth Based Perovskites for Integrated Electrochemical Storage and Generation Jonathan E. Halpert and Neha Tewari; Hong Kong University of Science & Technology, Hong Kong

The demand for sustainable energy has driven a recent burst of interest in solar storage devices. One such device, the photo-battery (PHBAT), is capable of providing both energy storage and generation from a single device architecture. This idea has existed for many decades, since the first demonstration in the 70's and such a design should permit increased energy storage efficiency and energy density, while reducing packaging requirements, ohmic losses, size, weight, and cost. Unfortunately, in past years, the poor efficiency of these devices failed to improve upon the standard industry solution: a solar cell wired to an external battery. Recent advances in the literature suggest a promising new start for this technology. Here we present he first lead-free, bismuth-based, all-inorganic halide perovskite photo-rechargeable *lithium-ion* PHBAT. This device enables both energy storage and photovoltaic power generation over several tens of cycles, after which the anode must be regenerated by electrical charging. In that work, we used the favorable charge transport behavior, high defect tolerance and wide absorption range for colloidal nanocrystals of $Cs_3Bi_2I_9$ perovskites, to fabricate a photo-active electrode, and a functioning photo-battery. The champion devices were able to achieve a peak photo conversion efficiency of ~0.43 %, for the first charge and an average efficiency of ~ 0.10 % for subsequent cycles. Devices showed good performance as batteries over the first ten cycles with capacity >300 mAh/g, but performance declined over the first 100 cycles. Under 1 sun and at low current, the battery could be operated with arbitrarily large *effective* capacity, demonstrated up to 900 mAh/g by essentially using the battery as a solar cell. These results compared favorably with other photo-battery devices using other materials as the active layers. We found that during the charge-discharge cycle, the lithium first intercalated into the bismuth perovskite, and, later, as the voltage decreased, formed reduced Li_xBi compounds. In addition we have found similar results are possible using Cs_2NaBiI_6 nanocrystals and 2D PEA3Bi2I9. We present these results, with high capacity and PCE of up to 0.27% and good stability. Mechanistic studies on these materials suggest future improvements are possible and give a general strategy for improving performance by perovskite engineering.

9:30 AM EL04.01.04
Dynamic Structural Fluctuations from Strongly Anharmonic Phonons in Metal Halide Perovskites Olivier Delaire[1], Xing He[1], Chengjie Mao[1], Tyson Lanigan-Atkins[1], Mercouri G. Kanatzidis[2], Matthew Krogstad[3], Stephan Rosenkranz[3], Raymond Osborn[3], Daniel Pajerowski[4] and Tao Hong[4]; [1]Duke University, United States; [2]Northwestern University, United States; [3]Argonne National Laboratory, United States; [4]Oak Ridge National Laboratory, United States

Besides their photovoltaic performance metal halide perovskites (MHPs) are attracting increased interest for their excellent performance in optoelectronic and radiation detection, as well as thermoelectric conversion applications. MHPs are known to exhibit a soft lattice with large-amplitude atomic fluctuations. While crucial to understand electron-phonon and phonon-phonon couplings, the spatiotemporal correlations of these fluctuations remain largely unknown. We discuss these correlations based on comprehensive neutron and x-ray scattering measurements, complemented with first-principles simulations augmented with machine learning. Our measurements and simulations reveal complex potential energy surfaces, resulting in multiple soft competing phonons that dynamically distort the lattice at finite temperature. These result in 2D dynamic fluctuations of cooperative halide octahedra tilts, as revealed by characteristic diffuse scattering rods. The short-ranged correlations are not static, and their dynamics are probed with inelastic measurements, revealing pervasive overdamped phonon spectra and quasielastic signatures. These results provide new insights into the atomic structure and fluctuations in MHPs, critical to understand their unusual electron-phonon and phonon-phonon couplings, underlying their optoelectronic, thermal transport and thermodynamic properties.

9:45 AM EL04.01.05
Ultrafast Spatiotemporal Dynamics of Room-Temperature Exciton Spins in a Two-Dimensional Layered Halide Perovskite Go Yumoto, Fumiya Sekiguchi, Ruito Hashimoto, Tomoya Nakamura, Atsushi Wakamiya and Yoshihiko Kanemitsu; Institute for Chemical Research, Kyoto University, Japan

Spin-polarized excitons in atomically thin two-dimensional (2D) semiconductors have attracted great interest for spin-optoelectronic applications because of their large exciton binding energies and unique spin-dependent characters. Spatially resolved optical measurements have revealed the formation of spatial patterns and long-range transport of the exciton spins in 2D transition metal dichalcogenides [1-3]. This spatial controllability of the exciton spins shows the potential of 2D semiconductors for exciton-based spin-optoelectronic applications. However, observations of such spatial dynamics have been restricted to cryogenic temperatures because the short exciton spin relaxation times at room temperature prevent formation of a spatial pattern and transport of the exciton spins. The absence of spatial evolution of spin-polarized excitons at room temperature limits the potential for applications such as information and signal processing and chiral nanophotonics.

This limitation could be overcome by utilizing exciton-exciton exchange interactions, where the repulsive force between excitons with the same spin drives fast expansion of a spatial profile of spin-polarized excitons. From this point of view, 2D Ruddlesden-Popper lead halide perovskites (RPPs) are promising candidates for demonstrating spatial evolution of exciton spins at room temperature. This is because 2D RPPs have stable excitons characterized by a total exciton angular momentum projection of ±1 [4-9] and exhibit substantial exciton-exciton interactions [10] and relatively long exciton spin relaxation times at room temperature [11]. We synthesized phase-pure 2D RPP single crystals of $(C_4H_9NH_3)_2(CH_3NH_3)_3Pb_4I_{13}$, and mechanically exfoliated the crystal flakes and transferred them onto a glass substrate.

To investigate the spatial and temporal dynamics of the exciton spins in 2D RPPs at room temperature, we developed polarization-resolved pump-probe microscopy with millidegree, submicrometer, and subpicosecond resolutions [12]. Because the pump-induced Faraday rotation angle is proportional to the spin-polarized exciton population, we measured the images of the time-resolved Faraday rotation angle. At low pump intensity, the spin-polarized exciton population decays keeping its isotropic Gaussian spatial profile, which reflects the pump beam profile. In contrast, at high pump intensity, we observed that the spatial profile of the spin-polarized exciton population evolves into a halo-like spatial pattern with increasing pump-probe delay time and ultrafast exciton spin transport occurs [12]. We found that the rapidly expanding halo-like spatial profile is caused by density-dependent nonlinear relaxation and repulsive interaction between excitons with the same spin, both of which are induced by exciton-exciton exchange interactions. Our findings reveal the impact of the exciton-exciton interactions on the spatiotemporal dynamics of exciton spins at room temperature and suggest the potential of 2D RPPs for spin-optoelectronic applications.

Excitons, Phonons and Symmetry Breaking in Complex Metal Halide Perovskites from First Principles Jeffrey B. Neaton[1,2,3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Kavli Energy NanoScience Institute, United States

The ability to synthesize and probe a diversity of metal halide perovskites has driven the need for new intuition to interpret and predict their structural, electronic, and optical properties and how they vary with composition, dimensionality, temperature, and pressure. Here, I will discuss recent examples of first-principles calculations – based on density functional theory and ab initio many-body perturbation theory – of the structural, electronic and optical properties of complex metal halide perovskites, drawing on recent advances in non-empirically tuned hybrid functionals and our ability to compute electron-phonon and exciton-phonon interactions. I will focus on recent studies of lead halide perovskites, and of novel lead-free double and mixed-valence perovskites. I will highlight new understanding of their phase behavior, electronic structure and photoexcited states, and discuss how these properties are influenced by phonons, composition, organic cations, dimensionality, and pressure, comparing with experiments where possible and emphasizing new intuition that emerges from our calculations. Portions of this work are supported by the Theory of Materials program and Center for Computational Study of Excited-State Phenomena in Energy Materials (C2SEPEM) at the Lawrence Berkeley National Laboratory, funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division, under Contract No. DE-C02-05CH11231, and by the U.S.-Israel NSF–Binational Science Foundation under Grant No. DMR-2015991. Machine-Learning-Assisted Characterization of Hybrid Perovskites' Optical Properties Abigail Hering[1], Meghna Srivastava[1], Juan Pablo Correa Baena[2] and Marina S. Leite[1]; [1]University of California, Davis, United States; [2]Georgia Institute of Technology, United States

The compositional tuning of the A- and X-sites in $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ (Cs-FA) hybrid perovskites allows bandgap engineering, relevant for light-emitting and -absorbing optoelectronic devices. However, the relationship between chemical composition and the effects of environmental stressors (light, bias, oxygen, temperature, and humidity) is currently not well understood. Thus, we use high-throughput, environmental photoluminescence (PL) to elucidate how the optical response of Cs-FA thin films with variable cation and anion concentrations changes upon materials' exposure to relative humidity (rH) cycles that emulate accelerated day-night weather variations based on summer days in Northern California. We use machine learning (ML) models to forecast the PL response of the samples. As expected, all samples present PL enhancement with increasing rH, as a direct result of trap states' occupation. We implement Linear Regression (LR), Echo State Network (ESN), and Seasonal Auto-Regressive Integrated Moving Average with eXogenous Regressors (SARIMAX) algorithms upon splitting the data into 50%-50% for training and testing. The latter algorithm is very suitable for predicting non-linear responses, achieving an average normalized root mean square error (NRMSE) of only 8% over a 50-hour window. Summarizing, our proof-of-concept accurate time series predictions demonstrate how ML can be realized for analyzing large sets of experimental data that can be used in a holistic approach for the further development of stable hybrid perovskites.

Equivalent Circuit and Defect Chemical Models of Hybrid Perovskite Devices Davide Moia, Mina Jung, Ya-Ru Wang and Joachim Maier; Max Planck Institute for Solid State Research, Germany

The design of models that successfully encapsulate the chemical and electrostatic effects of mobile ionic defects in hybrid perovskite solar cells is one of the most important research directions in the field. [1] This relies on the development of experimental methods able to probe the defect situation in these materials and to elucidate the influence of ionic defects on electronic processes.
In this contribution, we address the description of charge carrier behavior in hybrid perovskites for both the equilibrium and the out-of-equilibrium situations. First, we present a systematic study of mixed conduction in methylammonium lead iodide (MAPI) thin films in horizontal structures with ion

blocking contacts. The results highlight the importance of interfacial charging in the long time scale polarization behavior of MAPI devices, also allowing us to estimate values of the Debye length. This interpretation is consistent with the dynamics of electric field screening in MAPI devices probed with spectroscopic and optoelectronic methods. [2]
Secondly, starting from the description of the key disorder reactions expected for MAPI, we develop a defect chemical model that considers the electronic and ionic charge carrier situation when a perturbation term is included. Our investigation emphasizes the importance of the coupling between the ionic sublattices and the electronic charge carriers in the definition of the component (e.g., iodine for MAPI) chemical potential, and its implications in terms of light-induced stoichiometry variations and stability of the perovskite. We conclude by discussing the analysis of the experimental electrical response of hybrid perovskite devices under bias, and establish connections between the previously developed interfacial-transistor equivalent circuit model, which can reproduce much of the optoelectronic behavior of hybrid perovskite devices, [3] and the ionic and electronic disorder described in our model.

11:30 AM *EL04.02.04
Metal Halide Perovskites for Ultralow Energy Computation Bruno Ehrler; AMOLF, Netherlands

Metal halide perovskites are now used for solar cell, lighting and sensor applications. However, the materials are still suffering from stability issues, in part attributed to the motion of mobile ions. These ions move by voltage or light stimulus, or even by thermal activation at room temperature, demonstrating how little energy is required to move ions. Here we use these efficient ion conductors to built a memristor device which uses little energy to change its conductive state. A memristor can be used in an analog computation to store and process information at the same location, overcoming the Von-Neumann bottleneck. This energy efficient computation is achieved by chosing a perovskite that is an efficient ion conductor, and by miniaturizing the device dimensions. We achieve devices with a size $< 1\ \mu m^2$ and an energy consumption approaching the femtojoule regime. We will show the promise and limitations of this approach for perovskite-based computational devices.

SESSION EL04.03: Metal Halide Perovskites for Applications Beyond Solar III

Frenkel Excitons in Vacancy-Ordered Titanium Halide Perovskites (Cs_2TiX_6) Seán R. Kavanagh[1,2], Christopher Savory[1], Shanti Liga[3], Gerasimos Konstantatos[3], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]The Barcelona Institute of Science and Technology, Spain

Low-cost, non-toxic and earth-abundant materials are a long-sought after target in the thermoelectrics research community. "Perovskite-inspired" materials have emerged as promising candidates for thermoelectric applications due to their semiconducting nature and low lattice thermal conductivities.[1,2] Researchers commonly employ materials design strategies including structural, dimensional and compositional transformations to avoid the use of rare and toxic elemental constituents, while attempting to maintain the excellent electronic structure features of their Pb-containing counterparts. These strategies have recently been invoked to propose vacancy-ordered halide perovskites (A_2BX_6; **A** = Cs, Rb, K; **B** = Sn, Ti; **X** = I, Br, Cl) for thermoelectric applications. [3,4]

Theoretical investigations of the electronic structure of the Ti based systems, however, consistently overestimate the energy band gaps, which makes understanding dopability very difficult. In this work, we reveal strong excitonic effects as the origin of this discrepancy between theory and experiment; a consequence of both low structural dimensionality and band localization.[5]

These findings have vital implications for the optoelectronic and thermoelectric application of these compounds, while also highlighting the crucial importance of frontier-orbital character for chemical substitution materials design strategies.

2:15 PM EL04.03.03
Towards Low-Energy Consumption Artificial Synapses from Lead Halide Perovskite Jeroen J. de Boer and Bruno Ehrler; AMOLF, Netherlands

Lead halide perovskites are highly promising materials for a wide range of optoelectronic applications, such as photovoltaics and LEDs. However, perovskite optoelectronic devices typically display large hysteresis effects under mild operating conditions, which is unwanted for these applications. At the same time these large hysteresis effects under mild conditions are highly desirable for artificial synapses, which exploit hysteresis to change the conductivity of the device.
Artificial synapses based on lead halide perovskite have been demonstrated before[1]. Low energy consumptions were possible for these synapses made of methylammonium lead iodide ($MAPbI_3$), due to the diode behavior of the synapse and the low voltages at which hysteresis occurred. We estimate that downscaling devices based on $MAPbI_3$ to device areas of $1\ \mu m^2$ could already bring the energy consumption of switching events of the synapse to values as low as 1 to 100 fJ, the same range as that of biological synapses. However, the poor chemical stability of $MAPbI_3$, and lead halide perovskites in

general, makes downscaling of the device with standard lithography techniques difficult. Here, we investigate photolithography procedures that are compatible with halide perovskites to prepare artificial synapses with device areas down to the nanoscale. We show that downscaling of the synapse with these methods is indeed a viable strategy to reduce the energy consumption of the device. The goal is to further develop lead halide perovskite artificial synapses with the same energy consumption as biological synapses for ultra-low power physical computing systems.

2:30 PM EL04.03.04
Stable Poisson-Statistics-Limited X-Ray Imaging with Solution-Grown Perovskite Single-Crystal Detectors Kostiantyn Sakhatskyi[1,2], Sergii Yakunin[1,2], Gebhard Matt[1,2], Bekir Turedi[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

One of the main thrusts of medical X-ray imaging is to minimize the X-ray dose acquired by the patient, down to the fundamental limit set by the Poisson photon statistics. Such low-dose X-ray detection characteristics have been demonstrated with only a few direct-detection semiconductor materials such as Si and CdTe; however, their industrial deployment in medical diagnostics is still impeded by elaborate and costly fabrication processes. Hybrid metal halide perovskites – newcomer semiconductors -– make for a viable alternative owing to their scalable, inexpensive, robust, and versatile solution growth and recent demonstrations of single gamma-photon counting under high applied bias voltages. The major hurdle with perovskites as mixed electronic-ionic conductors, however, arises from the rapid material's degradation under high electric field, thus far used in perovskite X-ray detectors. Here we discuss the negative effects of the ion migration on X-ray detection performance and demonstrate the mitigation path by utilizing the perovskite X-ray detectors in the photovoltaic mode of operation at zero-voltage bias. We show both countings of almost every single incoming photon and long-term stable performance, by employing thick and uniform methylammonium lead iodide single crystal films, solution-grown directly on hole-transporting electrodes The operational device stability is equivalent to the intrinsic chemical shelf lifetime of $MAPbI_3$, being at least one year in the studied case. Furthermore, direct readout array integration of detectors is demonstrated as well. A high spatial resolution of 11 lp mm^{-1} is obtained with a linear detector array. We also comment the lack of a clear commonly accepted X-ray detection characterization, approach, particularly in the material research community, often leads to a misguiding assessment of performance. We propose the guidelines for the determination of figures of merit for the low-dose X-ray imagers. These findings pave the path for the implementation of hybrid perovskites in low-cost and low-dose commercial detector arrays for X-ray imaging.

2:45 PM EL04.03.05
Room-temperature Substrate Integration of Thick Halide Perovskite Single Crystal for X-ray Detection Min Kyu Kim, Youngseung Choi and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Halide perovskite has optoelectrical properties that are very suitable for direct X-ray detector application such as high stopping power against X-ray, tunable bandgap, high resistivity, large mobility-lifetime product and cheap fabrication cost. Halide perovskite as a photon-absorber in X-ray detector can be prepared in three different forms—polycrystalline thin film, polycrystalline wafer and single crystal. For hard X-ray imaging such as medical computed tomography (CT), the thickness of an X-ray photo-absorber needs to be in the range of several hundreds of µm's to several mm's. Halide perovskite thin films can be readily prepared with a solution process, however, their thickness is limited to several microns at maximum. A thick polycrystalline wafer can be fabricated but a strong electric field (> 100 V/mm) is often required for the operation owing to the presence of grain boundaries, which raises current noise. Halide perovskite single crystal (PSC) possesses a high potential as X-ray absorbing layer because it can be easily fabricated to a millimeter thick layer while maintaining a superior mobility-lifetime product due to the absence of grain boundaries.
Most of PSCs grown by a solution process have free-standing (substrate-free) form because a substrate provides nucleation sites and results in the growth of polycrystalline perovskite. As a target dimension of an X-ray absorber increases, it becomes more difficult to monolithically grow a single crystal on a substrate. A millimeter scale free-standing single crystal can be directly applied to either a lateral-structure detector where both anode and cathode locate on same plane or a vertical-structure detector where anode and cathode are formed on both sides of the crystal. For high resolution pixelated imaging, however, thin-film transistor (TFT) arrays must be integrated with the photo-absorber. In other words, the free-standing PSC should be attached to a TFT array substrate.
In this study, we have adopted an ionic liquid, methylammonium acetate (MAAc) to integrate inverse-temperature crystallized PSC onto an indium-tin-oxide (ITO) substrate. Hydrated MAAc, which exists as liquid at room temperature, chemically dissolves the interfacial part of methylammonium lead bromide ($MAPbBr_3$) into liquid and provides a strongly bonding between PSC and ITO after the solidification of the melted interfacial $MAPbBr_3$. The integration via MAAc is conducted at room temperature and therefore induced no crack during the process, unlike the integration using a low melting temperature metal (such as Gallium alloy) which involves heating over the melting temperature of the metal and cooling. PSC/ITO bonded by MAAc showed an adhesion force of 164 kPa which can hold a weight of 1.67 kg per 1 cm^2. This is the first quantitative measured adhesion force of PSC on any substrate. The PSC/ITO interface showed excellent ohmic contact which verifies that the interface is not only mechanically integrated but also electrically well-connected. A single pixel detector with 2 cm x 2 cm PSC integrated with MAAc showed a superior sensitivity of 9×10^4 µC $Gy_{air}^{-1}cm^{-2}$ which is the highest value among substrate-integrated direct X-ray detectors. Multiple PSCs are integrated onto a TFT panel for array imaging forming active area of 8 cm x 8 cm (~$10^3 \times 10^3$ pixel), which is the largest area ever reported for X-ray detector based on PSC. In addition, the MAAc integration effectively preserved electrical pixelation of the TFT due to its resistive nature unlike metallic integration. This study provided a strategy for integrating millimeter thick, large area (> 64 cm^2) PSC onto various substrates with the demonstration of high performance devices, which is essential towards the commercialization of halide perovskite radiation detectors.

Gold Perovskites Kurt Lindquist[1], Armin Eghdami[2], Christina Deschene[1], Alexander Heyer[1], Jiajia Wen[1], Alexander Smith[2], Edward Solomon[1], Young Lee[1], Jeffrey B. Neaton[2], Dominic Ryan[3] and Hemamala Karunadasa[1]; [1]Stanford University, United States; [2]University of California, Berkeley, United States; [3]McGill University, Canada

Halide perovskites play an important role in the history of gold chemistry. In fact, some of the earliest examples of halide perovskites contain gold. The mixed-valence Au(I)/Au(III) double perovskites have been studied since the 1920s. We have recently expanded gold perovskites to new architectures, which stabilize unexpected oxidation states. I will describe the physical and electronic structures and the properties of these new perovskites. I will also discuss how relativistic effects play a dominant role in the chemistry of gold perovskites, engendering unusual properties not seen in their lighter analogs.

4:00 PM EL04.04.02
Synthetic Control of the Structural, Electronic and Optical Properties of Lead-Free Two-Dimensional Double Perovskites Rik Hooijer[1], Andreas Weis[1], Alexander Biewald[1], Maximilian Sirtl[1], Julian Malburg[1], Rico Holfeuer[1], Simon Thamm[1], Amir Abbas Yousefi Amin[1], Marcello Righetto[2], Melina Armer[3], Firouzeh Ebadi[4], Mahdi Mohammadi[4], Clément Maheu[5], Bas T. van Gorkom[6], Sebastian Häringer[1], Rene A. Janssen[6], Thomas Mayer[5], Vladimir Dyakonov[3], Wolfgang Tress[4], Achim Hartschuh[1], Laura Herz[2,7] and Thomas Bein[1]; [1]LMU München, Germany; [2]University of Oxford, United Kingdom; [3]Julius-Maximilians-Universität Würzburg, Germany; [4]ZHAW School of Engineering, Switzerland; [5]Technische Universität Darmstadt, Germany; [6]Technische Universiteit Eindhoven, Netherlands; [7]Technische Universität München, Germany

Hybrid halide perovskites have attracted enormous interest in the context of developing energy conversion processes towards a green, zero-carbon energy future. The structural exploration of this class of materials (three-dimensional (3D) perovskites) evolved from mainly lead- and tin-based perovskites to lead-free perovskites, double perovskites and low-dimensional substructures such as two-dimensional (2D) perovskites.

2D hybrid double perovskites are a promising emerging class of materials, possessing an even greater structural diversity and tunability than their three-dimensional (3D) parent structures. They are formed through a chemically introduced dimensional reduction of the 3D structure, where suitable organic cations intercalate between the inorganic perovskite layers. This offers access to a large compositional diversity of the inorganic and organic building units, while resulting in a naturally formed, crystallographically defined quantum well electronic structure.
We have employed different synthetic strategies to alter key properties of these 2D structures such as: i) the type of layered structure and their interlayer connectivity (i.e. Ruddlesden-Popper vs. Dion-Jacobson structures), ii) the electronic properties of the organic cations, and iii) the perovskite orientation in thin-film form, which impacts potential applications in different device architectures due to the anisotropic properties of 2D systems.
Starting from the $Cs_2AgBiBr_6$ double perovskite, we have expanded this system to Ag-Bi and Cu-Bi based 2D double perovskites with the halides chloride, bromide and iodide. We have designed different organic layers employing mono- or divalent organic cations of different size, as well as different central functional groups based on cyclohexane, phenyl, naphthalene, pyrene and perylene systems.
The resulting highly crystalline materials were characterized in bulk and thin film form and investigated with standard X-ray techniques as well as grazing incidence wide angle X-ray scattering (GIWAXS), revealing a strong dependence of morphology on substrate choice and synthesis parameters. First-principles calculations give insights into the tunability of the band gap and its nature and show the typical variations of the band alignment for these quantum well structures. Optical characterization techniques, temperature-dependent photoluminescence, and optical-pump terahertz-probe spectroscopy reveal the absorption and emissive behavior of these materials as well as their charge-carrier dynamics. Overall, we develop a comprehensive picture of the electronic and emissive properties of these intriguing materials, dominated by phonon-coupled and defect-mediated polaronic states.
Finally, we address some of the challenges for the pure 2D double perovskites, such as taking advantage of the anisotropic properties and the design and modulation of composition and synthesis towards their incorporation into different optoelectronic devices, while also demonstrating the synergy in 3D/2D heterostructures to improve the photovoltaic performance of $Cs_2AgBiBr_6$ solar cells.

4:15 PM EL04.04.03
Local Structure of Metal Halide Perovskite Glassy-Crystalline Phase Switching Damara G. Dayton[1], Julian Mars[1], Michael Toney[1], David B. Mitzi[2] and Akash Singh[2]; [1]University of Colorado Boulder, United States; [2]Duke University, United States

Amorphous metal halide perovskites (MHP) are a novel materials class with promising potential to broaden the MHP application space to include neuromorphic computing and switchable spintronics. We present a fundamental structural study of the first stable glassy MHP, [(S-(-)-1-(1- naphthyl) ethylammonium]$_2$PbBr$_4$ or "S-NPB", which demonstrates facile amorphous-crystalline phase switching with moderate cooling rates under ambient conditions. [1] Over the past several years, chiral 2D MHPs have garnered substantial research interest due to their chirality-induced Rashba-Dresselhaus spin splitting. Research interest is continually growing, but existing work is heavily focused on crystalline chiral MHPs for spintronic and optoelectronic applications. [2] Though crystallinity offers numerous advantages, we demonstrate further exploitation of the structural chirality transfer to induce glass formation and extend the associated MHP structure-property paradigm. The inherent tunability of MHPs is further enhanced through the inclusion of amorphous phases that offer unique physical properties. We present a comprehensive multimodal characterization strategy to interrogate the complex structure of the amorphous MHP phase and the inorganic-organic interfacial dynamics, addressing significant knowledge gaps within the community. This fundamental understanding of chiral MHP crystallization dynamics pioneers a new class of MHPs with promising potential for phase-change random access memory (PCRAM) neuromorphic computing architectures, and to replace high thermal-budget chalcogenides for optical storage applications.

Upon crystallization, the chirality originating in the chiral cation bilayer of the organic sublattice is transferred to the inorganic sublattice as in-plane angular octahedral distortions, inducing the high melt viscosity and melting depression that enable glass stabilization along with unprecedented thermal stability. [3] Due to S-NPB's inherent structural complexity, insightful structural analysis requires the development of a multimodal analysis strategy probing the local atomic order, thin film confinement effects, and inorganic-organic lattice coupling and interfacial dynamics. In our analysis, we employed several complex structural characterization techniques to probe the intrinsic phenomena over various length and time scales, namely Pair Distribution Function (PDF), polarization-dependent Near-Edge X-ray Absorption Fine Structure (NEXAFS) spectroscopy, Raman Spectroscopy, Nuclear Magnetic Resonance (NMR), Quasi-elastic Neutron Scattering (QENS), and Grazing Incidence Wide Angle X-ray Scattering (GIWAXS). We conducted *in-situ* total scattering PDF studies supported with Reverse Monte-Carlo modeling, determining that the corner-sharing 6-fold octahedral coordination is largely maintained in the melt and glass, but disordered beyond the first coordination shell due to octahedral lattice distortions. The structure of the organic sublattice was informed with NEXAFS to selectively probe the chiral cation local coordination and orientation. To study the interfacial organic-inorganic dynamics, in-situ NMR and QENS were employed to identify the molecular motions facilitating the structural chirality transfer, attributed to H-bonding interactions with the terminal octahedral halide atoms. We conducted *in-situ* GIWAXS studies under various annealing conditions and temperature ramping rates to investigate and control S-NPB's morphological evolution and determine the rate-dependance of crystallization dynamics and enable the critical manipulation of crystal nucleation and growth to obtain preferred orientations. This multimodal approach establishes a comprehensive fundamental understanding of amorphous MHP structural dynamics, and presents the processing-structure-property relationships required to propose S-NPB as a promising candidate for PCRAM neuromorphic computing. 4:30 PM EL04.04.04
Photo-stable Lead Halide Wide Bandgap Perovskite Solar Cells through Frustration of Bromide Mediated I_2 Self-redox Yang Zhou[1], Simone V. Laar[2], Samuele Martani[1], Jia-Yong Heng[3], Kunal Datta[2], Jesús Jiménez-López[1], Feng Wang[4], E Laine Wong[1], Isabella Poli[1], Antonella Treglia[1], Daniele Cortecchia[1], Mirko Prato[1], Libor Kobera[5], Feng Gao[4], Ni Zhao[3], Rene A. Janssen[2], Annamaria Petrozza[1] and Giulia Folpini[1]; [1]Istituto Italiano di

Tecnologia, Italy; [2]Eindhoven University of Technology, Netherlands; [3]Chinese University of Hong Kong, Hong Kong; [4]Linköping University, Sweden; [5]Czech Academy of Sciences, Czechia

Bandgap tunability of metal-halide perovskites is a crucial characteristic for versatile optoelectronic applications. Nevertheless, halide photo-segregation in lead halide compounds impedes their exploitation when bandgaps larger than 1.65 eV are needed such as in perovskite/silicon and perovskite/perovskite tandem solar cells. Here, we show how the generation of I_2 in mixed-halide perovskites under illumination has a crucial role in halide segregation. In fact, I_2 reacts with bromide (Br^-) in the lattice to form a trihalide ion I_2Br^- (I^{d-}-I^{d+}-Br^{d-}), which mediates a Br^-/I^- ion exchange reaction and the formation of an I-rich phase. Importantly, we observe that the efficiency of the process is highly dependent on the binding strength of the bromide within the crystalline structure. Based on this, we propose a general paradigm where an iodine redox based model rationalizes the initiation and growth of halide photo-segregation. Thus, we show how the design of the chemical composition of the metal-halide perovskite crystalline unit can stabilize the semiconductor bandgap, and eventually the performance of related solar cells, not only acting on the reduction of the density of native defects, but stabilizing the elemental composition of the perovskite crystalline unit.

Optical Retardation in 2D Hybrid Copper Halides Lina Quan; Virginia Tech, United States

Light polarization and manipulation are important properties in many applications such as optical modulators, waveplates and also can generate qubits for quantum information technologies. To control the polarization, materials need to be response under polarized light due to either dichroism or birefringence. Although there are many candidate materials to perform the optical polarization effect, however, to achieve a broad range of wavelengths with homogeneous polarization is challenging. In this talk, I will present a new optical retardation material based on low-cost, non-toxic, organic-inorganic hybrid copper halide systems that exhibit strong optical anisotropy across a broad wavelength range. Such a broad degree of polarization control in hybrid copper halides offers new opportunities in polarization detectors and related applications.

Defect Tolerance in Halide Perovskites—A First-Principles Perspective Chris G. Van de Walle; University of California, Santa Barbara, United States

In recent years, the impressive photovoltaic performance of halide perovskites has been commonly attributed to their defect tolerance. This attribution seems intuitive and has been widely promoted in the field, but it has not been rigorously assessed. I will critically discuss the proposition of defect tolerance in halide perovskites based on state-of-the-art first-principles calculations. Rigorous assessments of defect formation energies and recombination rates demonstrate that halide perovskites actually *do* suffer from defect-assisted nonradiative recombination, i.e., they are *not* defect tolerant [1]. The nonradiative recombination rates in halide perovskites are comparable to or even greater than those in conventional semiconductors. We therefore conclude it is incorrect to call the halide perovskites “defect tolerant”. A more relevant distinction, compared to conventional semiconductors, is that halide perovskites with modest defect densities can be grown using low-cost deposition techniques; however, defect engineering is still key to improving the efficiency of perovskite solar cells.
For the prototypical hybrid perovskite $MAPbI_3$ [MA=(CH_3NH_3)] our results indicate that iodine interstitials are most harmful, and hence iodine-rich synthesis conditions should be avoided [2]. Experimental reports have indicated, however, that iodine-poor conditions are also detrimental. We explain this puzzle by demonstrating that iodine-poor conditions lead to formation of hydrogen vacancies on the MA molecule, which act as very efficient nonradiative recombination centers [3]. By contrast, hydrogen vacancies are not a problem in $FAPbI_3$ [FA=$CH(NH_2)_2$], rationalizing why FA is essential for realizing high efficiency in hybrid perovskites. Our findings also indicate the advantages of avoiding the organic cation altogether [4]. We show that the common belief that the organic cation suppresses defect-assisted nonradiative recombination is unfounded. Our study suggests that all-inorganic halide perovskites hold great promise for high-efficiency optoelectronic applications.

Symmetry-Breaking and Reconstruction at Point Defects in Perovskite Semiconductors Seán R. Kavanagh[1,2], Irea Mosquera-Lois[2], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

Point defects are a universal feature of crystalline materials, dictating the functional performance of materials across a wide range of applications (transistors, thermoelectrics, LEDs, power electronics, transparent conductors, photovoltaics…). The standard approach of simulating defects is, however, prone to miss the ground state atomic configurations associated with energy-lowering reconstructions from the high-symmetry crystal environment.[1–5] By yielding both incorrect energies and structures, this failing of current defect calculation approaches compromises the accuracy of calculated properties and behaviour of defects in semiconductors.

To address this issue, we report an approach to efficiently navigate the defect configurational landscape using targeted bond distortions and rattling.[6] Application of our workflow to a range of materials (ranging from perovskites to conventional semiconductors) reveals symmetry breaking in each material that is not found via conventional local minimization techniques. We demonstrate the impact of these reconstructions on derived properties, including formation energies, concentrations and charge transition levels of defects in perovskite materials and beyond.

Studying Defect Density Distributions in Mixed Perovskites Mriganka Singh, Michel D. Keersmaecker and Erin L. Ratcliff; University of Arizona, United States

The immoderate distribution of defects at grain boundaries (GBs), interfaces, and surfaces are dominant factors for highly efficient and stable perovskite solar cells. Here, we introduced an effective way to suppress interfacial defect densities using ionic liquids (ILs; 1-methyl-3-octylimidazolium tetrafluoroborate: $C_{12}H_{23}BF_4N_2$) as the surface passivation which accelerates the perovskite crystallization via two-step spin coating formed metal halide mixed perovskites without solvent engineering. Using a solid-state electrochemical approach [Ref 1], we measure defect densities for SnO_2/perovskite stacks with or without doping of ILs. To study defect density distributions of passivated and unpassivated SnO_2/perovskite films, the carrier recombination velocities of individual GBs are measured at the microscope scale by mapping the photoluminescence pattern in which changes in nonradiative recombination of carriers at GBs are captured.

Controlled Passivation by Lead Halides of Interfacial Defects of Perovskite Films for Emerging Electronic Applications Jihyun Kim, William Jo and Seho Yi; Ewha Womans University, Korea (the Republic of)

In mixed organic–inorganic lead halide perovskites $APbX_3$ (A = methylammonium (MA) or formamidinium (FA); X is Cl, Br or I), the formation of secondary-phase excess lead iodide (PbI_2) has some positive effects as a grain-boundary passivation on interstitial defects but can be detrimental to device stability and lead to large hysteresis effects in voltage sweeps. We converted PbI_2 into an inactive (NH_4^+)-PbI_2 compound via pre-extracted NH_4+/SnO_2 by NH_4Cl passivator [1], which effectively stabilizes the perovskite crystalline phase. These effects were discussed with density functional theory (DFT) and shown to grain voltage sweep measurement by conductive atomic force microscopy (C-AFM) and surface photo-voltage by illuminated Kelvin probe force microscopy. We compared the current and voltage properties for insulating domains of PbI2, (Cl)-PbI_2, and (NH_4^+)-PbI_2 in-situ perovskite films. The ferro-electric properties were discovered on PbI_2 and (Cl)-PbI_2, on the other hand (NH_4^+)-PbI_2 show no ion migration. This means that inactive (NH_4^+)-PbI_2 effects can be stabilized the indiscriminate ion movements on the perovskite-based optoelectronics. As a result, the perovskite solar cells (PSCs) achieve an average efficiency of 21.57 ± 0.45 % and best efficiency of 22.25 % [2] due to the dramatically enhanced open circuit voltage by 1.180 V, which is the main effect of efficiency improvement, and increase the operational device stability over 50 days in ambient conditions with ~50 % of relative humidity. It is very curious that the results also show passivated interface is an effective way to modify bifacial defects and electronic structures improving charge configuration with high resistant / low resistant states and its transfer and extraction, and eventually it is leading to new emergent electronic devices.

Degenerate Lattice Instability-Driven Amorphization under Compression in Metal Halide Perovskite $CsPbI_3$ Jung-Hoon Lee and Seho Yi; Korea Institute of Science and Technology, Korea (the Republic of)

Due to their good optoelectronic properties and inexpensive cost, halide perovskites have been intensively investigated for photovoltaic applications. Different high-pressure experiments report that they generally undergo the reversible phase transitions between different crystalline phases and between crystalline and amorphous phases under an external pressure. Herein, using first-principles density-functional theory (DFT) and ab-initio molecular dynamics (AIMD) calculations, we investigate the origin of the pressure-induced amorphization in halide perovskite $CsPbI_3$. We find that the amorphous-like structures obtained from AIMD calculations become more stable than the orthorhombic *Pbnm* phase above 6.66 GPa, in good agreement with the experimental value (4.44 GPa). Intriguingly, we further find that an imaginary flat band appears in the phonon dispersion of the orthorhombic $CsPbI_3$ phase across the Brillouin zone at 10 GPa, leading to degenerate lattice instabilities. We demonstrate that these energetically degenerated phonon modes are related to PbI_6 octahedral tilting modes and provide random local distortions, leading to amorphization. Our findings contribute to a greater comprehension of the mechanism behind the pressure-induced amorphization in halide perovskites.

Mixing and Matching Organic Cations in 2D Perovskites Rand L. Kingsford and Connor G. Bischak; The University of Utah, United States

Two-dimensional Ruddlesden-Popper perovskite quantum wells have an incredible degree of synthetic flexibility, as their optoelectronic and physical properties can be tuned by changing the halide or the organic cation spacer molecules. Mixing organic cations is a promising, yet underexplored, way to tune the properties of 2D perovskites. The underlying thermodynamics of whether organic cations will mix or phase separate is not well understood. Here, we investigate organic cation mixing in 2D perovskites and demonstrate that whether cations mix or demix depends on their chemical properties and length. We find that we can tune the phase transition temperature of organic cations in the 2D perovskites by blending alkylammonium cations of different length. We also show that cations with distinctly different chemical properties phase separate and we investigate the nanoscale ordering if these phase-separated perovskite domains using nanoscale infrared imaging with photoinduced force microscopy (PiFM). Our results demonstrate that cation mixing is a powerful way to tune thermodynamic properties of 2D perovskites and template these materials at the nanoscale.

Lightweight, Floating Perovskite-BiVO$_4$ Tandem Devices for Scalable Artificial Photosynthesis Virgil Andrei[1,1], Geani M. Ucoski[1], Robert Jagt[1], Chanon Pornrungroj[1], Demetra S. Achilleos[1], Katarzyna Sokol[1], Judith MacManus-Driscoll[1], Robert Hoye[2], Richard Friend[1] and Erwin Reisner[1]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom

Photoelectrochemical (PEC) artificial leaves hold the potential to lower the costs of sustainable solar fuel production by integrating light harvesting and catalysis within one compact device. However, current deposition techniques limit their scalability, while fragile and heavy bulk materials can affect their transport and deployment. Here, we demonstrate the fabrication of lightweight artificial leaves by employing thin, flexible substrates and carbonaceous protection layers.[1] Lead halide perovskite photocathodes deposited onto indium tin oxide coated polyethylene terephthalate achieve an activity of 4266 μmol H_2 g^{-1} h^{-1} using a platinum catalyst, whereas photocathodes with a molecular Co catalyst for CO_2 reduction attain a high CO:H_2 selectivity of 7.2 under a lower 0.1 sun irradiation. The corresponding lightweight perovskite-BiVO$_4$ PEC devices display unassisted solar-to-fuel efficiencies of 0.58% (H_2) and 0.053% (CO),respectively. Their potential for scalability is demonstrated by 100 cm^2 standalone artificial leaves, which sustain a comparable performance and stability of ≈24 h to their 1.7 cm^2 counterparts. Bubbles formed under operation further enable the 30-100 mg cm^{-2} devices to float, while lightweight reactors facilitate gas collection during outdoor testing on a river. The leaf-like PEC device bridges the gulf in weight between traditional solar fuel approaches, showcasing activities per gram comparable to photocatalytic suspensions and plant leaves.[1] The presented lightweight, floating systems are compatible with modern fabrication techniques,[2] and may enable open water applications, while avoiding competition with land use.

Perovskite Grain Wrapping by Converting Interfaces and Grain Boundaries into Robust and Water-Insoluble Low Dimensional Perovskites Haoyang Jiao; University of North Carolina at Chapel Hill, United States

Stabilizing perovskite solar cells need to consider all defective sites in the devices. Significant efforts have been devoted to stabilizing interfaces, while stabilization of grain boundaries received less attention. Here we report a molecule tributyl(methyl)phosphonium iodide (TPI), which can convert perovskite into a wide bandgap one-dimensional (1D) perovskite that is mechanically robust, water-insoluble. Adding TPI into perovskite precursor results in a wrapping of perovskite grains with both grain surfaces and grain boundaries converted into several nanometer-thick 1D perovskites during the grain-formation process as observed by direct mapping of it. The grain wrapping passivates the grain boundaries, enhances their resistance to moisture, and reduces the iodine released during light soaking. The perovskite films with wrapped grains are more stable under heat and light. The best device with wrapped grains maintained 92.2% of its highest efficiency after light soaking under one sun illumination for 1900 hours at 55 °C open circuit condition.

11:30 AM *EL04.06.04
Halide Perovskite Thin-Film Growth Control via Pulsed Laser Deposition—A Single-Source, Dry, Vapor Deposition Approach Monica Morales-Masis; University of Twente, Netherlands

The adoption of new semiconductor materials in high-end technologies, such as multi-junction devices, integrated circuits and other, demands fabrication processes that allow a high level of control over film properties such as composition, microstructure, thickness and conformality. The ability to control the film formation of semiconductors like indium phosphide, gallium arsenide, and several metal oxides and nitrides, opened the way for applications such as light emitting devices, high-efficiency photovoltaics and integrated electronics and photonics. Halide perovskites have demonstrated a huge potential in optoelectronic applications, and as the understanding and compositional landscape increases for this family of materials, interesting properties for applications beyond optoelectronics are being investigated. The ability to control the growth of these new perovskites in thin film form, with flexibility for composition exploration and full control on polymorph and thickness will aid the experimental validation of new physical phenomena as well as the exploration on various applications. In this presentation, we will discuss how we leverage pulsed laser deposition (PLD) as a unique single-source vapor deposition method allowing near-stoichiometric transfer of multi-compounds from a single solid target to a thin film. We demonstrate PLD of a variety of compounds from multi-organic cation perovskites, to inorganic halide perovskites and chalco-halide perovskites. The critical role of the PLD parameters to control deposition rate and microstructure from polycrystalline up to epitaxial formation will be discussed. In addition to growth control, PLD allows for heterostructure formation, conformal deposition and patterning, all important steps for integration in various device platforms. This work proposes strategies for growth control, versatile film deposition and the possibility of complex device integration of a large variety of halide perovskite compositions.

Exciton Photophysics of Halide Perovskites for Novel Applications Yoshihiko Kanemitsu and Go Yumoto; Kyoto University, Japan

Halide perovskite semiconductors exhibit unique optical, transport, and thermal properties even at room temperature. High-quality perovskite samples show no light scattering losses, high optical transparency in the visible and near-infrared regions, and efficient photoluminescence with no essential Stokes shift. Therefore, the dynamics of charge carriers, excitons, and spins can be studied using optical spectroscopy. We studied the exciton properties of halide perovskites using nonlinear optical spectroscopy, single dot spectroscopy, and terahertz spectroscopy [1-7]. In this talk, we discuss the exciton-phonon interactions, exciton-exciton interactions, and higher harmonic generation for optical refrigeration, spintronics, and light source applications.

Leveraging *Operando* Methodologies to Reveal Chemical Mechanisms for Perovskite Degradation Michel De Keersmaecker, Neal R. Armstrong and Erin L. Ratcliff; The University of Arizona, United States

To control lead halide perovskite degradation, characterization strategies have mostly counted on researcher dependent models that try to understand mechanisms by indirectly measuring defects, but rarely their chemical makeup and reactivity under stress are considered part of the long-term stability problem. To probe reactive defects and correlate their chemical composition to ultimately comprehend degradation mechanisms, the community will need to move towards powerful and advanced characterization tools that measure the chemical, electronic and physical evolution under real-time operation. Here, we demonstrate *operando* methodologies based on an innovative electrochemical approach that starts from a “peel and stick” electrochemical half-cell device stack that uses a solid elecrolyte top contact. Systematic potential modulation polarizes any chosen interface of any type of device stack to measure defect concentrations and their electrochemical activity. By integrating this probe into an environmental chamber, we reveal the evolution of defect concentrations and structural data under relevant bias and specifically chosen accelerated aging conditions. With the help of a near-ambient pressure X-ray photoelectron spectroscopy approach, we have recently discovered a realistic mechanism for the environmental degradation of lead halide perovskites linking both experimental and theoretical efforts in this field.
In conclusion, this electrochemical probe and its combination with complementary methods is shown to promote *operando* analysis of thin film perovskites, but potentially also (in)organic semiconductors, quantum dots, material blends and device stacks, where the removable electrolyte functions as a removable top contact. This type of advanced characterization platform will prove to be crucial for the improvement of perovskite stability and durability to close the gap towards an industry-scalable perovskite-based technology in the field of photovoltaics, spintronics, electrochemical charge storage systems, photoelectrochemical cells, etc.

2:15 PM EL04.07.03
Hidden Spin-Splitting in Globally Centrosymmetric 2D Ruddlesden-Popper Halide Perovskites Willa Mihalyi-Koch[1], Dongxu Pan[1], Zhenbang Dai[2], David P. Lafayette[1], Kyana M. Sanders[1], Simon Teat[3], Ilia A. Guzei[1], John C. Wright[1], Andrew M. Rappe[2] and Song Jin[1]; [1]University of Wisconsin–Madison, United States; [2]University of Pennsylvania, United States; [3]Lawrence Berkeley National Laboratory, United States

2D hybrid lead halide perovskites have emerged as promising materials for spintronic applications due to the observation of spin splitting effects when the inversion symmetry of the crystal structure is broken. The organic cations incorporated into the 2D structure template the lead iodide octahedral network, often dictating the resulting crystal symmetry. Unlike 3D perovskites, 2D Ruddlesden-Popper (RP) perovskites can host larger, oversized A-cations in the perovskite cage formed by corner-sharing lead iodide octahedra. Here we report crystal structures for a series of 2D lead iodide perovskites containing a set of six different A-site cations of varying size for the first time. The resulting library of 2D RP perovskites exhibit varying levels of symmetry breaking at the octahedral, layer, and unit cell levels. Second harmonic generation is used to experimentally investigate such complex scenarios of symmetry breaking. Several globally centrosymmetric structures exhibit polar layer symmetry, leading to calculated hidden spin polarization effects analogous to inorganic 2D materials such as MoS_2. This work suggests the existence of a large hidden class of centrosymmetric 2D RP perovskites that can be utilized for spintronic applications through perturbation of the compensated symmetry.

Molecular Doping Strategy in Low Dimensional Perovskites by Dopant Intercalation Keehoon Kang[1], Jonghoon Lee[1], Kyeong-Yoon Baek[1], Henning Sirringhaus[2], Jeongjae Lee[1] and Takhee Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]University of Cambridge, United Kingdom

Doping has been one of the most essential methods to control charge carrier concentration in semiconductors. In metal halide perovskite, which have revolutionized the field of solar cells and light-emitting diodes due to their favorable optoelectrical properties, extensive doping via atomic substitution still remains challenging due to their structural stability limited by tolerance factor and compensation of intentionally introduced defects by mobile halide ions. As an alternative non-invasive approach for, concepts utilizing molecular dopants for surface charge transfer doping have been previously reported for tuning the conductivity of metal-halide perovskite. However, most of the reports have been focused on charge transfer effects at the interface or grain boundaries which have limited the range of doping attainable. In this work, we use strong molecular p-dopant, tris(4-bromophenyl)ammoniumyl hexachloroantimonate (magic blue), for significantly improving the electrical conductivity of low-dimensional perovskite films. We identify that dopant incorporation into the bulk of the film as the structural origin of the improved conductivity and propose the solvent selection criteria for achieving effective molecular doping, which can potentially open up a controllable route towards tuning electronic structure for optimizing perovskite-based devices.

3:45 PM EL04.08.02
Anisotropy of Phonon Transition Dipole Moments and Hints of Anisotropy in the Photoconductivity of Single-Crystalline Two-Dimensional Lead-Halide Perovskites Jaco Geuchies[1], Johan Klarbring[2], Shuai Fu[1], Lucia Di Virgilio[1], Sheng Qu[1], Hai Wang[1], Maksim Grechko[1], Jarvist M. Frost[2], Aron Walsh[2], Mischa Bonn[1] and Heejae Kim[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]Imperial College London, United Kingdom

The lattice of hybrid organic-inorganic metal halide perovskites is both soft and ionic. The particular combination gives rise to interesting molecular physics: electrons in these materials are strongly coupled to vibrations and phonons. Analogous to the solvation of ions in water, when the coupling between vibrations and charge carriers is strong enough, it leads to the formation of polarons, where the charge carrier and lattice vibration cannot be disentangled into two separate entities anymore. Here, we study single crystals of butylammonium lead iodide (BAPI), a two-dimensional perovskite structure, with different, but well defined, thicknesses of the inorganic lattice. We measured angle-and-polarization dependent THz transmission through the samples to study the directionality of the transition dipole moments (TDMs) of vibrational modes between 0.3 – 3 THz; the vibrations in the inorganic planes inside the lattice. Next to this, we use optical-pump/THz probe spectroscopy to measure the materials' photoconductivity along different crystallographic directions. We find signatures of higher photoconductivity in the direction perpendicular to the 1 THz TDMs compared to parallel to it, and discuss possible origins of this phenomenon by comparison to theory.

Excitons in Quasi-Two Dimensional Metal Halide Perovskites from First Principles Computational Modeling Marina Filip; University of Oxford, United Kingdom

Quasi-two dimensional organic-inorganic metal-halide perovskites are a family of solutionprocessable semiconductors of unparalleled chemical and structural heterogeneity. Starting from prototypical 3D perovskites, organic cations of different sizes, shapes and charges can be used to "carve" out inorganic metal-halide layers of different thicknesses, shapes and alignments in a controlled way, leading to so-called Ruddlesden-Popper or Dion-Jacobson type perovskites, as well as other more complex structures, including perovskite-intergrowth hetero-structures [1,2]. These quasi-low dimensional systems combine the tunability of the optoelectronic properties of 3D perovskites, with quantum- and dielectric-confinement, and give rise to a wide range of excited state phenomena. In this talk I will present our study of the photophysical properties of Ruddlesden- Popper and Dion-Jacobson layered perovskites, using Green's functions based first principles
methods within the GW approximation [3] and the Bethe-Salpeter equation [4]. I will discuss the dielectric properties of layered perovskites, and present how the A-site cation takes a central role in the screening of excitons in layered perovskites [5]. Furthermore, I will present recent results on understanding the effect of layer alignment and interlayer distance on the photophysical properties of quasi-2D halide perovskites.

Photo-Induced Spin-Spin Coupling in Doped Organic-Inorganic Hybrid Perovskites Tao Xu; Northern Illinois University, United States

The fundamental understanding of light-matter interaction can provide mechanistic guidance to enhance the carrier generation and transport efficiency in photovoltaic materials. We will present a set of intriguing photo-induced spin-spin interaction between photoelectrons and dopants in organic-inorganic hybrid perovskites provides. We show that at cryogenic temperature, the spin impurity dopants and the light-induced photoelectrons exhibits strong spin coupling via exchange interaction which can further be modulated.

Manipulating Thermal Transport in Two-Dimensional Organic–Inorganic Perovskites Rahil Ukani[1], Alexander Christodoulides[2], Qichen Song[1], Ryan McGillicuddy[1], Yukyung Moon[1], Hong Ki Kim[1], Jinyoung Seo[1], Jonathan A. Malen[2] and Jarad A. Mason[1]; [1]Harvard University, United States; [2]Carnegie Mellon University, United States

Two-dimensional (2-D) organic–inorganic perovskites containing first-row transition metals and long-chain organic cations have recently been explored for thermal applications, including thermal energy storage and solid-state barocaloric cooling. Controlling the thermal conductivity of these materials is essential to capturing their value in practical systems, yet few studies have examined the transport mechanisms of these structures. Most importantly, much remains to be understood about the chemical and structural factors that regulate thermal transport at a molecular level. We report systematic investigations into the thermal conductivity of 2-D perovskites, seeking to understand the role of chemical interactions at the organic–organic interface in dictating thermal transport. Variable temperature frequency-domain thermoreflectance and nanomechanical indentation measurements were performed on a library of 2-D Mn–Cl perovskites to probe the relationship between structural features and the character of thermal vibrations. These measurements were carried out across their order–disorder phase transitions to evaluate the effects of structural disorder on thermal transport. Additionally, 2-D perovskites whose organic bilayers feature an array of chain flexibilities and chemical interaction networks have been explored in the context of tuning thermal conductivity *via* interlayer adhesion strengths.

SESSION EL04.09: Poster Session: Metal Halide Perovskites for Applications Beyond Solar
Session Chairs: Sebastian Reyes-Lillo and Carolin Sutter-Fella
Thursday Afternoon, April 13, 2023
Moscone West, Level 1, Exhibit Hall

University, United States; [2]National Renewable Energy Laboratory, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Helmholtz-Zentrum Berlin, Germany; [5]Institut national des sciences appliquées de Rennes, France

Low-cost green hydrogen is a critical objective for the renewabilization of chemical manufacturing and as an energy carrier for a clean energy economy. Integrated photoelectrochemical cells (PECs) directly couple the photoabsorber, anticorrosion barriers, and electrocatalysts to the electrolyte so that photogenerated carriers carry out electrochemistry on the device surface, resulting in lower costs and improved performance. State-of-the-art PECs have used III-V panel photoabsorbers and are limited by high cost. Alternative absorbers like Si have insufficient voltage, and particle photocatalysts, while stable, are inefficient. Halide perovskites are promising next-generation semiconductors which offer impressive photovoltaic performance at low cost.

Here, we demonstrate a high-efficiency halide perovskite-based photoelectrochemical device with solar-to-hydrogen efficiency. The HaP-PEC is enabled by the development of a high-performance anticorrosion barrier technology which is modular, scalable, low-cost, and importantly introduces no observable losses through series resistance or cell damage on deposition. This means that the photovoltaic efficiency is perfectly delivered to the catalyst active site. Using this approach, we demonstrate perfect preservation of photovoltaic efficiency for single and multijunction perovskite PECs, and a tandem silicon-perovskite photoanode with STH = 21.5% and t_{60} lifetime = 102 hours, which to the best of our knowledge is a record efficiency and state-of-the-art stability across all published PEC demonstrations. These figures of merit represent the first demonstration of high PEC efficiency coupled with low-cost photoabsorbers and pave a path to a surprising commercial pathway for halide perovskite devices producing solar fuels.

5:00 PM EL04.09.02

Impact of the Layer Number on the Biexciton Binding Energy in 2D Perovskite Series $[CH_3(CH_2)_3NH_3]_2(CH_3NH_3)_{n-1}Pb_nBr_{3n+1}$ (n = 1–3) Jun Sang Cho[1], Hyun Kyung So[1], Eugenia S. Vasileiadou[2], Mercouri G. Kanatzidis[2], Myung Hwa Jung[1] and Joon Ik Jang[1]; [1]Sogang University, Korea (the Republic of); [2]Northwestern University, United States

The Ruddlesden-Popper (R-P) series of metal organic halide perovskites can host tightly bound excitons even at room temperature due to strong quantum confinement. [1] This implies that two-dimensional (2D) confinement can also enhance the stability of their Coulomb bound state, the so-called biexciton. This confinement effect is supposed to increase when decreasing the perovskite layer number (n) in the Br-based R-P perovskite series, $(BA)_2(MA)_{n-1}Pb_nBr_{3n+1}$ ($BA = CH_3(CH_2)_3NH_3$, $MA = CH_3NH_3$, n = 1–3). Recently, it was shown that biexcitons are formed by binding of two dark excitons, which are stable up to around 100 K in $(BA)_2PbBr_4$ (n = 1). [2] However, there is no comprehensive study on the stability of biexcitons upon tuning the confinement effect by varying the layer number in the R-P series. Herein, we investigate the impact of quantum confinement on the biexciton binding energy as a function of n = 1–3 by employing precision photoluminescence (PL) spectroscopy and second harmonic generation (SHG) measurement. Based on the series of PL spectra obtained as a function of excitation intensity, polarization, and temperature, the biexciton binding energies are precisely determined to be 18.7, 25.5, and 12.0 meV at 10 K for n = 1, 2, and 3, respectively. Therefore, our results unexpectedly indicate that the quantum confinement effect seems to be strongest at n = 2, not n = 1. However. we show that this anomaly arises basically from the unusually small exchange interaction at n = 2, which is 6.9 meV. This value is much smaller than 21.8 meV (n = 1) and 12.6 meV (n = 3). Temperature-dependent SHG and PL spectra clearly demonstrate that this small dark-bright splitting energy of 6.9 meV is associated with a newly discovered structural phase transition near 100 K, occurring only in the n = 2 perovskite. We will discuss the nature of the structural phase transition and its impact on the dark-bright splitting that directly affects the biexciton binding energies of the series. Our study will deepen the understanding of the excitonic fine structure and structural phase transition as a function of layer number in these important materials and potentially pave a way toward 2D excitonics.

Carrier Multiplication in Perovskite Solar Cells Yue Wang, Senyun Ye, Jia Wei Melvin Lim, David Giovanni, Minjun Feng, Jianhui Fu, Harish N. Krishnamoorthy, Qiannan Zhang and Tze Chien Sum; Nanyang Technological University, Singapore

Harnessing solar energy is one of the sustainable methods for addressing the deepening energy crisis. Perovskite solar cells (PSC) emerged as a rising star due to their outstanding power conversion efficiency (PCE) which increased to more than 25% over a decade of development.[1] However, the theoretical maximum efficiency of single junction solar cells, which is also known as the Shockley-Queisser (SQ) limit, is around 33%.[2] One of the main loss pathways is the dissipation of excess energies of hot carriers into heat through lattice vibration.[3] Carrier multiplication (CM) or multiple exciton generation (MEG), generating multiple carriers or electron-hole pairs from the absorption of a single high-energy photon, is hailed as one of the advanced photovoltaic concepts to break the SQ limit.[4] Although CM/MEG effects in halide perovskites have been extensively studied primarily using ultrafast transient absorption (TA) spectroscopy on bare perovskite films, there remain several open questions on whether CM would (i) manifest in an actual PSC device operating under solar illumination; and whether it could (ii) contribute to performance enhancements. Here, we combine both the spectroscopic techniques and solar cell device performance studies to carefully assess the contributions from CM to the overall performance. Our findings provide new insights into the intricate interplay of numerous parameters that may negate the contribution of CM on PSC performance. I will also discuss about the challenges and opportunities to leverage this untapped potential to further enhance PSC performance using CM effects.

5:00 PM EL04.09.04

Tailoring the Thermal Conductivity of Two-Dimensional Metal Halide Perovskites Sandip Thakur and Ashutosh Giri; University of Rhode Island, United States

Proper thermal management of solar cells based on metal halide perovskites (MHPs) is key to replacing and surpassing the efficiencies attainable in the widely used silicon-based photovoltaics. In that aspect, the enhancement in thermal stability of two-dimensional (2D) MHPs with respect to their three-dimensional counterparts positions them as the next generation materials to revolutionize energy storage and conversion. However, the ultralow thermal conductivities of the 2D MHPs and the limited understanding of the heat transfer mechanisms in these materials is still a major bottleneck for their large scale incorporation in photovoltaic devices. Herein, we provide a detailed analysis of the heat transfer mechanisms in 2D MHPs through both experimental and computational approaches demonstrating a novel strategy to engineer enhanced thermal conductivities in these materials.

We use the time-domain thermoreflectance technique to measure the thermal conductivities of 0.19 ± 0.03 W m^{-1} K^{-1} and 0.18 ± 0.03 W m^{-1} K^{-1} for the Ruddlesden-Popper (RP) and Dion-Jacobson (DJ) phases of 2D MHPs (n=1) with 13.6 Å and 6.3 Å interlayer inorganic separations, respectively. Through our computational and experimental results, we find that changing the size of the organic spacers in between the 2D inorganic layers has a negligible influence in the thermal transport properties of these materials. We attribute this to coherent heat transport rather than incoherent scattering at the hybrid interfaces dictating the vibrational properties of these 2D MHPs. In contrast to conventional approaches utilized to increase thermal conductivity in layered materials (such as by decreasing interfacial scattering of phonons via reducing the interface density), we show that decreasing the distance between adjacent organic cations (by up to 40%) can lead to more than threefold increase in overall heat conduction which is mainly driven by the vibrational hardening of the organic spacers. Our experimental measurements along with our atomistic simulations provide new insights into the underlying physics and provide valuable strategies for tailor-made thermal conductivities in 2D MHPs, an emergent material for solar cell applications.

5:00 PM EL04.09.05

Exciton Quantum Coherence and Spin Relaxation in Halide Perovskite Nanocrystals Rui Cai, Indrajit Wadgaonkar, Jia Wei Melvin Lim, Stefano Forno, David Giovanni, Minjun Feng, Senyun Ye, Marco Battiato and Tze Chien Sum; Nanyang Technological University, Singapore

The recent discoveries of exciton fine structure splitting (FSS) in perovskite nanocrystals (NCs)[1, 2] suggest their great potential in optospintronics and quantum technologies. However, the coherent manipulation of these FSS states and the exciton multilevel coherence are lacking. Here, we provide new insights into the exciton and spin physics in ensembles of $CsPbBr_3$ NCs using ultrafast spectroscopy, including the observation and coherent control of exciton quantum beating and the underlying mechanisms for exciton spin decoherence.

First, the FSS multilevel coherence will be discussed with a quantum beating model. Using transient absorption (TA) spectroscopy, we observe periodically modulated TA kinetics that are sensitive to the light helicity, which enables ultrafast control of the excitonic degree of freedom. The low-temperature oscillatory dynamics allow to estimate the average FSS energies that are comparable to these measured by single-particle photoluminescence. The exciton spin relaxation mechanisms in halide perovskite NCs, which are now under intense debate will also be discussed. Combining the temperature-dependent exciton spin lifetimes with a Monte Carlo simulation, we present a full physical picture of the exciton spin depolarization processes. The dominating spin decoherence mechanism varies with both temperature and nanocrystal size, showing temperature crossovers from one mechanism to the other. The thorough understanding of exciton spin dynamics provides guidance for spin engineering in halide perovskites and their optospintronic applications.

5:00 PM EL04.09.06

Practical Demonstration of Deep-Ultraviolet Detection with Wearable and Self-Powered Halide Perovskite-Based Photodetector Thi My Huyen Nguyen[1], Shinkyu Lee[1], Sangmo Kim[2] and Chung Wung Bark[1]; [1]Gachon Univ, Korea (the Republic of); [2]Sejong University, Korea (the Republic of)

Flexible and self-powered photodetectors (PDs) have become one of the most popular topics, attracting researchers in the field of optoelectronic applications. In this study, for the first time, we demonstrate partial discharge detection in a practical environment with a prepared flexible device. Poly(vinylidene fluoride) (PVDF) is utilized as a highly transparent material in the UVC region, to create a flexible substrate with the antihumidity property. A detector that uses a mixed-halide perovskite $(FAPbI_3)_{1-x}(MAPbBr_3)_x$ as the photoactive material is constructed in a vertical structure on the as-prepared hydrophobic PVDF substrate. The fabricated device exhibits good performance with a fast response speed (and a high detectivity of 7.21×10^{10} Jones at zero bias under 254 nm UV illumination, along with superior mechanical flexibility at various bending angles. The critical parameters of our PD based on mixed-halide perovskite $(FAPbI_3)_{1-x}(MAPbBr_3)_x$ were higher than those of the PDs based on other kinds of photoactive materials such as inorganic perovskites ($CaSnO_3$, $BiFeO_3$, $BiTiO_3$, $SrTiO_3$), diamond, oxides (ZnO, TiO_2), and nitrides (GaN) reported in previous studies. Additionally, the air-exposure stability and reproducibility of the as-prepared device exhibit almost the original performance after 6 weeks of storage. For practical applications, we demonstrate a facile and sensitive detection for UVC leakage from a germicidal lamp and simulated a partial discharge system using our PD without energy consumption. As a realistic demonstration of UVC detection, the result shows a photograph of the measurement of partial discharge. The partial discharge inception at a high voltage occurs at 12 kV, and the voltage is then downregulated to 8 and 4 kV. The prepared flexible PD was hung on a holder placed 1 m from the rod-plane electrode, and data were recorded using the Keithley analyzer system. It can be observed that the current signals were generated during various partial discharges. this application confirmed that a halide perovskite-based PD can monitor and witness UV radiation leakage from insulation defects in high-voltage apparatus in the early stages to prevent unexpected damage. These results indicate that this new approach may be useful and convenient for the detection of partial discharge as well as for several practical applications.

5:00 PM EL04.09.07

Epitaxy of Halide Perovskites by Pulsed Laser Deposition (PLD)—The Case of $CsSnI_3$ and $MAPbI_3$ Junia Shelomi Solomon S. Solomon Sathiaraj[1], Yorick A Birkhölzer[1,2], Tatiana Soto-Montero[1], Wiria Soltanpoor[1] and Monica Morales-Masis[1]; [1]University of Twente, Netherlands; [2]Cornell University, United States

Halide perovskite (HP) materials have shown great promise for optoelectronic applications owing to their intrinsic material properties. However, HPs in their polycrystalline form are still limited by their environmental, thermal, and structural instability. Focusing on structural stability, here we explore the epitaxial growth of $CsSnI_3$ and $MAPbI_3$ on lattice-(mis)matched crystalline substrates using pulsed laser deposition (PLD). This allows us to monitor the polymorph stabilisation on achieving epitaxy. Additionally, it helps us understand the effect of strain and study the fundamental properties that become accessible when going from polycrystalline to single-crystalline films.

In the case of $CsSnI_3$, using reciprocal space maps we confirm the stabilisation of single orientation of the orthorhombic (γ) phase of $CsSnI_3$ on KCl substrates. Further, rocking curve measurements give insights into the mosaicity of the film and pole figure measurements confirm the film is epitaxial and not textured. Transmission electron microscopy (TEM), photoluminescence (PL) and optical absorption spectroscopy measurements were performed to confirm the epitaxial formation and its effect on the optical properties of the films.

In the case of $MAPbI_3$ films grown on KCl substrates, reciprocal space maps, rocking curve and pole figure measurements were also performed to validate epitaxial growth and stabilisation of the cubic phase at room temperature. The latter contrasts with the usually polycrystalline tetragonal phase growth of $MAPbI_3$ on typical solar cell contact layers. The highly oriented $MAPbI_3$ films on KCl showed a sharper PL peak over their polycrystalline counterparts and the band gap is also consistent with reports of cubic $MAPbI_3$ phase.

Overall, we demonstrate the successful epitaxial growth of homogeneous and dense thin films of $CsSnI_3$ and $MAPbI_3$ by PLD. This demonstrates the potential of this physical vapor deposition technique to achieve control of thin film deposition, from polycrystalline films all the way to epitaxial formation. In-depth structural analysis with different X-ray diffraction measurements was conducted to verify epitaxial growth and to understand the influence of lattice-(mis)matched strain on the stabilisation of the polymorphs. This work paves the way to further fundamental materials studies and high-end optoelectronic devices based on halide perovskite thin films.

5:00 PM EL04.09.08

Homogeneous Charge Distribution for Suppressing Charge Recombination in Perovskite Solar Cells under Low-Intensity Indoor Lights Min Jun Choi[1], Seok Woo Lee[2], Minwoo Lee[3,3], Sojeong Shin[1], Moonyong Kim[3], Geongguk Jeon[1], Sang Eun Yoon[1], Xiangyang Fan[2], Bo Ram R. Lee[2], Jan Seidel[3], Jae Sung Yun[3,4], Dong Wook Chang[2] and Jong Hyun Kim[1]; [1]Ajou University, Korea (the Republic of); [2]Pukyong National University, Korea (the Republic of); [3]University of New South Wales, Australia; [4]University of Surrey, United Kingdom

Due to the rapid advances on the Internet-of-Things (IoT) technology, the number of IoT sensors has recently explosive increased. most of wireless IoT sensors are expected to be installed in indoor environments. Instead of the using batteries that needed replacement and maintenance, Using the energy harvesting for self-powered IoT electronic devices is one of the most critical issues. Therefore, indoor photovoltaics (PVs) have been proposed as a great potential candidate for harvesting indoor light energy toward the long-term and stable operation of indoor IoT sensors.
Among the various types of light absorbers in PV cells, inorganic–organic hybrid perovskites are promising for indoor-light-harvesting applications, owing to their appealing merits such as high absorption coefficient in the visible range, high charge carrier mobility, and tunable bandgap (E_g). By exploiting these properties and through the E_g engineering of perovskites and the optimization of device architectures, perovskite solar cells (PVSCs) with high indoor power conversion efficiency (iPCE) have been developed.
Compared with 1 sun condition, indoor light has a very low intensity (200–1,000 lux). Due to the relatively small amount of carrier generation under low-intensity light environments than those under outdoor light conditions, photo-generated charge carriers can be more affected by the density of defects or trap sites, resulting in the non-radiative recombination. Therefore, frustration of the trap-mediated charge recombination is most critical issue in improving iPCEs. To suppress recombination, interface engineering is crucial for the indoor performance of devices.
In this work, we reported the effect with interfacial dipoles and uniformity of excited carrier distributions by using an interfacial dipole layer (IDL) material-quinoxaline-phosphine-oxide-based electron transporting small molecule [(2,3-diphenylquinoxaline-5,8-diyl)bis(4,1-phenylene))bis(diphenylphosphine oxide) (QDPPO)] on top of [6,6]-phenyl-C_{61}-butyric acid methyl ester ($PC_{61}BM$) electron transport layer (ETL). With high molecular electric dipole moment and efficient electron extraction properties, QDPPO induces the uniform accumulation of excited carriers on the ETLs under low-intensity illumination conditions. Electrochemical impedance spectroscopy, and transient photovoltage revealed that the homogeneous distribution of charge carriers effectively suppresses charge recombination, which result in a persistently high FF of PVSCs under low-intensity light-emitting diode (LED) condition. Furthermore, the photoluminescence (PL), time-resolved photoluminescence (TRPL), and Photo-CELIV measurement revealed that insertion of QDPPO facilitated charge extraction of PVs, resulting in high short circuit current densities.
As a result, QDPPO enabled with high indoor power density (iPD) and indoor power conversion efficiency (iPCE) of 65.63 *m*W/cm^2 and 27.49% under 800 lux LED, which were further enhanced to 36.90% by additional insertion of passivation layer. We also successfully fabricated mini-modules using QDPPO-based PVSCs exhibiting indoor power output (iPO) of up to 2.4 mW under 1,000 lux halogen light conditions, verifying the practical applicability of for operating indoor IoT sensors.
In summary, we investigated the effect of IDLs on the PV properties of the PVSCs under indoor low-intensity light conditions. The insertion of polar molecules revealed that homogeneous generation of excited charge carriers on the surface strongly affected the recombination reduction. Significantly improved uniformity of interfacial dipoles, in the QDPPO layer, effectively improved indoor PV properties while maintaining high FF under low-intensity light conditions. These results indicate that uniform charge distribution is an effective strategy to enhance PSCs performance in low light conditions.

5:00 PM EL04.09.12
Optimal Solvents for Interfacial Engineering towards Efficient Perovskite Solar Cells Wonjin Jang, Doyeon Heo and Sooyoung Kim; Korea University, Korea (the Republic of)

Perovskite solar cells (PSCs) have been attracting attention for several years due to their excellent optoelectronic properties, low processing cost, easy manufacturing process. However, improving the efficiency and long-term stability of PSCs still remains a challenge. Many methods have been studied to increase the efficiency and stability of the PSCs by controlling the perovskite manufacturing process, device structural design, compositional engineering, and interfacial modification. Among them, interfacial engineering is widely used to reduce the interfacial loss process caused by surface recombination, improve the crystallinity of the active absorption layer, the work function of the contact layer, and the intimacy of the contact at the interface, as well as help the long-term stability of the solar cell. To deposit the interfacial layer, solution process such as spin-coating or dip coating is commonly used because it is cheap and facile.
In the solution process, determining the solute is important, but determining the solvent is also important. In order to select the best solvent in the solution process, the most commonly used solvent was selected and tested, and the solvents were divided into two groups: a non-polar group and a polar group. We focused on the interfacial layer between electron transport layer (ETL) and perovskite, and checked how it affects perovskite and ETL by coating solvent between ETL and perovskite. It was confirmed that some solvents were detrimental to the efficiency of PSCs, and some solvents are effective in the efficiency of PSCs. The effects of solvents on PSCs were proved through various analyses. Among them, the best solvent used in the solution process and the solvent to be avoided were selected from the non-polar group and the polar group one by one.

5:00 PM EL04.09.14
Switchable Perovskite/Organic Dual-Band Photodetectors for Dual Optical Communication Applications Yu Gao, Zhaoming Wang, H.Y. Fu and Guodan Wei; Tsinghua-Berkeley Shenzhen Institute, China

It remains challenging to realize fast-switching speed and crosstalk-free high responsivity for visible and nearinfrared (NIR) dual-band photodetectors. Here we have carried out extensively interdisciplinary work on optoelectronic devices and their practical applications in optical communications for smart living: wavelength multiplexing and security enhancement. Herein, we report a fast switchable perovskite/organic bulk heterojunction (BHJ) dual-band PD with high selective responsivities over 100 mA/W in distinct visible (<820 nm) and near-infrared (NIR) bands (>850 nm). The dynamic dual-band response could be conveniently switched under a low-voltage modulation range from forward bias of +0.3 V for visible light to reverse bias of −0.8 V for NIR light. To note, the visible/ NIR response switching frequency has been reached as high as 1 MHz, which has been the highest values to our best knowledge for dual-band photodetectors. Due to such as switching speed, two novel optical communication applications: wavelength division multiplexing (WDM) and encryptedsecurity enhancement have been successfully established. The WDM application has been realized with a sum rate of 1.1 Mbps without any complicated circuit design and computation. The demonstrated encrypted scheme combining visible/invisible light in one channel to deceive cryptanalysts can support a data rate of 200 Kbps, where counterfeiting data are always accompanying to protect the real data. These findings demonstrate the feasibility of dual-band PDs for variety applications in the future optical communication networks.

5:00 PM EL04.09.15
Anion-Vacancy-Defect Passivation of a 2D-Layered Tin-Based Perovskite Thin-Film Transistor with Sulfur Doping Jaehyeok Cho and Myung-Gil Kim; Sungkyunkwan University, Korea (the Republic of)

Metal halide perovskites have attracted a considerable amount of research attention with significant progress made in the field of optoelectronics. Despite their outstanding electrical characteristics, structural defects impede their potential performance due to the polycrystalline nature of solution-processed perovskite films. Herein, the effective *p*-type doping and defect passivation of phenethylammonium tin iodide ($(PEA)_2SnI_4$) perovskite films using xanthate additives as a sulfur source is reported. Sulfur can be introduced to the iodine vacancies mainly at the grain boundaries of the perovskite film, passivating the electrical defects originating from the iodine vacancy and increasing the hole concentration. The Fermi-level shift toward the valence band maximum of the sulfur-doped perovskite film is confirmed using ultraviolet photoemission spectroscopy, resulting in *p*-type doping. Finally, the electrical performance improvement for the 0.2% sulfur-doped $(PEA)_2SnI_4$ thin-film transistor with a mobility of 1.45 cm^2 V^{-1} s^{-1}, an on/off ratio of 2.9×10^5 is demonstrated, and hysteresis of 10 V is reduced.

5:00 PM EL04.09.16
Optoelectronic Properties of Magnetic Halide Perovskites with Green's Function-Based Many-Body Perturbation Theory Linn Leppert and Kostas Fykouras; University of Twente, Netherlands

In the past years metal-halide perovskites with the structural formula ABX3 have emerged as promising candidates for applications ranging from photovoltaics to lighting and detectors. In these materials, the A site is a monovalent cation such as Cs+ or CH3NH3 +, the B site a divalent metal such as Pb2+ and the X site is a halide such as I−, Br−, or Cl−. Despite their facile fabrication and attractive and highly tunable optoelectonic properties, the commercialisation of these materials has been limited by the inherent toxicity associated with Pb and the fact that they are prone to degradation when exposed to a humid environment. Pb-free double perovksites with formula A2BB'X6 allow for alternating metal B sites, thereby introducing tremendous chemical and electronic diversity and the potential for new applications [1-3]. Recently, a new class of halide double perovskites featuring 3d transition metals such as Fe3+ has been reported [4]. Cs2AgFeCl6, in particular, exhibits excellent optical absorption properties with an optical band gap of around 1.6 eV [5]. However, little is known about the band structure and the excitonic properties of this material and how they are affected by the magnetic ordering of the alternating Fe sites.

Here, we use first-principles density functional theory (DFT) and Green's function-based many-body perturbation theory in the GW and Bethe-Salpeter Equation approach, to study these properties in Cs2AgFeX6 (X= Br−, Cl−) and alloys in which Fe3+ is partially replaced by Bi3+. Our results demonstrate that the band structure of these new materials considerably differs from that of previously known halide double perovskites, featuring flat conduction bands derived from Fe 3d orbitals. We show that not only the band gap energy but also the relative ordering of the lowest-energy conduction bands sensitively depends on the approximations used in the DFT and GW calculations and on the magnetic ordering of the Fe sites. Finally, we present preliminary results for the excitonic properties of this class of materials.

How do Halide Perovskite Dynamics Explain Lack of Defects, Sustainability and Stability? Sigalit Aharon[1] and David Cahen[2,1]; [1]Weizmann Institute of Science, Israel; [2]Bar-Ilan University, Israel

Different types of experiments have yielded results that are consistent with low to ultra-low densities of structural imperfections (that are opto-electronically active) in Pb-halide perovskite, HaP, single crystals, or polycrystalline films, prepared at or near STP from organic solvents. The leading argument for these low defect densities is that the materials are Defect Tolerant. We showed, by *simple logic*, that DT cannot be the sole cause and, if present, must include an active mechanism to repair damage[2]. Such process, Self-Healing, SH, was invoked earlier (with a different mechanism) to explain $CuInSe_2$ (àCIGS) stability[1].
For single crystals of 3D HaPs experimental evidence has been presented for SH, using PL as reporter for photodamage. SH, in inanimate matter, is explained by equilibrium thermodynamics.[3] Recovery from photodamage in 2D and 2D-3D HaP single crystals, was found, too,[4] showing the wider SH applicability.
We will report on healing on and in polycrystalline thin films of primarily Pb-iodide perovskites, which are encapsulated to prevent reaction with, and escape of degradation products into the ambient.
SH, which explains the low defect densities, is, on an atomic scale, likely connected to the lattice ***dynamics*** of the HaPs. As such the SH mechanism in HaPs appears to differ from the mechanism of repair and healing in other inorganics, esp. CIS/CIGS, or in organics.[1,5]
Still, films can also show higher (~ 10^{16} cm^{-3}) carrier densities, which we then relate to doping densities, and we will address how surface defects (@ ~ 10^{11}-10^{12} cm^{-2}) readily explain such densities. That, then begs the question of how, for other films, surface defects can be (much) lower, a crucial topic that we will discuss.
To follow the arguments and models for HaP defect, doping, and carrier densities, it is important to distinguish between static defects, of the textbook kind, familiar to, and used by us commonly for semiconductors, and ***dynamic*** ones, which might well dominate in high-quality crystals and films.[6]

"Imperfectly perfect" Semiconductors—Static Disorder in Lead Halide Perovskites Ardalan Armin; Swansea University, United Kingdom

Perovskites are often characterised by small Urbach energies on the order of 12-14 meV. Whether this relatively small Urbach energy originates from small structural disorder or low dynamic disorder is not clear. In my talk I will discuss the static disorder in different perovskite compositions. I will show that Einstein solid model, based upon single mode harmonic oscillator, cannot describe temperature dependence of the Urbach energies of perovskites. This points towards existence of anharmonicities in perovskite lattice. Einstein's model is then modified and employed to evaluate static and dynamic disorder in single, double and triple cation perovskites. I will provide compelling evidence that static disorder in perovskites is predominantly caused by zero-point motion of phonons rather than structural imperfections. This makes us believe that such perovskites are "imperfectly perfect" which means, even though films are often poly-crystalline, each crystallite is nearly structurally perfect with its static disorder being only limited by the quantum zero point fluctuations in the lattice. This is also in accordance with multiple reports on self-healing characteristics of these material.

Zero-point-motion-limited static disorder is unusual for solution processed semiconductors but broadens the potential application of perovskites further to quantum electronics and devices operating at low temperature.

Scattering toward Local Order in Hybrid Metal Halide Perovskites Dylan Ladd[1], Nicholas J. Weadock[1], Jared Fletcher[2], Mercouri G. Kanatzidis[2] and Michael Toney[1]; [1]University of Colorado Boulder, United States; [2]Northwestern University, United States

Research activity in hybrid metal halide perovskites for photvoltaics materials has brought a surge of interest in their "2D" layered and colloidal nanocrystal analogues. Countless organic molecules may serve to separate slabs of metal halide octahedra or terminate nanocrystal surfaces, and their chemical structure has significant impact on orientation and distortion of the corner sharing lead halide octahedra. The design freedom here has produced MHP systems with emergent properties of interest for spintronics, lasing, and beyond.[1,2] To date however, lattice dynamics of the inorganic constituents, structural constraints imposed by ammonium cations, and correlations between the two have not been well established. To achieve a better understanding of MHP systems overall, characterization methods that probe the structural local order are required.

Recent advances in X-ray beam probes now enable study of the local order to reveal static and dynamic lattice distortions, defects, and critical information otherwise hidden under the average crystal structure assigned by conventional crystallography. Preceding studies of local order by our group have established the presence of a dynamic lower symmetry phase in the globally higher symmetry cubic structure of the bulk 3D MHP and raise the question whether similar dynamics are driving optoelectronic properties in other MHP systems.[3] Here we present a study of the local order in hybrid MHP using synchrotron X-ray diffuse scattering which reveals significant deviation from a perfectly periodic crystal structure. Analysis of oriented three-dimensional reciprocal space from scattering of single crystals provides spatial understanding of dimensionally correlated disorder in the inorganic sublattice. Ready comparison across systems highlights the dependence of octahedral distortions on cation species. The unique local order revealed in MHP provides unique structural information to toward explaining emergent properties otherwise ill-explained by the crystallographic space group. Establishing structure-property relationships in this material class helps enable the intentional design of new MHP systems for application in topological materials, ferroelectrics, phase-change memory, and engineered heterostructures for improved environmental stability of photovoltaics.

Controlling Halide Segregation in Mixed-Halide Perovskites Asaph Widmer-Cooper; The University of Sydney, Australia

Metal halide perovskites (MHPs) are a promising class of materials for optoelectronic and other applications that are energy efficient, printable, low-cost and solution processable. A key requirement for many MHP applications, including tandem solar cells, LEDs, photodetectors and lasers, is the ability to tune the material bandgap by varying the halide composition, i.e. the ratio of I^-, Br^- and Cl^-. This can be well controlled at the manufacturing stage by changing the relative amounts of halide precursors in solution. However, in practice, the performance of devices made using mixed-halide perovskites has been limited by poor material stability as the halides phase segregate upon light exposure. This leads to localized changes in the material bandgap which in turn affect the optoelectronic properties. This effect is known as photoinduced halide-ion segregation (PHS). Understanding its origin and how to reverse it, is therefore vital to develop stable MHP devices and to promote their adoption into the market.

In this work [1] we present a method by which PHS can be reversed *in situ,* effectively controlling the amount of homogeneous (mixed) and inhomogeneous (phase-segregated) halide domains. This is achieved using light alone and demonstrated experimentally. To understand the fundamental process underlying the observed photoinduced remixing, we developed a lattice model based on the Ising spin theory and on the hypothesis of polaron mediated segregation. In the model, halide ions are represented as nodes on a 2D lattice that can exchange position with neighboring ions. The exchange depends on the interaction felt with neighbors and with polarons. Simulations of photoinduced halide migration within single crystals have been performed using a Monte Carlo (MC) algorithm which, akin to Kinetic MC, allows the simulation to resemble the time evolution of an actual phase space trajectory as the system approaches equilibrium. These simulations show excellent agreement with the experimental results.

Our results add to the ongoing debate about what mechanism is ultimately responsible for PHS and proposes a solution to the problem of PHS of MHPs, with potential new applications for mixed halide perovskites.

Photo De-Mixing and Ion Transport in Two-Dimensional Dion-Jacobson Mixed Halide Perovskites Ya-Ru Wang[1], Marko Mladenović[2], Ursula Roethlisberger[2], Jovana V. Milic[3], Davide Moia[1], Michael Grätzel[2] and Joachim Maier[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]EPFL, Switzerland; [3]University of Fribourg, Switzerland

Using mixtures of iodide and bromide in 2D halide perovskites has proved to be a powerful tool for tunable optoelectronic material design. However such mixtures suffer from photo-induced phase segregation when exposed to light(photo de-mixing), similarly to their 3D counterparts[1]. While the process is reversible (two phases remix back in the dark to the pristine state, dark re-mixing),[2] this phase instability can potentially lead to unstable optoelectronic properties and device performance, making its understanding essential to progress the field of halide perovskites. Since the observed light-induced evolution of different phases involves significant ion transport, clarifying the underlying defect chemical mechanisms involved in photo de-mixing is critical.
Here, we study thin films of 2D Dion-Jacobson mixed halide perovskites (PDMA)Pb(Br0$_{.5}$I$_{0.5}$)$_4$ (PDMA: 1,4-phenylenedimethanammonium spacer) as model material to investigate their phase behavior both under light and in the dark using a wide range of experimental techniques. First, we are able to track the compositional evolution in the films during de-mixing and re-mixing by analyzing their time-dependent in-situ optical absorption properties. We simultaneously monitor the electrical conductivity of the sample, which provides a probe of defect concentration in and ion transport through the de-mixed phases. We furthermore take advantage of SEM and TEM to investigate the morphological changes and the nature of the iodide-rich and bromide-rich phases resulting from phase segregation. Lastly, we propose a model that considers possible opto-ionic effects, which can contribute to the driving force of de-mixing[3] and should therefore be considered in the overall energy balance of the process, together with the electronic effects discussed in the literature.[4]

Halide Perovskites Application Toolkit Tze Chien Sum; Nanyang Technological University, Singapore

Halide perovskites have firmly established themselves as the forerunners in next generation photovoltaics and light-emitting devices. Underpinning this spectacular rise are their exceptional properties such as large absorption cross-sections, defect tolerance, large spin-orbit coupling, long balanced charge diffusion lengths, slow hot carrier cooling, ion migration, radiation tolerance etc. Hence, there has been a rapid proliferation of their applications beyond conventional optoelectronics to fields such as spintronics, radiation detectors, memristors, bioimaging *etc*. Cutting across the boundaries of these emerging perovskite applications, artificial intelligence (AI) and machine learning are key enablers advancing the state-of-the-art in perovskite materials discovery optimized for each niche area. In this talk, I will examine some of our studies in these unconventional applications ranging from advanced photovoltaics concepts of hot carriers (Li et al., 2017) and multiple exciton generation (Li et al., 2018); high order multi-photon spectroscopy(Chen et al., 2017); spintronics (Giovanni et al., 2019); strain engineering and structural dynamics(Fu et al., 2022); as well as our latest foray into perovskite materials design and discovery leveraging fresh Mathematical AI methods based on topology and geometry (Anand et al., 2022).

Manipulating the Cooling Bottleneck Through Quantum Confinement in Halide Perovskite Nanocrystals Jia Wei Melvin Lim, Yuanyuan Guo, Minjun Feng and Tze Chien Sum; Nanyang Technological University, Singapore

Halide perovskites have recently been cast into the limelight for their potential in next-generation photovoltaic concepts such as hot carrier solar cells (HCSCs) [1]. The strong phonon bottleneck and high carrier temperatures in these materials make them excellent candidates for HCSCs. One way to further enhance these properties is through quantum confinement in halide perovskite nanocrystals or quantum dots, where an intrinsic cooling bottleneck can be induced due to the discretization of energy levels [2]. However, reports on the size dependence of the intrinsic cooling bottleneck in halide perovskite nanocrystals are still divergent. With advancements in methods to synthesize strongly confined perovskite nanocrystals recently, it is worthwhile to re-examine this effect [3]. In this talk, we attempt to rationalize these divergent observations. The size, shape, and composition effects on the cooling bottleneck will be discussed. Through independent ultrafast spectroscopy measurements, we show that the nature of the cooling bottleneck in halide perovskite nanocrystals can be tuned. Ultimately, we wish to provide a broad overview of the quantum confinement effects on this cooling bottleneck to resolve the existing controversy.

Utilizing Transient Absorption Spesctroscopy to Characterize the Anionic Composition of Perovskite Films Rebecca Scheidt, Matthew C. Beard, Kai Zhu and Qi Jiang; National Renewable Energy Laboratory, United States

Tandem solar cells require the development of efficient and stable wide band gap perovskites to be used at the top absorbing layer. This necessitates the need for mixed halide (i.e. mixed bromide and iodide perovskites) in order to obtain the optimum band gap needed for tandem applications. However, mixed halide perovskites often suffer from phase segregation under operating conditions. In order to combat this issue, we have recently developed a technique to create stable wide band gap perovskites with a variable band gap that contains both bromide and iodide. This variable band gap perovskite has an anion composition that shifts from low iodide concentration at the surface to high iodide concentration deeper into the film.

The variable band gap perovskites we have developed have a complex anionic composition that cannot be characterized using traditional methods, such as TOF-SIMS, due to the short length scales the halide gradient develops on. Using transient absorption optical spectroscopy, we have developed a model that allows us to fit transient absorption spectra taken at varying pump excitation energies to elucidate the physical composition of the perovskite. We are able to characterize the films and ascertain the composition of the films at different depths, more precisely than other characterization techniques are able to at the length scales of interest. With this model, we are also able to understand the movement of photogenerated charge carriers throughout the film as well as the implications this movement on operational solar cells.

1:30 PM *EL04.12.01

Study of the Formation Mechanism of 2D/3D Hybrid Halide Perovskite Heterostructures Using Phenylethylammonium Amino-Aroups
Emmanuelle Deleporte; ENS Paris-Saclay, France

Halide perovskites have proven recently to be excellent materials for optoelectronics, showing relevant properties both in the photovoltaic and light emitting devices context. In particular, perovskite-based solar cells, using three-dimensional (3D) perovskites, have reached power conversion efficiencies (PCE) up to 25.7%, close to silicon technology. However, it is still limited for commercialization by the instability of the 3D perovskites when exposed to light, temperature, oxygen, and moisture. Thanks to properties like surface passivation, reduction of nonradiative recombination, or inhibition of ionic migration, remarkable achievements have been made on PCE and stability by realizing 2D/3D heterostructures, using new cations and innovative architectures. Nevertheless, the understanding of the phenomena driving the formation of the 2D/3D interface remains to be deepened as it is a crucial challenge for the optimization of devices. In order to study the formation mechanisms occuring at the interface between the 2D and 3D perovskites, we focus here on phenylethylammonium (PEA) based amino-groups, commonly used for synthesizing 2D-3D perovskites film with optimum optical properties for solar cells and light-emitting devices.

We first report on the synthesis of a 2D/3D perovskite heterostructure by depositing a solution containing the para-fluorophenylethylammonium iodide (4FPEAI) cation salt on a triple cation 3D perovskite layer, commonly used in efficient solar cells. This leads to the formation of a thin layer of 2D perovskite crystallized on top of the 3D bulk perovskite layer. In order to optimize the 2D layer, we tested different synthesis parameters, such as the concentration of 2D cation solution, the time soaking between the 2D cation solution and the 3D perovskite, and the lead iodide content of the 3D perovskite. We studied more particularly the formation mechanism of the 2D perovskite and the chemical and physical phenomena occurring at this interface, by performing a large panel of characterizations, ranging from the analysis of extreme surface (XPS) and morphology (SEM) to the optical and structural characterization (PL, XRD). We find that the 3D perovskite composition affects the stoichiometry of the 2D layer formed on top. We thus conclude that the 2D layer formation results from at least two concomitant mechanisms: the reaction of the PEA-based organic spacer with the excess PbI_2 from the 3D layer as commonly observed and a cation exchange reaction between the 3D phase and 4-FPEAI [1]. The presence of this second mechanism is confirmed by forming a 2D perovskite phase even after removing the PbI_2 excess from the 3D perovskite stoichiometry. We revealed that these mechanisms occur concurrently to form the 2D layer until all the 4-FPEAI cation is consumed, making it the limiting reactant of the process.

We then report the use of PEA in the synthesis of CsPbBr3 nanocrystals (NCs) to reach a very high monodispersity without the need for several centrifugation steps [2]. In this method, some polydisperse CsPbBr3 NCs are first synthesized with usual protocols. Then, their size and size distribution are reduced with the help of PEA acting as a pair of scissors cutting the preformed NCs. From optical and TEM characterizations, we propose a mechanism involving a cation exchange reaction between the 3D perovskite cation of the preformed NCs and the PEA , leading to a structural modification of 3D perovskite in a 2D perovskite structure. This step is then followed by a reorganization of the remaining CsPbBr3 NCs in presence of the reactants present in the solution.

Solution Patterning Approach for Two-Dimensional Perovskite Nanocrystal Arrays Yoonho Lee, Jee Yung Park, Peiran Niu, Hanjun Yang, Dewei Sun, Libai Huang, Jianguo Mei and Letian Dou; Purdue University, United States

Two-dimensional perovskite crystals have attracted intensive interest for its diverse optoelectronic characteristics owing to their superior semiconducting properties. However, most studies to date have been limited to one single crystal that are difficult to implement for integrated device arrays due to their incompatibility with selective growth or typical lithography processes. Here, we report facile one-step solution process for synthesizing 2D perovskite crystal arrays through the meniscus-guided coating on pre-patterned substrates. We further utilize this novel method for synthesis of lateral hetero-structured perovskite nanocrystal arrays. Six different 2D perovskite crystal arrays showing red, blue, and green colored emission including heterostructures have been successfully realized. Structural and optical characterizations demonstrate that the crystals display excellent crystalline quality and optical properties. Moreover, the method has been used to prepare high-performance 2D perovskite crystal photosensors. We believe that this strategy can be utilized as a guideline for the fundamental investigation of optical properties and development of high-performance optoelectronics of perovskite materials including photosensors and displays.

2:15 PM EL04.12.03
Non-blinking, Wide-bandgap Single Photon Sources with Simultaneously High Brightness and Single Photon Purity Enabled by Surface Rigidity Engineering of Strongly Confined Perovskite Quantum Dots Yitong Dong and Chenjia Mi; The University of Oklahoma, United States

Single photon sources are essential elements of photonic based devices for quantum computing and quantum information sciences that can operate at room temperature. Current single-photon emitters (SPEs) are limited to specific materials, such as color centers and epitaxial quantum dots (QDs) that have well-spaced energy levels, and isolated luminescence centers to regulate emission dynamics under random classical light excitations. As a result, current SPEs material lack tunability to their emission energies and operating conditions. To date, most single photon emitters are limited to small band gap materials. Developing a wide-bandgap material emitting blue single photons are therefore highly desired for applications like free-space and underwater quantum communications. Additionally, a bright blue SPE can act as quantum excitation sources to enable passive SPEs using conventional fluorescence materials that are incapable of regulating emission dynamics and otherwise good SPE materials.

Colloidal QDs have emerged as promising SPE materials due to their high luminescence efficiency at room temperature and facile and scalable synthesis. However, traditional wide-bandgap II-VI QDs are subjective to low fluorescence efficiencies even with epitaxially coated shells. Lead halide perovskites emerge as a promising alternative QD material due to their unique defect tolerance, which allows perovskite nanocrystals to exhibit a high luminescence quantum yield without shells. Despite limited success on red and green perovskite SPEs, blue perovskite SPEs have not been demonstrated because of the challenges in modifying the surface of blue perovskite QDs such as strongly confined $CsPbBr_3$ perovskite QDs (SCPQDs) with sizes ranging from 4 nm to 7 nm.

Perovskite QD surface ions are extremely dynamic. When making SPE samples, the colloidal QDs must be diluted, and dried onto the substrate. During these processes, the surface ligand will detach from the QD, leading to the loss of surface halide ions which is detrimental to the photoluminescence quantum yield. Additionally, the labile surface of SCPQDs has profound effects on their photophysical properties such as fluorescence intermittency (also referred as “blinking”). This phenomenon reduces the emission stability and efficiency of the light source, posing a significant barrier to the development of QD SPEs.

In our pioneering work we have developed a method to embed SCPQDs in an organic halide salt matrix to inhibit the surface ion loss. Using this method, we have revealed a new blinking mechanism with in SCPQDs that happens when exciton is self-trapped by the soft surface lattices albeit being well-passivated. By using various conjugated organic ligands in the salt matrix and adjust the conjugations and crystallinities of organic molecules, we can tune the surface rigidity of SCPQDs. We found that the blinking can be strongly suppressed when the surface rigidity is increased. Additionally, the emission spectral linewidth of single SCPQD narrows down to < 50 meV when the surface ions are anchored with matrix that has high crystallinity. By introducing inorganic halide slat in matrix such as sodium bromide, we can further fix the surface lattices of SCPQDs and obtain essentially non-blinking SCPQDs. The new QD-in-matrix SPE material have enhanced photo-stability. Taking advantage of the unique ultrafast bi-exciton annihilation process in SCPQDs, high single photon purities (> 95%) can be achieved under high excitation rates that can usually compromise single photon purity in normal QDs. Our work will accelerate the adoption of photonic based quantum communication devices, and accommodate the application of SPEs that require tunable emission properties.

3:00 PM *EL04.13.01
Halide Perovskites Beyond Methylammonium Lead Iodide for More Than Optoelectronics Mikaël Kepenekian[1], B, Cucco[1], G. Volonakis[1], Claudine Katan[1] and Jacky Even[2]; [1]Univ Rennes, ENSCR, CNRS, ISCR-UMR 6226, France; [2]Univ Rennes, INSA Rennes, CNRS, Institut FOTON − UMR 6082, France

If 3-dimensional (3D) halide perovskites AMX_3 (A: organic cation, M: metal ion, X: halide) have shown spectacular results in optoelectronic devices, they offer limited choice of metals and organic cations. This is not the case of the other shapes that impose far less constraints over the chemical design of the organic spacer, such as layered (2D) halide perovskites A_2MX_4 [1]. In addition to strictly 2D and 3D materials, there is a wealth of compounds with features of both dimensionality and intriguing properties. Among those, one can find the ‘deficient’ or ‘hollow’ perovskites [2], but also perovskitoids consisting of not-only corner-shared octahedra [3] down to 1D materials. Another direction recently explored aims at moving away from toxic lead using double perovskites structures [4] or even by making a side-step towards cousin structures of perovskites where $[MX_6]$ octahedra are no longer corner-shared [5]. These compounds often present attractive properties beyond optoelectronic and are used for electronic component, spinorbitronic or photocatalytic devices [6].

However, once the 3D structural lock is lifted, the number of suitable candidates for A becomes so large that guidelines would be desirable for the design of future devices. Here, based on computational investigations conducted on experimental and model systems, we propose to contribute to the writing of those rules. In this contribution, we will navigate this wide range of materials and highlight how modelling and computational investigations, in close contact with experimental approaches, can help rationalize the electronic, optical, magnetic and ionic transport properties of compounds but also lay done rules for the design of new materials for targeted applications [7].

Bright Circularly-Polarized Photoluminescence in 2D Chiral Lead-Halide Perovskites Shangpu Liu[1], Mikaël Kepenekian[2], Stanislav Bodnar[1], Sascha Feldmann[3], Markus W. Heindl[1], Natalie Fehn[4], Jonathan Zerhoch[1], Andrii Shcherbakov[1], Aras Kartouzian[4], Ian D. Sharp[5], Claudine Katan[2], Jacky Even[2] and Felix Deschler[1]; [1]Physikalisch-Chemisches Institut, Germany; [2]Univ Rennes, United States; [3]Rowland Institute, United States; [4]Catalysis Research Center and Chemistry Department, Germany; [5]Walter Schottky Institut, Germany

Chiral 2D hybrid halide perovskites, which combine the advantages of chirality and exceptional optoelectronic properties, are promising materials for chiroptical and opto-spintronics applications. However, hybrid perovskites with strong chirality from highly distorted crystal structures have shown low luminescence efficiencies so far. Here, we report chiral 2D $(R/S/Rac)\text{-}3BrMBA_2PbI_4$ perovskite single crystals and thin films with external photoluminescence quantum efficiency as high as 39% and circularly polarized photoluminescence up to 52%, at room temperature. We use single-crystal x-ray diffraction and density-functional theory to elucidate the chirality transfer from chiral crystal structures to spin orbit split band structures. Using time-resolved chiroptical spectroscopy, we find very fast radiative recombination rates, which outcompete loss channels and rationalize the excellent photoluminescence yields. We further find polarized excitons with depolarization times exceeding the radiative decay times, which underpin the highly polarized luminescence. We assign the superior optoelectronic properties of our layered hybrid perovskites to their unique crystal structures controlled by cation engineering. Our report paves the way for high-performance hybrid perovskite photonic devices for chiroptical and spin-orbit logic applications.

3:45 PM EL04.13.03
Chiral Halide Perovskite Based Spintronic Devices Matthew Hautzinger, Ian Leahy, Kirstin Alberi and Matthew C. Beard; National Renewable Energy Laboratory, United States

The chirality induced spin selectivity (CISS) effect is the ability of chiral molecules or chiral structural motifs to control electron spin orientation and propagation.[1] As a result, materials exhibiting the CISS effect can behave as an effective spin filter or spin polarizer in solid state devices producing spin polarized current. Recently, the CISS effect has been demonstrated in low dimensional hybrid organic-inorganic halide perovskite semiconductors with a chiral organo-ammonium cation being incorporated into the structure.[2] These “chiral halide perovskites” have been shown to exhibit circular dichroism, emit circularly polarized (CP) luminescence, and detect CP light.[3] The work we present here demonstrates the incorporation of chiral halide perovskites into electronic devices relying on spin polarized current. Specifically, we have integrated the chiral perovskites into new light emitting diode (LED) architectures, where the chiral perovskite serves as an effective spin filter, allowing only polarized current to be injected into the emissive layer. As a result, the LED emits circularly polarized light that is right or left-handed based on the chirality of the organic motifs. Complementary experimental results demonstrating the spin polarizing behavior of the chiral halide perovskites in pseudo spin-valve devices will also be presented. These results are significant steps forward towards understanding the CISS effect as well as incorporating chiral materials into spintronic devices.

Surface Modification Strategies for Chiral Perovskite Nanostructures Markus W. Heindl[1], Tim Kodalle[2], Natalie Fehn[3], Lennart Reb[3], Shangpu Liu[1], Constantin Harder[3,4], Maged Abdelsamie[2], Lissa Eyre[5], Stephan V. Roth[6,4], Alexander S. Urban[7], Peter Muller-Buschbaum[3,3], Ian D. Sharp[3], Aras Kartouzian[3], Carolin M. Sutter-Fella[2] and Felix Deschler[1]; [1]Universität Heidelberg, Germany; [2]Lawrence Berkeley National Laboratory, United States; [3]Technische Universität München, Germany; [4]Deutsches Elektronen-Synchrotron (DESY), Germany; [5]University of Cambridge, Germany; [6]KTH Royal Institute of Technology, Sweden; [7]Ludwig-Maximilians-Universität München, Germany

The generation, manipulation and detection of light is a key requirement for a wide range of technologies reaching from consumer electronics to communication via fiber optic cable and state-of-the-art sensors. Recent discoveries on the design of chiral metal-organic perovskites now promise cheap, sustainable materials for energy efficient generation and detection of polarized light.[1-3] However, the available choices of chiral perovskite materials are so far limited to a range of one- and two-dimensional crystal structures that allow for the incorporation of chiral organic molecules. Colloidal perovskite nanocrystals or -sheets do present an appealing alternative and have been shown to display desirable chiroptical properties when modified with chiral ligands.[4-5] However, since these nanomaterials are more intricate to synthesize and process, research on perovskite nanostructure semiconductors with surface-induced chirality has been limited.

Here, we present novel strategies to produce perovskite thin films with chiral surface modification directly, without having to obtain colloidal nanocrystals first. For this we utilize the chiral small organic 3-aminobutyric acid for the modification of DMAPbI3 using a simple spin-coating-based approach. We find that the resulting compound displays strong circular dichroism effects in the blue spectral region, which can be adjusted in their intensity by varying synthetic parameters. Furthermore, we perform an extensive structural investigation into the origin of these phenomena utilizing XRD and GIWAX experiment. We also study the effects of synthetic parameters on material performance using in-situ optical spectroscopy methods, monitoring the film formation throughout the spin coating process.

Our findings provide a novel approach to introducing chiral properties into hybrid perovskite materials. Additionally, they give insights into the structural origins of effects relating to chiroptical properties and provide synthetic strategies for their maximization. Our surface-based modification can be transferred to other, lead-free metal-halide materials that do not typically allow for the integration of organic molecules into their crystal structure.

EL04-virtual

8:00 AM *EL04.14.01
Phenomena at Surfaces and Interfaces of Halide Perovskites Liang Z. Tan; Lawrence Berkeley National Laboratory, United States

Understanding surface and interface phenomena has been a long-standing area of research in materials science. In the halide perovskite materials, the combination of large spin-orbit interactions and unusual structural dynamics pose new questions in this area. In this talk, we present a first-principles theoretical study of electronic, structural, and magnetic behavior of their low-dimensional interfaces. We show that these systems host electronic layer edge states stabilized by internal fields, and support several edge phonon modes which suppress dynamic disorder at the surface. We examine the role of molecular ligands in eliminating surface trap states to enhance photoluminescence. Finally, we consider anisotropic excitonic behavior at grain boundaries, and its impact on the magneto-optical properties of these materials. These results point to surfaces and interfaces of the halide perovskites as being able to robustly support rich phenomena with applications in optoelectronics, spintronics, and beyond.

8:30 AM EL04.14.02
Anion Exchange via BMIM-PF$_6$ in the Solid Lattice of MAPbCl$_3$ Single Crystal Materials at Room Temperature—New Insights into the Mixed Halide Perovskites Behnaz Akbari; Boston University, United States

Due to high optical absorption and long carrier-diffusion lengths, lead halide perovskites (LHPs) or organo-lead halide perovskites [MAPbX$_3$ (MA = CH $_3$ NH$^+_3$, X = Cl$^-$, Br$^-$, or I$^-$)] have opened new avenues into the scientific spotlight, showing fascinating optoelectronic properties as well as developing efficient optical devices.
Since ionic liquids, as a novel class of compounds, have high ionic conductivity, a low melting point below 100 °C, high polarity, low vapor pressure, non-flammability, good thermal stability, wide electrochemical window and non-volatility, potential applications toward electrochemistry, molecular biology, materials science, engineering, Physics, and healthcare (particularly in drug delivery) have been introduced. The ionic crystal structure of the perovskite materials enables us to tune the band gap and optical absorption, which are intentionally performed by altering the ions while their original lattice structure is maintained.
To study morphology and halide transport inside a solid lattice of MAPbCl$_3$ single crystal, first, Methylammonium Lead Chloride (CH$_3$NH$_3$PbCl$_3$ or MAPbCl$_3$) single crystal was fabricated via oversaturated MAPbCl$_3$ precursor solutions as a new and doable methodology. After two months, small growing sizable and transparent crystals were observed at room temperature and then subjected to surface analysis for topographic analysis, elemental composition, and halide diffusion through a scanning electron microscope equipped with Energy-dispersive X-ray Spectroscopy (SEM-EDX) and a home-built microscope equipped with a Zelux camera and a field of view of AC254-150-AB.
Room-temperature processing simplifies the fabrication procedure, makes these hybrid organic-inorganic materials closer to commercial devices, and gives important advantages over current vapor-phase deposition designs for perovskite materials. With that in mind, attempts were made to introduce an optimized, simple, fast, and economical procedure for the dissolution of Methylammonium iodide (MAI) in 1-butyl-3-methylimidazolium hexafluorophosphate (BMIM-PF$_6$) as a halide ion source with a density of 1.38 gr/ml i) to monitor halide diffusion and ii) to form a gradient of mixed halides (MAPbCl$_{3-x}$(F/I)$_x$, $0 \leq x \leq 3$) at room temperature. After sonication at 50°C within 30 minutes, a bright yellow transparent solution was produced, and the MAI-BMIM-PF$_6$ was dissolved entirely. Before SEM-EDX analysis, a droplet of MAI-BMIM-PF$_6$ solution was placed on the MAPbCl$_3$ single crystalline samples. It was concluded that the ion exchange is controllable in supersaturated MAPbCl$_3$ perovskite materials. The outcome can be ascribed to discovering new approaches toward modulations in the composition of anions and cations inside the MAPbCl$_3$ single crystal materials under room temperature deposition and providing novel insight into the chloride-based perovskite materials in the fabrication of optoelectronic devices using BMIM-PF$_6$ ionic solution.

8:45 AM EL04.14.03
Light-induced Phase Segregation in Surface and Bulk of All-inorganic Mixed Halide Perovskites Nuerbiya Aihemaiti, Yifan Jiang, Yizhou Zhu and Siying Peng; Westlake University, China

Halide perovskites attract great attention because of easy synthesis, high visible light absorption, high quantum efficiency, etc. Mixed halide perovskites possess tunable bandgaps by modulating the ratio of halogen compositions. They have been widely used as active materials for photovoltaics, light-emitting diodes (LEDs), lasers, and photodetectors. Despite their extraordinary properties, instability under light (e.g. phase segregation) is one of the bottlenecks for their further commercialization. Under illumination, mixed halide perovskites phase segregate into iodide-rich (I-rich) phase and bromide-rich (Br-rich) phase by defect-assisted I and Br exchanges. The mechanism behind light-induced phase segregation in mixed halide perovskites is still to be studied.
We used the chemical vapor deposition (CVD) method to prepare single-crystal-like CsPbBr$_{2.1}$I$_{0.9}$ microplates. Combining time-dependent photoluminescence (PL), in-situ environmental PL with time-resolved photoluminescence (TRPL) and X-ray photoelectron spectroscopy (XPS), we investigated the influence of power density (e.g. carrier concentration), surface defects on phase segregation in this model material system.
The fast appearance of pure I phase followed by I depletion was observed under the illumination of a 500 nm laser beam at a power density of 2000 W/cm^2 by time-dependent PL, while a gradual I accumulation was observed under a focused beam laser at 3000 W/cm^2. Power density-dependent phase segregation evolutions indicate the influence of carrier concentrations. In-situ environmental PL results also show the appearance of pure I phase followed by I depletion under the influence of dry air (N$_2$ + O$_2$). Based on TRPL before and after illumination in air, carrier populations and carrier lifetime

increased due to oxygen-surface interactions. XPS characterizations after illumination show that illumination with oxygen decreased Pb^0 and I/Pb ratio. This indicates the possible decrease of deep-level defects I_i and Pb_I.
Our experimental results elucidate the effect of surface defects and carrier concentration on phase segregation evolution in crystalline mixed halide perovskites microplates. XPS results support that oxygen passivation of the surface is caused by superoxide filling and oxidation of Pb^0. Surface passivation increases carrier concentration (supported by TRPL) and further changes the evolution of phase segregation. Detailed microscopic phase segregation evolutions will be discussed based on experimental results.

9:00 AM EL04.14.04
Stability Of Mixed Lead Halide Perovskite Films Encapsulated In Cyclic Olefin Copolymer (COC) Mutibah S. Alanazi; University of Oxford, United Kingdom

Mixed lead halide perovskites (MHPs) like $CsPbBrI_2$ are attracting significant interest as promising candidates for optoelectronic applications due to their relative stability and infrared band gap. An outstanding challenge is that over time they segregate into Iodide-rich and Bromide-rich phases under illumination, which degrades their optical properties and could compromise the operational reliability of devices. Such halide segregation can be attributed to strain, photo-induced ionic defects and charge carrier stabilization along grain boundaries. Here, we use micro-photoluminescence spectroscopy and time-resolved photoluminescence to investigate the light impact on charge carrier dynamics and properties of $CsPbBrI_2$ films at room and cryogenic temperatures. We also provide an effective strategy to mitigate the halide migration of Br/I ions in the $CsPbBrI_2$ films by modifying their crystalline grains with cyclic olefin copolymer (COC). Our observations reveal that COC-treated films exhibit a lower phase segregation rate under prolonged illumination compared to untreated films at room temperature due to the suppression of non-radiative recombination processes by increasing the grain sizes, improving the crystallinity, and reducing trap states. Our results also show that COC-treated $CsPbBrI_2$films at cryogenic temperature show higher photo-stability and can effectively suppress the halide demixing- remixing cycle that occurs in pure $CsPbBrI_2$ films. Therefore, COC treatment is more likely to increase the energy barriers for halide ion migration and limit drivers like lattice strain, trap states or polaron effects.

9:05 AM *EL04.14.05
Charge Self-Trapping in Halide Perovskites Julia Wiktor; Chalmers University of Technology, Sweden

Metal halide perovskites have attracted remarkable interest as promising materials for optoelectronic applications and beyond. One of the characteristics underpinning their performance is the nature of the photogenerated excess charges. Compounds from the family of halide perovskites are generally easily polarizable, which leads to strong charge-lattice interactions, and formation of polarons. I will first discuss the computational challenges in modeling polarons in complex materials on the example of halide perovskites. In particular, I will show how various effects, such as self-interaction, spin-orbit coupling and temperature affect the computed properties of the polaronic states. I will then describe different types of polaronic states that have been predicted computationally in different types of halide perovskites and how they affect the functioning of devices based on these materials.

SESSION EL05.01: Anisotropic Gold Nanoparticles
Session Chairs: Viktoriia Babicheva and Svetlana Neretina
Tuesday Morning, April 11, 2023
Moscone West, Level 2, Room 2000

10:30 AM *EL05.01.01
Gold Nanostars as Structural Valency Probes Teri W. Odom; Northwestern University, United States

Anisotropic gold nanoparticles exhibit shape-dependent optical properties beneficial for optical sensing, biomedical imaging, and photocatalysis. This talk will discuss the fundamentals and applications of gold nanostars that support positive, negative, and neutral curvature. We will describe the details of gold nanostar growth and mechanistic insight gained from unconventional analytical tools. We will also discuss their functionalization with biological ligands that can facilitate both nanoparticle assembly and single-particle imaging of live-cell interactions.

11:00 AM *EL05.01.02
Gold Nanostars – Ideal Plasmonic Substrates or Not? Amanda J. Haes; University of Iowa, United States

Gold nanostars exhibit size and shape tunable plasmonic properties. In this presentation, we explore how fine morphological variations influence (or not) their plasmonic properties. Implications of morphology are used simultaneously to tune the adsorption of small molecules in sensing applications using surface enhanced Raman scattering (SERS). Because molecules must interact with the metal at short distances, molecule-surface interactions are important for successful small molecule detection. Herein, the surface chemistry of Good's buffer-stabilized gold nanostars is evaluated using computational, microscopic, and spectroscopic methodologies. Evaluation of these materials in spectroscopic measurements is pursued for a variety of small molecules. Determination of when these materials yield reproducible results (or not) will be conveyed.

11:30 AM *EL05.01.03
Improving Sensing Efficiency through Controlled Synthesis Kaleigh Scher[1], Jinisha Chheda[1], Anita Nair[1], Supriya Atta[2] and Laura Fabris[3,1]; [1]Rutgers, The State University of New Jersey, United States; [2]Duke University, United States; [3]Politecnico di Torino, Italy

Anisotropic plasmonic nanoparticles can display exceptional field enhancement properties and tunable resonant modes that can be leveraged in several fields, from imaging to catalysis. Among these nanoparticles, gold nanostars have emerged as extremely promising, in particular as it concerns the creation of effective imaging tags, phototherapeutic agents, and hot electron-based photocatalysts. The intriguing properties of these nanostructures stem from their structure-property relationships, that can be fully exploited only through the rational control of their synthesis. In my talk, I will discuss our approach to the design and synthesis of nanostars focusing in particular on six-branch gold nanostars with high shape anisotropy. These particles combine the unique advantages of nanostructures fabricated from the top-down and those synthesized from the bottom-up, showcasing a unique plasmonic response that remains largely unaltered on going from the single particle to the ensemble. These nanostars display multiple, well-separated, narrow resonances, the most intense of which extends in space much farther than that observed before for any plasmonic mode localized around a colloidal nanostructure. Importantly, the unique close correlation between morphology and plasmonic response leads the resonant modes of these particles to be tunable between 600 and 2000 nm, a unique feature that could find relevance in cutting edge technological applications. Along with the fundamental properties of the bare nanostars, I will discuss the synthetic protocols we have developed to coat them with thin semiconductor shells, further extending their applicability in spectroscopy and catalysis, and the study of the fundamental molecule-metal interactions that lead to the realization of bright sensing tags for detection based on surface enhanced Raman scattering.

SESSION EL05.02: Plasmonic Sensing
Session Chairs: Viktoriia Babicheva and Svetlana Neretina
Tuesday Afternoon, April 11, 2023
Moscone West, Level 2, Room 2000

2:00 PM *EL05.02.02
Towards Real-Time Bacterial Detection in Wastewater with Tailored Plasmon-Pathogen Interactions Jennifer A. Dionne[1], Loza Tadesse[1,2], Liam Herndon[1] and Halleh Balch[1]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States

Elevated pathogen levels in wastewater are one of the first indicators of disease outbreaks, making wastewater a powerful tool for surveilling the infections present in a community. Wastewater-based epidemiology (WBE) has gained popularity for viral infections, particularly to monitor ongoing epidemics of COVID-19, monkeypox, and polio. WBE monitoring of bacterial pathogens is likely to become increasingly important, especially as antimicrobial bacteria become a threat to public health. However, bacterial WBE presents several outstanding challenges. Foremost, the nucleic acid-based methods currently used to identify pathogens in wastewater require amplification or sequencing, and are limited by the need for pathogen-specific probes; therefore, is challenging to scale WBE to the many dozens of bacterial species and strains that can be present in a community. Further, high false negative rates can result from substances in wastewater, such as nucleases that degrade nucleic acids, heavy metals that bind to nucleic acids, and sugars that inhibit the activity of enzymes involved in DNA amplification and sequencing.

Here, we describe a new method to rapidly and accurately detect and identify bacteria in wastewater without the need for targeted probes or nucleic acids by combining surface-enhanced Raman spectroscopy (SERS) of
pathogens with machine learning (ML). We: 1)maximize bacterial Raman signal in wastewater using plasmonic materials that selectively enhance the pathogen Raman spectra across a variety of pathogens; 2) create an ML algorithm that can discern between the most common bacterial species in wastewater; and 3) validate this identification system on real wastewater samples using an integrated microfluidic setup. Au nanorods with five distinct aspect ratios are synthesized using CTAB and NaOL as the surfactants. We also synthesize rods with polyethylenimine (PEI) and thiol polyethylene glycol (thiol-PEG) to vary the nanorod charge. Gram negative species such as *E.coli and S.marcescens, and* G positive species such as *S.epidermidis* and *S.aureus* are grown to log phase in Lysogeny broth (LB) culture medium and then spiked into wastewater with concentrations ranging from 10^5cells/mL-10^9 cells/ml. The nanorods are mixed into the wastewater, and liquid Raman spectra are collected in a miniaturized flow cell. By controlling the nanorod chemistry and concentration, we obtain uniform bacterial SERS enhancements of ~300X for all bacterial species, compared to the bacteria-only samples in both water and wastewater. We compare wastewater from various locations, each with their own unique compositions, pHs, and salinities, and show how machine learning based spectral data analysis enables high (>88%) classification accuracy of both species and antibiotic susceptibility for these bacteria. Our work allows high signal-to-noise bacterial SERS measurements from wastewater, providing a foundation for rapid and label-free bacterial WBE.

2:30 PM *EL05.02.03
Polymer-Enabled Plasmonic Sensing Christy L. Haynes; University of Minnesota, United States

There are a variety of small molecule toxins found in crops that present hazards in food production and consumption. This work exploits polymers as capture agents for various toxin targets such as mycotoxins. By attaching short, anchored polymer chains complexed with the target of interest to plasmonic substrates, surface-enhanced Raman spectroscopy (SERS) can be employed to detect the mycotoxins. SERS is an attractive analytical signal transduction mechanism due to its high enhancement factors and the ability to assign specific vibrational modes to certain molecules, even at very low concentrations. By providing fingerprint spectra for various targets, one can easily detect more than one target mycotoxin in relevant complex matrices. Pairing experimental SERS with computational modeling helps confirm hypotheses about binding and target/polymer interaction. Overall, this talk will demonstrate optimization of SERS sensing to achieve limits of detection comparable to current detection methods with a simpler and more flexible signal transduction mechanism, providing an opportunity for future applications in complex matrices where these toxins are traditionally found.

3:00 PM BREAK

3:30 PM *EL05.02.04
Metal-Adsorbate Interactions Modulate Molecular Reactivity in Plasmon-Driven Photocatalytic Reactions Hui Wang; University of South Carolina, United States

Molecular adsorbates on the surfaces of optically excited metallic nanostructures may undergo intriguing plasmon-mediated photocatalytic transformations that are mechanistically distinct from the catalytic reactions under thermal conditions. The energy distribution of the plasmonic hot carriers, the local electric field enhancements, and the plasmonic photothermal heating are all crucial factors that may profoundly influence the kinetic enhancement of the plasmon-driven photoreactions. While the photoexcitation and relaxation of localized plasmons involve ultrafast photophysical processes that occur on the timescales from fs to ns, the plasmon-driven photochemical reactions have been observed to be kinetically much slower, strongly suggesting that the rate-limiting kinetic bottle-neck of plasmon-driven photocatalysis is associated with the interfacial chemical transformations of molecular adsorbates rather than the plasmonic hot carrier or resonance energy transfer processes. Here we use plasmon-driven reductive coupling of nitrophenyl derivative adsorbates on Ag nanoparticle surfaces as a model reaction system to investigate how the chemical nature of the metal-adsorbate interactions influences the molecular reactivity and the reaction kinetics. We systematically compare the transforming behaviors of three nitrophenyl derivatives, including nitrothiophenol, nitrophenylisocyanide, nitrophenylacetylene, which chemisorb to the Ag surfaces using different functional groups. We use surface-enhanced Raman scattering as an in situ spectroscopic tool with unique time-resolving and molecular finger-printing capabilities to fine-resolve the mechanistic and kinetic features of the plasmon-driven coupling reactions. Fast reaction rates and high reaction yields are observed when the molecular adsorbates interact with Ag through σ-donation, whereas the reactions become significantly slower if the metal-adsorbate interactions are dominated by π-back donation. The experimental observations are further corroborated by density functional theory calculations.

4:00 PM *EL05.02.05
Correlating Carrier Density, Emergent Plasmonic Features and Light-Driven Catalytic Performance of $Cu_{2-x}Se$ Nanocrystals and Their Derivatives Jill Millstone; Univ of Pittsburgh, United States

Recently, a wide variety of non-noble metal materials have been identified as plasmonically active including earth-abundant species such as aluminum, highly doped semiconductors, and metal pnictides. For semiconductor compositions, plasmonic properties are tuned not only by traditional methods of particle size and shape, but also by carrier density. Here, we discuss the use of ^{77}Se solid state nuclear magnetic resonance spectroscopy to quantitatively determine charge carrier density in a variety of $Cu_{2-x}Se$-based nanoparticles and correlate this charge carrier density with both particle crystallinity and plasmonic figures of merit. With these correlations in hand, we then study the surface chemistry of the particles in detail using electron paramagnetic resonance spectroscopy, and are able to connect plasmonic behavior and surface chemistry to demonstrate plasmon driven chemical conversions.

4:30 PM *EL05.02.06
The Interface of Plasmonics and Catalysis Prashant K. Jain; University of Illinois Urbana-Champaign, United States

The interaction of light with molecules can be used to access new modes of chemical reactivity; however, this interaction is often difficult to exploit in a universal manner. I will describe how plasmonics is proving to be a general strategy for interfacing photons with molecules and activating chemical transformations. This strategy involves heterogeneous catalysts comprised of plasmonic nanoparticles. Plasmonic excitation of the catalyst generates electronically and vibrationally excited states, which modify chemical activity at the interface and even induce emergent activity. I will describe how catalysts based on plasmonic nanoparticles are allowing light to be used as a redox equivalent in chemical reactions, for driving non-equilibrium chemical processes, for modifying product selectivity, for photosynthesizing fuels, and for boosting electrochemical conversions. The ultimate vision is a future where plasmonic excitations can be used to power chemical transformations or direct them with bond-level precision.

SESSION EL05.03: Poster Session
Session Chairs: Viktoriia Babicheva and Svetlana Neretina
Tuesday Afternoon, April 11, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM EL05.03.01
Quantification of Dopamine Using Surface-Enhanced Raman Scattering (SERS) of Constrained Vibrational Mode Yongheum Choi[1], Chang Su Jeon[2], Kwang Bok Kim[1], Hyun-Jong Kim[1], Sung Hyun Park[2] and Young Min Park[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Speclipse, Korea (the Republic of)

Dopamine (DA) is known as a crucial neurotransmitter playing a significant role in the hormonal, nervous, and vascular systems. Abnormal DA levels is related to diverse neurological and psychiatric disorders, including Parkinson's disease (PD) and Alzheimer's disease (AD). Therefore, DA quantification in biological samples has drawn attention for the tracking, diagnosis, and therapeutics of DA-related diseases. To date, quantitative detection of DA has been developed using electrochemistry, chromatography, and fluorescence [1,2]. These approaches, however have still confronted great challenges due to low sensitivity and selectivity. Meanwhile, surface-enhanced Raman spectroscopy (SERS) has come into the limelight as an analytical tool over the past few decades due to its extraordinary advantages such as single molecular-level detection and finger-printing signals. Nonetheless, the low affinity of DA to metal surface attenuates DA selectivity and poses a challenge for SERS-based DA sensors [3]. Although aptamer, antibody, and molecular chelation bound noble metals have been employed in several studies to enhance DA selectivity, only few of them are validated with real biological samples [4]. Therefore, it is imperative to devise rapid and simple methods to detect DA with ultra-sensitivity and high-selectivity in complicated biofluids.
Herein, we introduce a SERS-based ultrasensitive DA quantitative sensor adopting Raman-peak shift resulting from the constrained vibration mode of 4-mercaptophenylboronic acid (4-MPBA). Ag nanostructure was fabricated on Si wafer with a simple one-step sputtering process using gas-flow sputtering to augment plasmon resonance. 4-MPBA is a biocompatible Raman reporter, capable of covalently bonding with DA and metal-thiol conjugation to Ag substrate. It is adopted as a linker to enhance the affinity between DA and Ag substrate and the Raman signal of DA. 4-MPBA was coated through vapor-phase deposition to curtail impurity and background noise in Raman spectra. We identified a shift in the position of representative SERS peak of 4-MPBA proportionally to DA concentration. Our experimental result, indicating the peak shift stemming from the combination between 4-MPBA and DA was well supported by numerical simulation based on density functional theory. To the best of our knowledge, although Raman-peak shift has been used in many sensor-based applications previously, it has never been reported for DA sensing with constrained Raman mode. Tracking the peak shift confers more stable

and reliable measurement than intensity-based quantification because it focuses more on the analytes themselves rather than the enhancement performances of individual SERS substrates that rely on chip-to-chip variation. We also applied human serum on the DA sensor to validate that it works out similar results in real biological samples. The proposed method based on SERS peak shift depicted the ability to quantitatively detect DA concentrations in biofluids exhibiting selectivity with respect to other biomarkers as well as high sensitivity up to picomolar level.

Detection of Gunshot Residue Analytes on a Portable Raman Spectrometer using Magnetic Nanoparticles Ellen Hondrogiannis[1], Mary Sajini Devadas[1], Megan Harper[1], Taylor Shafirovich[1], Dariush Aligholizadeh[1] and Lynn Krushinski[2]; [1]Towson University, United States; [2]Purdue University, United States

The signal detection limit (SDL), limit of detection (LOD), and limit of quantitation of a portable Raman spectrometer were measured for organic gunshot residue (GSR) components, diphenylamine (DPA) and ethyl centralite (EC), in 1:100 ODCB:hexanes. Diphenylamine yielded the lowest LOD at 998 wavenumbers (cm^{-1}) and EC at 1003 cm^{-1}. The addition of iron cobalt (FeCo) nanoparticles (NPs) to the DPA and EC solutions produced statistically signficant changes in DPA and EC band intensities and band areas. The DPA 1220 cm^{-1} and EC 1599 cm^{-1} bands produced the greatest percent change in band intensities overall (244.92 ± 10.65 % and 736.38 ± 38.59 % for DPA and EC, respectively upon the addition of 48.4 µg/mL FeCoNPs). When FeCoNPs were added to a mixture containing both EC and DPA all DPA band intenities increased with the DPA 1220 cm^{-1} showing the greatest percent change in band intensity (219.19 ± 21.00 %). The EC 711 cm^{-1} band showed 291.56 ± 12.59 % percent change in band intensity. The EC 1003 cm^{-1} band was not differentiated from the DPA 998 cm^{-1} band with a new band maximum at 1001 cm^{-1}, and this band increased by 35.59 ± 3.04 % upon the addition of FeCoNPs. Likewise, the EC 1599 cm^{-1} and DPA 1608 cm^{-1} bands were also not differentiated on this instrument and produced a band maximum at 1608 cm^{-1} that increased by 163.58 ± 7.21 % upon the additon of FeCoNPs. Solvent extraction was succesful at recovering 78.93 ± 5.04% of the FeCoNPs indicating the potential for reusing the NPs. This recovery of the magnetic FeCoNPs, coupled with ehancement of the DPA and EC signals when in solution with FeCoNPs on a portable Raman spectrometer, illustrate that these NPs are promising surfaces for future development leading to the rapid and inexpensive screening of GSR in the field for forensics analysis.

Controlled Crystalline Assembly of Nanocubes Yeonhee Lee, Seungsang Cha, Yuna Kwak and Jwa-Min Nam; Seoul National University, Korea (the Republic of)

The bottom-up approach of self-assembling nanoparticles is a promising strategy for fabricating desired nanostructures. However, current methods that utilize ligands and physical/chemical stimuli to control the forces between particles have certain limitations, such as limited material selection or the use of a fluidic template. Thus, novel approaches in nanoparticle assembly are necessary for future applications.
In this study, we explore the synthesis and assembly of gold nanocubes with a focus on achieving controlled morphology and crystalline structure. Representative cases of assembled structures are presented using gold nanocubes. These advancements could open new ways for further expansion, including optics, sensing, imaging, and catalysis.

5:00 PM EL05.03.04
Designing Plasmonic Janus Microgels for Direct Raman Detection of Small Molecules in Pristine Samples Jiwon Yoon and Shin-Hyun Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Raman spectroscopy enables molecular identification since each molecular species has different molecular vibrational modes. However, the probability of Raman scattering is low, limiting its pragmatic use as a detection method. When metal nanostructures or metal nanoparticles (NPs) are illuminated, a strong electric field is generated nearby the metal surface through surface plasmon resonance at the specific wavelength of the incident light. This leads to the enhanced Raman signal of target molecules in the vicinity of the metal surface, referred to as Surface Enhanced Raman Scattering (SERS). For target molecules to approach the metal surface, metal needs to be protected from contamination by adhesives such as protein. Therefore, pretreatment is required to remove adhesives from samples before SERS detection.
The way to obviate the pretreatment is a metal nanoparticle-embedded hydrogel microparticle. The hydrogel network serves as a protection layer for the infusion of target molecules and the exclusion of adhesives. However, preparing gold nanoparticles (AuNPs) and encapsulating AuNPs with a hydrogel network using microfluidics is time-consuming. In addition, signal uniformity is not achievable due to the aggregation of AuNPs. In that sense, micromolding is an alternative to microfluidics, which can remarkably shorten the time taken to produce plasmonic microgel. Moreover, a gold precursor is reduced to AuNPs in the presence of PEGDA providing the nucleation sites. Combining these two, microgels where AuNPs are uniformly embedded are quickly produced. This not only obviates the preparation of AuNPs but also provides the signal uniformity of the microgel.
Here, we design charge-selective plasmonic Janus microcylinders produced by the micromolding method. Microcylinders make up the charge-selective plasmonic microgel for SERS detection and the photonic crystal. By imparting the charge to the SERS microgel, SERS sensitivity is enhanced through the concentration of oppositely charged molecules. Since the charge of the microgel is not distinguishable from the naked eye, photonic color plays a role as an indicator of the charge of the plasmonic microgel. To fabricate Janus microcylinders, a solution containing gold precursor, water, PEGDA monomer, charged monomer, and photoinitiator is infiltrated into the cylindrical hole arrays of the PDMS mold. The residual solution is removed, followed by the evaporation of water and the curing of the solution by UV for 10 min. As a result, the SERS microgel whose height is half the cylindrical hole is produced. Subsequently, silica-ETPTA suspension is infiltrated into the remaining holes of the PDMS molds on a slide glass. Suspension is cured and plasmonic Janus microcylinders are collected through blading. To develop vivid structural color, Janus microcylinders are immersed in HF solution to etch out the silica NPs. As the SERS sensitivity of microcylinders varies with the concentration of the photoinitiator and gold precursor, concentrations are optimized by measuring the SERS spectra of R6G molecules. A higher concentration of charged monomer concentrates more oppositely charged molecules, but it may interrupt the formation of AuNPs due to the competition between charged monomer and gold precursor toward PEGDA. Therefore, the concentration of charged monomer is also optimized and the internal structure is investigated to observe the AuNP density. Optimized microgels exhibit signal uniformity in any spot, indicating the uniform dispersion of AuNPs inside microgels. As proof of concept, we detected charged molecules using our

plasmonic Janus microcylinder. Since specific photonic color indicates the charge of the plasmonic microgels, molecules with a specific charge can be detected using the oppositely charged microcylinder. In the mixture of positively and negatively charged molecules, each molecule is identified with high sensitivity from the microcylinder based on photonic colors.

Fast, and Simple Fabrication of Core-Satellite Plasmonic Nanostructures from Different Shapes and Materials for Robust, Stable, and Reproducible Surface-Enhanced Raman Scattering Hoa D. Trinh and Sangwoon Yoon; Chung-Ang University, Korea (the Republic of)

Developing low-cost, fast, and easy fabrication methods for highly sensitive and stable surface-enhanced Raman scattering (SERS) substrates is an actively pursued goal in sensors and diagnostics. In this study, we present a simple but efficient method for constructing different core-satellite (CS) configuration plasmonic nanostructures. CS nanostructures with multiple hotspots are assembled using small linker molecules that also serve as SERS labels. Multiple hot spots in the structures and narrow nanogaps in each hot spot produce a significantly enhanced Raman scattering signal. The sequential and alternating immersion of glass slides in different noble nanoparticles (Au or Ag) and linkers forms CS nanostructures with perfect yield and wide range of optical resonances. The method is highly reproducible and flexible that can be applied to many types of nanoparticles with different shapes, sizes, and capping ligands. The assembling process is fast and simple which is assisted by air plasma treatment. The CS nanostructures show robust, reliable, and stable SERS signal intensity. Furthermore, it is possible to detach CS nanostructures from supported glass slides and then encapsulated them in silica (CS@SiO_2) which makes the CS@SiO_2 an ideal SERS probe for sensitive detection of diseases and viruses.

Tunning the Shell Thickness for Plasmonic-TiO 2 Core-Shell Nanoparticles and its Effect on the ROS Generation Luis G. Morales Valenzuela[1,2], Paulina Segovia Olvera[1] and Jose M. Romo-Herrera[2]; [1]Centro de Investigación Científica y de Educación Superior de Ensenada, Mexico; [2]Universidad Nacional Autónoma de México, Mexico

The direct conversion of solar energy to chemical energy using photocatalysts has received significant attention in the last decade due to the great potential for fuel generation using environmentally friendly energy.

Conventionally, semiconductors are the basis of heterogeneous photocatalysis, trapping light with the energy necessary to generate electron-hole pairs, capable of generating reactive oxygen species (ROS) of great utility for the transformation of different molecules into fuels.

Although Titanium oxide (TiO_2) is one of the most efficient semiconductors as photocatalyst, its band gap is of 3.2 eV in anatase phase, which limits its application to light in the Ultraviolet region of the electromagnetic spectrum. During the last decade, Plasmonic NPs have been promoted as efficient additives to TiO2 to increase and take advantage of the harvesting of visible light and increase the photocatalytic efficiency of the hybrid material. Nanoparticles (NPs) with a core-shell architecture (AuNPs@TiO2) are examples of this type of hybrid materials, where the properties of both materials can be combined by having them in close contact, generating a synergy between them.

Plasmonic NPs have caught great attention due to their optical properties, low toxicity and good chemical stability. They can interact with visible and/or infrared light generating a resonance condition known as "localized surface plasmon resonance" (LSPR). This LSPR is very useful for applications in photochemistry, photodesorption, photothermal or detection of analyte molecules at low concentrations.

In this work it will be shown the synthesis of core-shell NPs (AuNPs@TiO_2), from the seed-mediated growth of the gold NPs (AuNPs) cores for tunning their size and plasmonic properties, to the subsequent controlled coating with TiO_2 using SOL-GEL method.

During this process, different shifts of the LSPR peak are observed from the UV-Visible spectroscopy signal of the AuNPs, which are directly related to the type of material and its thickness around the AuNPs. Therefore, such shifts can be used to monitor the synthesis process of AuNPs@TiO_2 coreshell NPs at each stage, using simple and standard tools such as a UV-Visible spectrophotometer.
Then, a theory-experiment study is presented using transmission electron microscopy (TEM) complemented with numerical simulations (COMSOL multiphysics) to validate the causes of the LSPR peak shifts for its usage as a monitoring tool at each stage of this type of synthesis.

Even more, the synthesis methodology was optimized to modify the thickness of the TiO_2 grown as a shell on the AuNPs. This allowed us to study the effect of the thickness of the shell on the generation of reactive oxygen species (ROS), which will contribute improving the efficiency of conversion of light energy to chemical energy towards the generation of alternative fuels using environmentally friendly processes.

5:00 PM EL05.03.07
Highly Sensitive Near-Infrared SERS Nanoprobes for *In Vivo* Imaging Using Gold-Assembled Silica Nanoparticles with Controllable Nanogaps
Yun Sik Choi[1], Sungje Bock[2], Dae Hong Jeong[1], Hyejin Chang[3] and Bong-Hyun Jun[2]; [1]Seoul National University, Korea (the Republic of); [2]Konkuk University, Korea (the Republic of); [3]Kangwon National University, Korea (the Republic of)

In vivo imaging using NIR light has attracted considerable attention owing to good penetration ability of NIR raditation through tissues. However, previous NIR imaging probes still possess issues such as lack of multiplex capacity, due to spectral overlap. In vivo imaging using surface-enhanced Raman scattering (SERS) has emerged as effective solution, owing to its high sensitivity, multiplexing ability, and non-photobleaching feature. To take such advantages, development of highly enhanced SERS nanoprobes in near-infrared (NIR) region is needed. A well-controlled morphology and biocompatibility are essential features of NIR SERS nanoprobes. Among several types of nanoparticle(NP)s, Gold(Au) NPs has been widely used under biological conditions owing to its good biocompatibility, but nanoprobes based on Au NP still suffer from weak SERS signal enhancement ability. Herein, we suggest Au-assembled nanostructures with controllable nanogaps with highly enhanced SERS signals within multiple hotspots as an breakthrough.

Au-assembled silica (SiO_2) nanoparticles (NPs) (SiO_2@Au@Au NPs) as NIR SERS nanoprobes are synthesized using the seed-mediated growth method. SiO_2@Au@Au NPs with six different sizes of Au NPs (SiO_2@Au@Au_{50}–SiO_2@Au@Au_{500}) were prepared by controlling the concentration of Au precursor in the growth step. The nanogaps between Au NPs on the SiO_2 surface could be controlled from 4.16 to 0.98 nm by adjusting the concentration of Au precursor (hence increasing Au NP sizes), which resulted in the formation of effective SERS hotspots. SiO_2@Au@Au_{500} NPs showed effective absorption of NIR light, with a 0.98-nm gap between Au NPs. SiO_2@Au@Au_{500} NPs showed high SERS enhancement factor of approximately 3.8×10^6 under 785-nm photoexcitation with good uniformity. SiO_2@Au@Au_{500} nanoprobes showed detectable *in vivo* SERS signals at a concentration of 16 µg/mL in animal tissue. SiO_2@Au@Au_{500} nanoprobes showed good penetration ability at animal tissue, detectable until it reaches 7 mm deep inside the porcine tissue. SiO_2@Au@Au_{500} NPs with 14 different Raman label compounds exhibited distinct SERS signals upon subcutaneous injection into nude mice. SiO_2@Au@Au NPs showed high potential for *in vivo* applications as multiplex nanoprobes with high SERS sensitivity in the NIR region.

Shifting the Size-Dependent Redox Potential of Gold Nanoparticles Using CTA^+ Micelles Randy Espinoza, Daniel B. Valenzuela Cahua and Son C. Nguyen; University of California, Merced, United States

Here, we demonstrate an unusual negative shift in the size-dependent reduction potentials of gold nanoparticles (AuNPs) attributed to the presence CTA^+ micelles. Our model reaction follows the chemical equilibrium reaction of CTAB-protected gold nanospheres and the Fe^{3+}/Fe^{2+} redox couple which allows us to use the Nernst equation and compute their standard redox potentials. The measured redox potentials decrease with decreasing nanoparticle size, following a size-dependent trend that negatively shifts by ~300 mV under the presence of CTA^+ at micellar concentration. This shift in the redox potential of AuNPs suggest that controlling the metal-ligand complex interactions with the micelles can serve as a strategy to tune the redox potential of metallic nanoparticles and metal-surfactant complexes. This reaction strategy can also be useful to compute the formation constant of the metal-surfactant complex in relevance to growth and etching of metal nanoparticles.

5:00 PM EL05.08.10
Emission Mechanism of Luminescent Silver Nanodots in the Presence of Calcium Sungmoon Choi and Junhua Yu; Seoul National Univ, Korea (the Republic of)

Stable luminescent silver clusters, named as silver nanodots (AgNDs), have been successfully encapsulated in several scaffolds. Silver nanodots consisting of a few silver atoms are becoming excellent fluorophores thanks to their small size, high brightness and excellent photostability. The synthesis of a series of spectrally-pure silver nanodots with emissions ranging from the blue to the near-IR prompts the application of such fluorophores for optical imaging. The high brightness and two photon absorption cross section of silver nanodots make them useful for cellular imaging. Particularly, the cost-effective poly(acrylic acid)-stabilized silver nanodots (PAA-AgNDs) show advantages of easy preparation and good stability.

In addition to its chemical properties, the low emission efficiency and loose structure of the PAA-AgNDs enable such nanodots a useful platform as optical probes. We found that PAA-AgNDs are extremely sensitive to the presence of calcium ions. The complexes between PAA-AgNDs and the ions significantly enhance the emission quantum yields due to cross-linking of the polymer chain by positively-charged metal ions. The high selectivity towards calcium ions can be explained by guest-host chemistry, in which the best match between the polymer chain and the ions further increases the rigidity of the polymer chain, and consequently minimize the non-radiative decay from the excited states of the PAA-AgNDs.

We have further developed these complexes to gels by surface printing for probing in various environments.

Colloidal Synthesis of Copper Nanocrystals for Plasmonic and Related Applications Younan Xia[1] and Zhiheng Lyu[2]; [1]Georgia Institute of Technology, United States; [2]University of Illinois at Urbana-Champaign, United States

Copper (Cu) nanocrystals have received a lot of interest in recent years because of the high natural abundance and low cost of copper, as well as their outstanding performance in applications related to plasmonics, electronics, and catalysis. In this talk, I will discuss a number of solution-phase methods for the colloidal synthesis of Cu nanocrystals with well-defined and controllable shapes or morphologies. The methods involve both self-nucleation and seed-mediated growth. In the presence of proper capping agents, the nanocrysatls could be directed to grow into nanoscale cubes and right pyramicds, as well as one-dimensional rods and wires with a penta-twinned structure. The surface of these nanocrystasl is typcially enclosed by {100} facets. These nanocrystals could be prepared in high purity, together with controllable edge lengths down to 20 nm, offering an interesting system for the exploration of plasmonic application and electrocatalytic conversion of CO_2 to ethylene.

9:30 AM BREAK

10:00 AM *EL05.04.04
Synthesis of Metal-Metal Oxide Core-Shell Nanostructure with Plasmonic Properties Jingyi Chen; University of Arkansas, United States

Inorganic hybrid core-shell nanoparticles integrate the material properties from individual components which may open doors for new applications. However, the synthesis of core-shell nanoparticles made of dissimilar materials such as metal and metal oxide remains challenging due to strain and interfacial mismatch. In this work, we develop a metal-on-metal thin film growth approach to control the conformal deposition of nonprecious metal shells on the Cu-based metal cores to form core-shell structures of metal-metal oxide hybrids. The deposition kinetics could be controlled by a temperature-regulated, thermal decomposition of zero-valent transition metal complexes. It is found that the conformal deposition can be promoted by keeping the initial deposition temperature close to the thermal decomposition temperature of the zero-valent precursors. While maintaining a slow reaction kinetics, the strain reduction and interdiffusion facilitate conformal deposition over island growth in the synthesis. This study provides insightful guidance to metal-on-metal growth in solution at the nanoscale and thus the seed-mediated approach to hybrid core-shell structures. The optical properties of these metal-metal oxide hybrids are investigated experimentally and interpreted by theoretical simulation. Despite damping effects, the plasmonic properties of these Cu-based core-metal oxide shell structures may have the potential to enable plasmon-enhanced applications. Coupling with selective chemical etching of the Cu core, this synthesis approach developed in this study allows to access hollow nanoshells of metal oxides with well-defined morphology adopted from the core.

10:30 AM *EL05.04.05
Plasmon-Assisted Synthesis of Hybrid and Reconfigurable Nanomaterials Michelle L. Personick; Wesleyan University, United States

The synthesis of plasmonic nanomaterials with tailored interfaces requires fine control over competing reductive and oxidative chemical processes. Differentially modulating the rates of these reactions using only chemical and thermal parameters can be prohibitively challenging. In such cases, excitation of the plasmon resonance of the growing nanoparticles using visible light can yield hybrid structures and morphological transformations that are not accessible via standard colloidal approaches. For example, in the synthesis of hybrid bimetallic nanoparticles composed of a plasmonically-active silver (Ag) core and a catalytically-active platinum (Pt) shell, excitation of the plasmon resonance of the core nanostructure selectively drives the reduction of a Pt precursor under chemical conditions that limit the competing galvanic exchange between Pt ions and Ag. The combination of plasmon-driven reduction rate control with chemical reduction rate control also enables the synthesis of Ag core-Pt satellite nanostructures that are not accessible via other approaches. In another example, plasmonic excitation of Ag triangular prisms drives a cycle of oxidation and re-reduction of Ag to yield a conversion of the planar twinned prisms to multiply twinned icosahedra. The use of light to reconfigure the defect structure of Ag nanoparticles opens opportunities for visible-light-tunable catalysis and recyclable catalyst materials.

11:00 AM *EL05.04.06
Plasmonic Nanostructures on Paper Test Strips for Acute Disease Testing Nianqiang Wu; University of Massachusetts Amherst, United States

This talk will present our effort to develop plasmonic nanostructures toward testing of acute diseases such as traumatic brain injury, HIV and COVID-19. We tailor the chemical composition, microstructure and geometry of plasmonic metallic nanostructures to tune the optical mode of surface plasmonic resonance for light management. We construct surface-enhanced Raman spectroscopy (SERS) and fluorescence sensor and amplify optical signals with plasmon. Next, we incorporate plasmonic optical sensors into paper-based lateral flow assays to develop all-in-one test strips, which enables testing by laypersons at home, clinics and emergency departments.

Modeling the Effect of Ligands on Growth and Assembly of Nanocrystals Michael Engel; Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Ligands play a central role for the energetics and kinetics of plasmonic nanocrystals. During nanocrystal synthesis, ligands bind to the surface of a growing seed. Growth can result in shapes distinct from equilibrium Wulff polyhedra if ligands are designed with specificity for crystallographic facets. Ligands are also important during nanocrystal assembly. They act as spacers and provide functionality by controlling nanoparticle interactions. Finally, a surplus of ligand molecules in solution can result in depletion effects. Here, we present advances in the computational modeling of ligand effects on both nanocrystal growth and nanocrystal assembly. We model nanocrystal growth via a grand-canonical kinetic Monte Carlo simulation where ligand covering is described by kinetic factors. We observe a roughening transition at high temperature and search for optimal conditions for desired nanocrystal shapes. For understanding the effects of ligands on assembly, we utilize coarse-grained simulations of nanoprisms with directional, facet-specific interactions. For this purpose, we develop a generalizable two-step simulation methodology that, in a first step, generates a table for the interaction of two ligand-covered nanocrystals and, in a second step, utilizes this table in molecular dynamics. We apply our simulations to a number of self-assembly experiments of anisotropic nanocrystals with polymer ligands. Our macromolecular ligand-engineering strategies control, characterize, and model four molecular parameters of grafted polymer chains: chain length, chain dispersity, grafting density, and chain distribution. This work is a step towards theoretical models for particle brush materials and paves the way for the precision synthesis of nanocrystal hybrid materials.

2:30 PM *EL05.05.03
Periodic Arrays of Epitaxially Aligned Atomically Flat Single-Crystal Gold Nanoplates Robert Hughes, Robert Neal, Spencer Golze, Zachary Lawson, Walker Tuff and Svetlana Neretina; University of Notre Dame, United States

Well-tailored nanomaterials with a single-crystal character provide ideal building blocks for on-chip plasmonic devices. Although colloidal methods have demonstrated mastery over the synthesis of such structures, it has proven quite difficult to deploy these same nanomaterials on substrate surfaces in a highly deterministic manner where precise control over position and orientation is ensured. Only three examples currently exist in the literature where standalone single-crystal noble metal nanoplates have been formed on substrate surfaces in periodic arrays. These demonstrations, while impressive, are deficient in that they have either been demonstrated over small areas (< 1 mm^2) or where the nanoplate yield is low (78%). In this talk, we demonstrate the utility of using a crystalline substrate as the primary driver for forming substrate-based gold seeds with the internal defect structures and crystallographic alignment required for nanoplate growth. Using this capability along with other controls that are unique to substrate-based syntheses, we implement chemical reduction methods for generating large-area arrays of gold hexagonal and triangular nanoplates. The devised methods, hence, advance the integration of single-crystal gold nanoplates into device platforms and provide an overall fabrication strategy that is adaptable to other nanomaterials.

3:30 PM *EL05.07.01
Plasmonic Hotspots Illuminate Cellular Biochemical Response to Environmental Conditions Regina Ragan; University of California, Irvine, United States

Bacterial responses to stress are critical to their survival in dynamic and challenging environments. Stresses can be general, e.g., nutrient deprivation, or specific, e.g., targeted antibiotic activity. Regardless, they result in rapid and profound shifts in metabolite concentrations within cells to maintain homeostasis. Thus, new technology for facile and rapid decoding of the complex cascade of chemical signals has been developed for medical diagnostics and environmental monitoring. I will present results of chemically assembled of plasmonic hotspots with defined nanogap chemistry able to tune interactions with metabolites, leading to single molecule limits of detection and quantification. Sensors are integrated in a microfluidic channel and performance is comparable on a confocal microscope and a portable spectrometer due to molecular scale control of nanofabrication over large area. Machine learning analysis of vibrational spectra of metabolite changes provides insight into the biochemical network response. Spectral feature analysis of *Pseudomonas aeruginosa* and *Escherichia coli* post antibiotic exposures indicates that purine biosynthesis is disrupted within 5 min of exposure, thus providing a rapid antibiotic susceptibility test for use in clinics. Further results to be presented show that *E. coli* cells can be used for transducing metal ions into chemical signals via the biochemical network response. Machine learning analysis of the vibrational spectra of metabolites released in response to chromium and arsenic exposure detects concentrations 10^8 times lower than those leading to cell death. Consequently, this platform is promising for monitoring changes in water quality below regulatory limits to provide early warning of water contamination and accurate longitudinal tracking of contaminant concentrations. The network response is detectable at ratios on the order of one metal ion to bacterium in solution, according to the level of toxicity. For example, the ratio of metal ions to bacterium in solution is 0.6 for As^{3+} and 8.2 for Cr^{6+}, showing sensitivity at the single cell level. These values correlate well with the fact that the EPA regulatory limit of Cr^{6+} is ten times higher than As^{3+}. Due to their distinct mechanisms of toxicity in bacteria, this sensing platform also distinguishes the metabolic response of As^{3+} and Cr^{6+} with 99% accuracy when analyzed with support vector machine models. Machine learning analysis shows the largest variance is in the spectral range between 700-750 cm^{-1}, which is a band consistent with SERS features associated with DNA methylation associated with the stress response of *E. coli*. Transfer learning of trained algorithms are further demonstrated to be generalizable to unseen tap water and wastewater samples using data obtained in less than 10 min. Drinking water safety, i.e., above or below WHO recommended limits is determined with greater than 96% accuracy. For more complex samples, secondary treated wastewater, with multiple background contaminants, the fine-tuned models can determine if waste water samples are above or below recommended safety limits with 92% accuracy. Thus, this platform provides an alternate technology to sophisticated and centralized analytical instruments identify biochemical networks involved in cellular response to environmental conditions.

4:00 PM EL05.05.05
Open- and Close-Packed Oligomers via Template-Directed Assembly of Shape-Engineered, Lithographically-Fabricated Nanoparticles Yiyu Cai[1], Asma Fallah[1], Shengsong Yang[1], Yun Chang Choi[1], Aaron Stein[2], James M. Kikkawa[1], Nader Engheta[1], Christopher B. Murray[1,1] and Cherie R. Kagan[1,1,1]; [1]University of Pennsylvania, United States; [2]Brookhaven National Laboratory, United States

We report a top-down lithographic fabrication process for producing nanoparticles (NPs) with well-defined sizes, shapes, and compositions that are not accessible synthetically. Using a template-assisted assembly technique, lithographically-fabricated Au NPs are driven by capillary forces to assemble into open or close-packed structures. The sizes and shapes of the templates control the interparticle gap size, coordination number, disorder, and location of defects such as voids in the NP assemblies. We characterize the optical properties of our assembled structures using dark-field scattering spectroscopy. Fano resonances are observed in the spectra and show dependencies on the symmetry, interparticle distance, and orientation with respect to the polarization of incident light. We further develop a multistep assembly method to co-assemble different types of NPs into multimaterial architectures.

4:15 PM EL05.05.06
Creating Chiral Plasmonic Nanostructures with Circularly Polarized Light Tian Qiao, Tsumugi Miyashita and MingLee Tang; The University of Utah, United States

Chiral plasmonic nanostructures have attracted much interest in recent years as new platforms for polarization modulation. Other than photonic devices, chiral plasmonic nanostructures facilitate the ultrasensitive detection of chiral biological materials, e.g. DNA. To synthesize chiral plasmonic nanostructures, the most well-established method is chirality transfer from biological materials to the inorganic nanostructures. Alternatively, circularly polarized light can be used to control the formation of the plasmonic enantiomeric nanostructures, where the chirality of the product is solely defined by the polarization of the light. This synthesis method may be more cost-effective while allowing the wavelength and intensity of light to be used as tunable parameters. Here we investigate the use of circularly polarized light to create chiral gold nano bipyramids. Hot charge carriers can be generated with light and consumed to fabricate chiral plasmonic structures. Scanning electron microscopy (SEM) coupled with cathodoluminescence measurements comparing the nano bipyramids before and after circularly polarized light illumination is used for characterization. We will show that both dielectric or plasmonic chiral additions can be deposited depending on the identity of reagents. Circular dichroism (CD) spectra of the chiral plasmonic nanostructures further demonstrate the polarization dependent light-matter interaction of the materials synthesized.

Stress Induced Mesoscale Assembly of Nanoparticles for Active Nanostructures Hongyou Fan; Sandia National Laboratories, United States

Due to the size- and shape-dependent properties, nanoparticles have been successfully used as functional building blocks to fabricate 1-3D ordered assemblies for the development of artificial metamaterials. At ambient pressure, entropy driven self-assembly of monosized or binary nanoparticles generally results in polycrystalline 2- or 3D close-packed arrangements, and extensive efforts have been made to develop structural perfection of nanoparticle arrays or ‘single crystal-like’ domain structures with precise long range order for their definite advantages for electron transport. To date, fabrications of ordered nanoparticle assemblies have been relied on specific interparticle chemical or physical interactions such as van der Waals interactions, dipole-dipole interaction, chemical reactions, etc. Recently we have discovered a pressure-induced assembly method to engineer nanoparticle assembly at mesoscale and to fabricate new nanoparticle architectures without relying on specific nanoparticle interactions. We show that under a hydrostatic pressure field, the unit cell dimension of a 3D ordered nanoparticle arrays can be manipulated to reversibly shrink, allowing fine-tuning of interparticle separation distance. Under a uniaxial pressure field, nanoparticles are forced to contact and coalesce, forming hierarchical nanostructures. Depending on the orientation of the initial nanoparticle arrays, 1-3D ordered nanostructures including nanorod, nanowire, and nanoporous network can be fabricated through the pressure-induced self-assembly method. Guided by computational simulations, we were able to rationalize the pressure-induced self-assembly of nanoparticle arrays for predictable nanostructures. Moreover, we discovered for the first time a transition from an ordered polycrystalline nanoparticle mesophase to quasi-single crystalline nanoparticle lattices induced by PDA process. Exerting pressure-dependent control over the structure of nanoparticle arrays provides a unique and robust system to understand collective chemical and physical characteristics and to develop novel electronic and photonic behavior for energy transduction related applications.

8:30 AM *EL05.06.01
Synthesis and Applications of Plasmonic Hydrogels Francis Zamborini, Rajiv Singh, Sharadkumar Karangiya and Harikrishnan Nambiar; Univ of Louisville, United States

The drop-wise addition of sodium alginate to a solution of calcium ions results in the formation of spherical Ca-alginate hydrogel beads. Gold nanoparticles (NPs) or nanoclusters (NCs) of varied size become incorporated into the hydrogel beads by adding them to the sodium alginate solution prior to synthesis. The extent of NP/NC loading depends on the concentration used in the sodium alginate solution while the size of the beads depends on the drop size and water content. The synthesis of hydrogel beads with gold NPs of varied size, shape, and aggregation state leads to plasmonic hydrogels with controlled optical properties due to their different wavelengths of the localized surface plasmon resonance (LSPR) peak of the NPs in the beads. The plasmonic properties can be further tuned by changing the composition of metal NPs within the hydrogel beads. The chemistry and properties are very different compared to the behavior of the NPs in water solutions without incorporation into the hydrogel. Functionalization and cross-linking the hydrogel by linkages other than Ca also affects the properties and provides advantages in terms of chemistry, stability, and applications. The hybrid hydrogel-metal NP plasmonic materials have applications in optical sensing, electrochemical analysis, photochemistry, and catalysis.

9:00 AM *EL05.06.02
Synthesis and Photocatalytic Properties of Hybrid Metal-Semiconductor Nanoparticles Yongchen Wang and Jing Zhao; University of Connecticut, United States

Metal and semiconductor nanoparticles exhibit excellent light absorbing ability and size-tunable properties. When the two components are combined in one hybrid structure, effective charge separation could occur upon photoexcitation and the long-lived charge-separated state along the electrons or holes to transfer to molecules nearby; therefore, they can be employed to catalyze photochemical reactions. In our work, we developed a method to synthesize Ag-tipped CdS nanorods with varying lengths using a seed-mediated growth method. The length of the nanorods can be controlled by the ratio of the Ag and Cd/S precursors. The Ag-CdS nanorods were applied as photocatalyst for methyl orange degradation reaction and their catalytic activities were affected by their length. Specifically, rods of intermediate lengths showed higher degradation rates than the short and long ones. Steady-state and time-dependent fluorescence spectroscopy was used to measure photoluminescence (PL) spectra and decays of the Ag-CdS nanorods and rod-like CdS nanoparticles. The Ag-CdS nanorods exhibited broad, red-shifted PL spectra and much slower PL decays compared to that of the CdS nanoparticles. By fitting the PL lifetime distribution of the decay curves, we attributed the high photocatalytic activities of the intermate-length Ag-CdS nanorods to the higher probability of populating the charge-separated states than that of the short or long rods.

9:30 AM *EL05.06.03
Detection of Nanoplastics in Ocean Water using Plasmonic Effects Tengfei Luo[1], Seunghyun Moon[1], Leisha Martin[2], Seongmin Kim[1], Qiushi Zhang[1] and Wei Xu[2]; [1]University of Notre Dame, United States; [2]Texas A&M University, Corpus Christi, United States

Plastics production surpasses all other synthetic materials globally, with 5-13 million tons of them entering the oceans every year, posing serious environmental challenges. Plastics in the environment can be fragmented by UV irradiation and mechanical means into micro- or even nano-particles. Although nanoplastics have been detected in ocean water using techniques like mass spectrometry, they have never been visually seen and thus their morphological features are unknown, which are critical to their toxicity. Here we report the direct observation of nanoplastics in ocean water around the world leveraging a unique shrinking surface bubble deposition (SSBD) technique. SSBD concentrates suspended nanoplastic particles onto a surface, allowing direct visualization using electron microscopy. With the plasmonic nanoparticles co-deposited in the SSBD process, surface-enhanced Raman spectroscopy effect is enabled for chemical identification of trace amount of nanoplastics deposited on the surface. From the water samples collected from locations on the coastlines of China, South Korea, and the United States, and deep (>300 m) in the Gulf of Mexico, we observed nanoplastics with a variety of compositions, including polycaprolactam (Nylon), polystyrene (PS), and polyethylene terephthalate (PET) – all commonly used in daily consumables (e.g., textiles, coffee cup lids and water bottles). The plastic particles we found possessed diverse morphologies, such as nanofibers, nanoflakes, and ball-stick nanostructures. These diverse nanoplastics may have profound impacts on marine organisms, and our results can provide important information for appropriately designing their toxicity studies.

11:00 AM EL05.06.05
Noble Metal-Nonstoichiometric Copper Chalcogenide Dual-Plasmonic Hybrid Heteronanostructures with Tunable Optical Properties and Optimized Photocatalytic Activities Hao Jing[1], Mariia Ivanchenko[1], Vida Nooshnab[2], Andrew Evangelista[1], Alison Carroll[1], Nicolas Large[2], Alline F. Myers[3] and Andrea Brothers[4]; [1]George Mason University, United States; [2]The University of Texas at San Antonio, United States; [3]National Institute of Standards and Technology, United States; [4]American University, United States

Multicomponent plasmonic nanoparticles, especially structurally well-defined noble metal-nonstoichiometric copper chalcogenide (p-type) dual plasmonic hybrid hetero-nanostructures, have emerged as an intriguing platform of superstructures due to their synergistically reinforced optical properties. The integration of two intrinsically dissimilar plasmonic constituents in one nano-entity empowers us to explore many new-yet-unexpected features, holding tremendous potential for plasmon-mediated energy transfer, plasmon-enhanced photocatalysis, and plasmon-related photothermal and photodynamic theranostics. Over the past decades, the research on dual plasmonic nanostructures has been burgeoning and much progress has been made with respect to the synthesis of a wide variety of dual plasmonic nanostructures with distinctive sizes, shapes or mophologies. Several dual-plasmonic hybrid heteronanostructures with geometrically tunable optical properties and tailored photocatalytic performance synthesized and characterized in our lab will be discussed in this symposium.

11:15 AM EL05.06.06
Synthesis & Functionalization of Hybrid Plasmon-Semiconductor Nanoparticles for Cancer Phototherapy Yuzhou Pu and Thomas Pons; ESPCI Paris PSL, France

Clinical modality based on light activation and photosensitizers, phototherapy, has been recognized as a novel alternative for cancer therapy owning to its high selectivity, safety and compatibility with other tumor ablation modalities. However, key challenges such as low light penetration, low generation rate of reactive oxygen species (ROS) for photodynamic therapy (PDT) or of heat for photothermal therapy (PTT), along with poor distribution specificity of photosensitizers have restricted its widespread clinical use, which requires rational design and improvement on photosensitizers. Herein we propose a strategy that combines plasmonic gold nanorods (AuNR), which can efficiently generate hot electrons under laser irradiation thanks to its localized surface plasmon resonance, with semiconductor materials such as TiO_2. The generated hot electrons can be injected into the conduction band of TiO_2 and eventually produce ROS (Hydroxyl radicals), radicals that will lead to cell apoptosis. By controlling the aspect ratio of AuNR, the longitudinal absorption of AuNR can be tuned from 700 to 1000 nm, a region where light gets an optimal penetration into the tissue. We characterized the production of hydroxyl radicals by AuNR/TiO_2 nanoparticles under continuous wave or pulsed irradiation at 800 nm by measuring the degradation rate of methylene blue. Then we designed surface polymeric ligands based on polyethylene glycol to ensure the colloidal stability of these hybrid AuNR/TiO_2 nanoparticles in a physiological environment. Finally, these functionalized AuNR/TiO_2 nanoparticles were incubated with HeLa cells. We demonstrated that irradiation of these nanoparticles by a continuous 808 nm laser was effective to produce ROS and kill cancer cells, while incubation with nanoparticles in the absence of irradiation or irradiation in the absence of the nanoparticles did not modify the cell viability.

11:30 AM *EL05.06.07
Multiscale Chirality of Self-Assembled Nanostructures Nicholas A. Kotov; University of Michigan, United States

Nanoscale chirality is a rapidly emerging field in science and engineering. The early observation of giant circular dichroism for assemblies of gold nanoparticles due to their high polarizability and dimensional match with visible wavelengths. They encompass a large family of mirror-asymmetric constructs from metals, semiconductors, ceramics, and nanocarbons with multiple chiral geometries with characteristic scales from Ångströms to microns. Versatility in, scales, dimensions and polarizability of the inorganic materials enables their multiscale engineering to attain a broad range of optical and chemical properties. These capabilities as chiral materials enabled their fast technological translation for biosensing and optoelectronics, which, in turn, opened new venues for scientific inquiry into the unifying role chirality at the interface of materials science, biology, chemistry, and physics.
In this talk the relationships between multiscale chirality, structural/functional complexity and strong chiroplasmonic activity will be established. The concept of chirality vectors with scale-specific chirality measures will be introduced. Engineering of the self-assembled structures wither complexity starting from the tetrahedrons of gold nanoparticles, twisted nanorods pairs, chains of gold nanorods and chiral superlattices from tetrahedrons will be discussed. These self-assembled structures open a pathway to a large family of complex hierarchical structures with gradually tunable chiroptical properties for biosensing and chiral photonics.

SESSION EL05.07: Active Plasmonics II
Session Chairs: Ateet Dutt and Pier Carlo Ricci
Thursday Afternoon, April 13, 2023
Moscone West, Level 2, Room 2000

1:30 PM *EL05.07.02
Active Epsilon-Near-Zero Photonics Aleksei Anopchenko, Sudip Gurung, Christopher Gonzalez, David Dang, Quynh T. Dang, Leon Zhang, Kent Nguyen, Yu-Hsun Chen, Scott Kiehn, Juan M. Calixto and Ho Wai (Howard) Lee; University of California, Irvine, United States

Discovery of novel active materials is fundamental for photonic applications. The epsilon-near-zero (ENZ) materials have been shown to be as one of the most promising optical materials in the recent years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties, including strong electromagnetic wave confinement, enhanced quantum emission near ENZ media, non-reciprocal magneto-optical effects, unique topological properties, and abnormally large optical nonlinearity. While ENZ optics have been investigated extensively in the last few years, the current commonly used ENZ materials suffer from limited optical enhancement because of the lack of precise control of ENZ frequency, loss, and thickness for efficient ENZ mode excitation. In addition, the active tunability and enhanced nonlinearity and emission properties in ENZ materials have yet been fully experimentally explored.

This talk will review our recent studies on the active linear, nonlinear, and emission properties of conducting oxide and metallic nitride epsilon-near-zero materials in planar and optical fiber platforms [1-7]. I will present a method to engineer the field intensity enhancement of the Al-doped zinc oxide (AZO) ENZ thin films synthesized by atomic layer deposition (ALD) technique. I will then discuss the observation of abnormal nonlinear temporal dynamic of hot electrons and enhanced optical nonlinearity in AZO and ITO ENZ thin films under different pump fluences and excitation angles using a degenerate pump-probe spectroscopy technique. Finally, I will also discuss the first experimental demonstration of optically confined ENZ resonance excitation in an optical fiber waveguide uniformly coated with AZO nanolayer. These studies enrich the fundamental understanding of emission and nonlinear properties on ENZ thin films and the integration of ENZ materials and optical fiber will open the path to revolutionary ultracompact in-fiber optical devices for optical communication, imaging, sensing/laser applications.

2:00 PM EL05.09.01
Self-Assembly of Cadmium Dipeptide Nanoparticles into Bowtie Complex Microparticles with Chirality Continuum Prashant Kumar[1], Thi Vo[1], Minjeong Cha[1], Anastasia Visheratina[1], Ji-Young Kim[1], Wenqian Xu[2], Wonjin Choi[1], Sharon Glotzer[1] and Nicholas A. Kotov[1]; [1]University of Michigan, United States; [2]Argonne National Laboratory, United States

Mathematical descriptors of mirror asymmetry are continuous, but chirality in chemical disciplines is often viewed as a binary characteristic of molecules and there was no known chemical structure with widely variable chirality measures. Here we show that sub-microscale nanostructured particles can be self-assembled from anisotropic building blocks with widely variable geometry, chirality measures and optical asymmetry while retaining consistent bowtie shapes. The self-limited self-organization of anisotropic building blocks [1] makes possible high synthetic reproducibility and computational predictability of their geometries for different concentrations of reagents, ionic components, enantiomeric compositions, media polarity and other parameters. The positive and negative chiroptical peaks observed from UV to IR parts of the spectrum originate from absorptive and scattering phenomena with contribution from both dipolar and quadrupolar modes characteristic of nanostructured particles with submicron scale chirality.[2] The dependence of geometrical chirality measures and chiroptical characteristics enable the predictive synthesis of bowties with desirable polarization rotation. Controllable pitch, length, width, and thickness leads to tunable chiroptical activity across from UV to IR, which can be used to print chiroptical metasurfaces for photonic markers for machine vision devices. Mechanically Interlocked Plasmonic Nanocatenanes Yoonhee Kim and Jwa-Min Nam; Seoul National University, Korea (the Republic of)

The design of nanostructures is often inspired by the geometries of molecular systems. Inspired by mechanically interlocked catenane architectures, here we report the synthesis of permanently interlocked inorganic nanocatenanes. In this presentation, I will cover the novel insights on the chiroptical and opto-mechanical properties of the plasmonic nanocatenanes and demonstrate the underlying principles stemming from the mechanically interlocked structure. Assemblies of colloidal inorganic nanocrystals show outstanding optical, magnetic, and catalytic properties not found in individual nanostructures. However, because of the weak nature of the interparticle interactions, the structural stability of such assemblies is vulnerable to environmental conditions. To overcome this intrinsic limitation, unbreakable bonds between the constituent nanostructures are required. Thus, the nanocatenanes are invented and prepared in a strategy analogous to the template synthesis of [2]catenane developed by Jean-Pierre Sauvage. As we use plasmonic materials to synthesize gold nanocatenanes (AuNCats), the structural characteristics of catenane architectures are combined with the distinctive optical properties of plasmonic materials. We present an analysis of the behavior of the localized surface plasmon resonance of AuNCats comprised of two gold nanorings in terms of D_{2d} spatial symmetry. Moreover, the rocking motion of one nanoring relative to the other causes structural desymmetrization into D_2 symmetry, and induces mechano-helical chirality of an AuNCat as a structural analogy of the [2]catenane. This results in the occurrence of chiroptical responses and remarkably high g-factors. As a proof of concept, we constructed a nanoactuator using an AuNCat in tandem with a thermoresponsive polymer. The incident light induces interband transitions of gold and the resultant thermal actuation of the plasmonic nanomachine transforms rectilinear force into rotational mechanical motion, which enables control of the circular dichroism of the plasmonic nanostructure. We anticipate that mechanically interlocked plasmonic platforms will introduce a new class of nanostructures with unprecedented capabilities. This work was selected as the cover for the August issue of *Nature Synthesis* and introduced in *Research Briefing* in the issue.

2:30 PM EL05.09.04
Pre-ceramic Polymer-Assisted Nucleation and Growth of Anisotropic, Chalcogenide Nanostructures Patricia A. Loughney[1], Kara Martin[2], Paul Cuillier[1], Edward Trigg[2,3], Nicholas Posey[2,3], Matthew Dickerson[2], Timothy Pruyn[2] and Vicky Doan-Nguyen[1]; [1]Ohio State University, United States; [2]Air Force Research Laboratory, United States; [3]UES, Inc., United States

Polymer-derived ceramics (PDC) are of interest due to their industrially favorable processing steps which allow shaping to various form factors not readily achievable with conventional ceramics. PDCs are also a viable material to mix with functional nanoparticles to produce advanced nanocomposites. PDCs are already highly tunable systems without property-rich nanoparticle dispersion, and the inclusion of functional nanoparticle fillers allows for increasingly tailorable properties. This has made PDCs a viable matrix for several applications including photocatalysis, energy storage, and functional coatings. Nanoparticle fillers can lend interesting properties to a ceramic matrix that are tunable based on nanoparticle size and morphology if in a small enough regime (<10 nm). Often, these morphologies are targeted with a bottom-up thermolysis route due to its control over the nucleation and growth events for nanostructures already established in the field. However, conventional capping ligands used in nanoparticle thermolysis have poor miscibility with pre-ceramic polymers due to dissimilar geometry, chain lengths, and chemical components. This leads to aggregated nanofillers and therefore diminished functional properties. To control dispersion, secondary nanoparticle processing is performed by adhering PCP-miscible caps to the nanoparticle surface after synthesis. This often sacrifices size control established for small and reactive, non-noble nanoparticles. In this work, we have successfully eliminated the need for secondary nanofiller processing prior to dispersion through the development of a novel, one-pot, copper sulfide synthesis in which a pre-ceramic polymer with dual functionality both assists the stable formation of nanoparticles and serves as the final graft molecule. We monitored the success of this pre-ceramic polymer-assisted nucleation and growth (PPANG) and the role of the pre-ceramic polymer in the reaction through several characterization methods probing both the nanoparticle core and polymer graft. These methods include synchrotron X-ray scattering and pair distribution functions, transmission electron microscopy, *in-situ* small-angle X-ray scattering, nuclear magnetic resonance, and Fourier transform infrared spectroscopy. In our findings, we have discovered that the pre-ceramic polymer acts as a reducing agent, reactant, capping ligand, and shows promise to control and tune growth to various sizes and anisotropic morphologies for chalcogenide nanoparticles.

2:45 PM EL05.09.05

Dual SERS Enhancement Using Silver Nanoshells and Graphene Quantum Dots Hanyoung Lee and Hyejin Chang; Kangwon National University, Korea (the Republic of)

Recently, advanced Raman enhancement platforms using plasmonic nanoparticles (NPs) and non-plasmonic materials such as graphene or graphene quantum dots (GQDs) simultaneously have been reported, named 'dual enhancement' platforms. Compared to plasmonic substrates generally used, the dual enhancement platform has several advantages from advanced charge transfer-induced chemical mechanism enhancement (CM) between the molecules and graphene and attracting the analyte molecules even with weak affinity to plasmonic NP surfaces. In this study, novel design of dual SERS substrate is proposed based on bumpy Ag nanoshells (Ag NSs) and two type of GQDs with different edge structures, zigzag and armchair form. The fabricated SERS substrates were characterized by SEM, EDS, AFM and Raman spectroscopic analysis. Our dual SERS substrate exhibits enhanced signal compared to Ag NSs substrates. By controlling edge of GQDs, electronic structure of GQDs was tuned, leading to different CM effect for Rhodamine 6G. Detailed results will be described in the presentation.

***In Vivo* Real-Time Multiplex Detection of Plant Signalling Molecules Using Surface-Enhanced Raman Scattering Nanosensor** Won Ki Son, Seon-Yeoung Kwak and Dae Hong Jeong; Seoul National University, Korea (the Republic of)

International food crisis caused by population growth, environment pollution and climate change has been emerged as one of humanity's the most important problems demanding new agricultural approaches such as smart farm. To understand the biological and chemical dynamics of plants is essential part in next-generation agriculture, and various sensor technologies are studied and applied. The chemicals as known as '*signalling molecules*' which are released against adverse stimuli to activate defense system of plants are drawing attention as a key to understand plant's biological status under stressors. As one of the analytical approaches to detect signalling molecules, surface-enhanced Raman scattering (SERS)-based optical nanosensor has shown strong potential for its non-invasiveness, water-transparency and capability of real-time detection of chemical dynamics from fingerprint spectra which depend on molecules' own vibration modes.

In our research, we fabricated PDDA-capped Ag bumpy nanoshell (AgNS@PDDA) which has high enhancement factor of *ca*. 10^7 and introduced it into plants by infiltrating through stoma. Infiltrated AgNS@PDDA were found to be localized in intercellular space. Thanks to the plasmonic properties of AgNS@PDDA in near-IR window, it was possible to evade chlorophyll's strong autofluorescence and obtain SERS signals with signal-to-noise ratio of up to 64 with an acquisition time of ~100 ms. PDDA polymer provided aqueous stability for maintaining colloidal stability and effectively attracted signalling molecules most of which are negative conjugate base form by coulombic interaction. As an example, adenosine triphosphate (ATP), known to play a critical role in plant autoimmune systems, is difficult to detect in SERS because of its poor affinity toward metal surface. However, with the PDDA chain forming hydrogen bonding, it was possible to detect with LOD of 10 nM in aqueous solution. Since the interaction between the polymer chain and analytes was reversible, AgNS@PDDA was found to be effective to monitor the change of the concentration of signalling molecules in real time. Also, for quantitative analysis in complicate mixture, we made mathematical models to calculate the concentration of each component from the intensities of SERS signals.

Then, we studied the plant's reaction against biotic and abiotic stress with SERS signal monitoring. When plants leaf was physically wounded, nasturlexin B, one of the phytoalexin, and eATP were detected and those molecules were successfully to monitor the change of concentration in real time for 1 hour after the wound occurred. In addition, glutathione could be detected in watercress exposed to non-freezing cold stress (4 °C, 24 h). The signals from both stresses showed statistically significant difference compared to the signals from the control group. Meanwhile, biotic stress was studied for the plants infected with fungal disease. *F. Graminearum* was cultured and injected into the plant, and the emerging of signaling molecules in the plant was monitored with nanosensors according to the elapsed days after injection. Even only 2 hours after the fungi injection, when no lesion was detectable, SERS signals of eATP and salicylic acid related to systemic acquired resistance (SAR) were successfully detected. Fungal signals were also detectable after day 2 when the lesion began to be visible. It indicated that the fungal infection was successfully diagnosed at a very early stage with SERS nanosensor, while real-time PCR analysis, an existing diagnostic method, could not confirmed fungal infection until day 1.

Based on our research, we expect that the SERS nanosensors provide novel approach for plant stress diagnosis and early diagnosis of diseases.

9:15 AM EL05.08.02
Dynamic Surface-Enhanced Raman Spectroscopy (d-SERS) Using Plasmonic Metal-Semiconductor Hybrid Nanoparticles for Biosensing with Improved Sensitivity, Selectivity and Reliability Tabitha Jones and Tung Chun Lee; University College London, United Kingdom

Hybrid nanomaterials of plasmonic metals and semiconductors have been the focus of growing research in surface-enhanced Raman spectroscopy (SERS).[1] Significant increase in SERS signals can be achieved by harnessing additional chemical enhancements which occur due to photo-induced charge transfer between a plasmonic metal and a semiconductor. A notable example is photo-induced enhanced Raman Scattering (PIERS), where additional boost of SERS signals can be achieved via UV-light irradiation that creates oxygen vacancies and consequently activates the chemical enhancement.[2] Recently, our group demonstrated the first UV-irradiation-free PIERS effect by employing nanoscale coatings of SnO_2 that are intrinsically rich in oxygen vacancies.[3]

Here, we present a new and unusual SERS phenomenon.[4] Colloidal Ag@SnO_2 core@shell nanoparticles (NPs) were synthesised and fabricated into a compact layer of solid substrate. When SERS measurements were performed, the signal showed a significant and irreversible increase over time (up to 25-fold enhancement after an hour). We name this effect dynamic-SERS (d-SERS). While not observed for uncoated Ag NPs, d-SERS results in much larger signals than conventional SERS (by more than 1 order of magnitude) and reveals target-specific dynamic information. We performed d-SERS measurements for a range of clinically relevant analytes, including uric acid and ketamine, achieving sub-mM limit of detection. Notably, the rate of increase of the characteristic SERS peaks can be used for quantitative detection of these analytes, showing improved reliability of the measurement by reducing the signal variability due to non-uniform substrate morphologies.

In attempt to elucidate the underlying mechanism of d-SERS, we performed X-ray photoelectron spectroscopy (XPS) and studies on laser powers and external heating. We propose that the enhancement is due to plasmonic heating of the Ag NPs, which generates additional oxygen vacancies in the SnO_2 enabling charge transfer and boosting the chemical enhancement component of SERS. This work opens up new possibilities for plasmonic metal-semiconductor hybrid SERS and paves the way for improved detection of a range of analytes, with applications in healthcare, security and environmental monitoring.

The Translational Approach of Colloidal Surface-Enhanced Raman Nanoparticles— Multiplexed Biomedical Imaging and In Vivo Clearance
Jung Ho Yu, Jianghong Rao and Sanjiv Sam Gambhir; Stanford University School of Medicine, United States

In this presentation, I will present our chemistry efforts to engineer surface-enhanced Raman scattering (SERS) nanoparticles for multiplexed biomedical imaging and its translation.
(i) Along with the biomedical applications of SERS for molecular assays and sensing, we have utilized the high spectral resolution of SERS signals for multiplexed preclinical imaging of cancer. To gain sufficient brightness for the in vivo imaging condition, we controlled SERS nanoparticles oligomerization to produce multicore SERS nanoparticles, which displayed Raman scattering as bright as near-infrared (NIR) fluorescence. The large enhancement factor from hot-spot geometry of the multicore nanoparticles along with the NIR-resonant Raman reporters produced the SERS signals as bright as NIR fluorescence. With the multicore SERS nanoparticle palettes, we demonstrated noninvasive and five-plex ratiometric imaging of tumors in live preclinical models, which simulated the noninvasive assessment of multiple biological targets within tumors (Yu JH *et al*. ACS Nano 2021).
(ii) While the colloidal SERS nanoparticles have limited their use in humans because of their inability to excrete from the body, we address this problem by creating supraparticles composed of small-sized nanoclusters. We performed the FDTD simulation of the supraparticle design, in which the maximum enhancement factor of 10^6 was achieved. Then, we chemically synthesized bright supraparticles that enabled in vivo Raman imaging of rodent models. Furthermore, the supraparticles were highly excretable, offering great potential for clinical application of the surface-enhanced Raman scattering imaging by replacing non-excretable SERS nanotags (Yu JH *et al*. bioRxiv 2022).

9:45 AM EL05.08.04
Designing Sequence-Defined Peptoids for Bio-Inspired Synthesis of Plasmonic Nanomaterials Chun-Long Chen; Pacific Northwest National Laboratory, United States

In nature, biomolecules (e.g. proteins) play significant roles in the assembly of hierarchical structures and delivering sequence-specific functions ranging from photosynthesis, to molecular separation, selective ion transport, and tissue mineralization. Inspired by nature, many sequence-defined polymers have been designed and exploited for the bio-inspired materials synthesis. [1] While bio-inspired synthesis offers great potential for controlling nucleation and growth of inorganic particles, precisely tuning polymer-particle interactions has been a long-standing challenge. [2] On the other hand, despite that the morphology-dependent physical and chemical properties of plasmonic nanomaterials are significant for applications in sensing, photonics and catalysis, achieving the high-level of control over morphology seen in biomineral formation controlled by proteins and peptides is still a significant challenge and the rules governing bio-controlled formation of plasmonic nanomaterials remain to be exploited. [3] Among various peptide mimetics, peptoids have received particular attention for achieving predictive materials synthesis because they offer unique opportunities for tuning inter-molecular and molecule-particle interactions solely through variations in side-chain chemistry, while still emulating the capacity of peptides and proteins for molecular recognition. [4]
In this talk, I will report our recent progress in designing sequence-defined peptoids for controlled synthesis of well-defined plasmonic nanomaterials. By engineering peptoid sequences and investigating resulting particle formation mechanisms, we developed a rule of thumb for designing peptoids that predictively enabled the morphological evolution from spherical to nanocoral-shaped metallic nanoparticles. We demonstrate that the individual nanocoral-shaped gold particles exhibit a plasmonic enhancement as high as 10^5 fold. Our study shows that tuning peptoid-peptoid and peptoid-particle interactions and peptoid amphiphilicity are crucial for driving particle attachment during the early stages of formation of the branched nanostructures. [3] In another study, [5] we used variations in peptoid sequence to manipulate peptoid-Au interactions, leading to the synthesis of concave five-fold twinned, five-pointed Au nanostars *via* a process of repeated particle attachment and facet stabilization. Control over peptoid-particle interactions provides diverse possibilities for directed formation of plasmonic nanomaterials. These mechanistic studies will offer molecular level understanding of peptoid-induced plasmonic nanomaterials formation and guide the design of new peptoid sequences that enable the precise tuning of peptoid-peptoid and peptoid-particle interactions for particle attachment and facet-specific stabilization.

Ag Nanogap Shell-Based SERS Immunoassay for Diagnosis of Pancreatic Cancer Chanhee Choi, In-Jun Hwang, Sin Lee, Yoonhee So, Ye-Sol Myeong, Jun-Hyeong Lee and Jong-Ho Kim; Hanyang University, Korea (the Republic of)

Cancer is one of the most leading causes of death in the world. In particular, pancreatic cancer shows the lowest 5-year survival rate mainly due to difficulty in its inaccurate diagnosis at the early stage. In the early stage of pancreatic cancer, most of the patients have no subjective symptoms, and some blood biomarkers used for its diagnosis are very low in concentration. Hence, it is of great significance to design a sensitive diagnostics that can effectively detect the blood biomarkers, including CA19-9, at the early stage of pancreatic cancer in a rapid and accurate manner. Herein, we demonstrate a surface enhanced Raman scattering (SERS) nanoprobe-based immunoassay capable of sensitively detecting blood biomarkers for the diagnosis of pancreatic cancer. To this end, Ag nanogap shells (AgNGS) were prepared as SERS nanoprobes emitting very strong signals through the Raman labels-mediated kinetic control of nanogap sizes. The as-prepared AgNGSs exhibited their own SERS signals with an enormous intensity enhancement of 10^7 and the superior signal stability. After a detection antibody specific for CA19-9 was conjugated onto AgNGSs (denoted AgNGS nanoprobes), they were incubated with capture antibody-conjugated magnetic nanoparticles to detect the target CA19-9 based on the AgNGS SERS signals. This AgNGS nanoprobes-based sandwich immunoassay was able to detect CA 19-9 as the concentrations as low as 0.35 ng/mL from serum samples. The use of this AgNGS nanoprobes-based immunoassay can be extended for the sensitive and selective detection of various blood biomarkers, allowing the early-stage diagnosis of other diseases.

10:45 AM EL05.08.06
Nanoplasmonic On-Chip Immunoassay for Cancer-Derived Exosome Profiling and Exosome-Mediated Cell Communication Analysis Chuanyu Wang, Chung-Hui Huang and Pengyu Chen; Auburn university, United States

Exosomes are nano-sized extracellular vesicles (EVs) that carry unique surface compositions derived from their cells of origin. Tumor cell-derived exosomes play a vital role in the development of cancer by creating a biological milieu in which primary tumor cells can interact with their microenvironment to enhance cancer cell survival, proliferation, and the evasion of immune surveillance. Recent studies suggest that tumor cells can evade immune inspection by secreting excessive exosomes with surface expression of programmed death ligand 1 (PD-L1). Moreover, tumor cell-derived exosomes can stimulate immune cells to secrete cytokines with pro-tumorigenic function. Therefore, we have developed on-chip immunoassays to analyze the role of tumor cell-derived exosomes in the immune system. First, Au@Ag core-shell nano-bipyramids and gold nanorods based on-chip nanoplasmonic sandwich immunoassay provide rapid, sensitive quantification of exosomes and also accurate subtyping exosomes upon PD-L1 expression levels. Second, a specially designed on-chip device consists of cell isolation chambers and a gold nanosphere-based nanoplasmonic digital immunoassay, rendering *in situ* remote cell communication and immune analysis of cellular secretions and traces. These developed platforms provide new methods for tumor cell-derived exosome detection and analysis that have high potential as a future clinical diagnostic tool for monitoring cancer progression and as an analytical tool for accurate and comprehensive analysis of the immune system.

11:00 AM EL05.08.08
Degradation of Rhodamine B Through Plasmon-Assisted R.O.S Generation of Gold Nanorods Ramprasath Rajagopal, Tianhong Ouyang, Gwen Liu, Shyamsunder Erramilli and Bjoern Reinhard; Boston University, United States

Plasmonically enhanced femtosecond irradiation was found to exhibit a remarkable selective inactivation of pathogens while exhibiting minimal side effects on representative biologic and mammalian cell targets. Within the rich set of femtosecond light-matter interactions, nanocavitation was found to be the primary method of inactivation. Under comparable conditions, we report R.O.S mediated degradation of Rhodamine B in the presence of gold nanorods with longitudinal surface plasmon resonance (LSPR) of 750-760nm irradiated by 800nm 100-fs Ti-Sapphire regeneratively amplified laser pulses up to $3mJ/cm^2$. Rhodamine B is a known carcinogenic waste-water pollutant that cannot be degraded easily by current waste-water treatment technologies. We also utilize it as a reporter of generated R.O.S, through a robust and accessible fluorescence monitoring scheme to track kinetics of Rhodamine B degradation. We elucidate the dependence of R.O.S generation on nanorod volume, presence of ligands, and pump fluences. Alongside ongoing theoretical and experimental studies on plasma and R.O.S generation through ultrafast irradiation of gold nanorods, it is interesting to explore R.O.S generation for therapeutic and chemical applications, and better theoretical understanding of the ultra-fast high power light-matter interactions.

11:15 AM EL05.08.09
Tuning Multi-Polar Plasmonic Modes of NIR Absorbing Long AuNRs Toward Ultra-Sensitive Optical Sensor Kyoungweon Park[1,2], Eva Yazmin S. Santos[3], Alexander Govorov[3] and Richard A. Vaia[1]; [1]AFRL, United States; [2]UES, Inc., United States; [3]Ohio University, United States

Ensembles of large aspect ratio gold rods (AuNRs) are of technological interest due to their extreme optical extinction coefficients at visible and near infrared wavelengths, ultra-fast plasmonic and excitonic character, and self-assembly and field responsivity in concentrated systems that tunes optical and rheological behavior via permanent or temporal order. Furthermore, with increasing aspect ratio and volume, higher order harmonics appear due to phase retardation within the excited particle. Such multipole plasmonic resonances exhibit even larger quality factors due to greater electromagnetic field localization, and are useful in applications pertaining to light signal routers, light manipulators, or multistep enhancers in processes such as second harmonic generation. However, suspensions of large aspect ratio AuNRs often exhibit large polydispersity, which obscures these physicochemical behaviors across the ensemble and at the macroscale. Herein, we discuss synthesis procedures that simultaneously satisfy production scalability with no loss to quality and geometric tunability. Quadrupole and octupole resonances are observed in solutions and films from an ensemble of concentrated AuNRs (>1 mg/mL) with aspect ratios ranging from 5 to 10 and structural dispersity less than 0.1. The relationship between multipole resonance, aspect ratio, particle volume, dielectric environment, and polarization agrees with theoretical predictions.

432 Symmetric Chiral Gold Nanoparticles for Enantioselective Sensing Ki Tae Nam; Seoul National University, Korea (the Republic of)

Characterizing molecular chirality and understanding their roles in physiochemical situations has been important in broad research scope such as, biology, chemistry, and pharmaceutics. Despite its importance for biochemical principles and relevant applications, it has been considered impossible to in-situ monitor the chirality change of a few molecules with simple optics because of the scale mismatch with the incident light. Previously we demonstrated strong polarization controllability in 432 symmetric chiral gold nanoparticles (432 helicoids) [1,2], synthesized by exploiting chirality transfer between peptide and high-Miller-index gold surfaces. Based on the 432 helicoids, here we discovered a new mode of circular dichroism (collective CD) that can emerge as a result of collectively resonant oscillations (collective resonance) of hexagonally assembled 432 symmetric chiral gold nanoparticles (2D helicoid crystal) and admit extremely low-density enantioselective detections [3]. The slanted incidence of circularly polarized light (CPL) on the 2D helicoid crystal results in collective oscillation and spinning behavior of optically induced electric dipoles of helicoids, and these spinning dipoles leads to strong and uniform chiral electromagnetic field (optical helicity) across the array. The chiral molecules interact with this field modulate the electromagnetic energy of the 2D helicoid crystal depending on the molecular handedness, which substantiated by the asymmetric shift of transmission spectra. Furthermore, we found the opposite optical responses in 2D helicoid crystal for illumination of oppositely handed CPL which leads drastic contrast in CD spectra. Utilizing the new mode of circular dichroism, we achieved the fluidity-based, in-situ monitoring of molecular chirality at an ultrahigh sensitivity. Then, we further elucidated the importance of collective circular dichroism by translating it into the proof-of-concept devices such as a colorimetric cuvette chiral sensor, an on-chip chiral sensor, the total reflection based SPR system, which enable in-situ, enantioselective, and picomolar monitoring of the DNA/RNA hybridization and the protein folding of the SNARE complex. We believe that our collective circular dichroism-based strategy offers a new paradigm and rational design rules of chiral plasmonic structures for robust enantioselective sensing.

Modeling Colloidal Photonic Nanostructures - from Quantum Simulations to Optimizing Self-Assembled Plasmonic Nanoparticle Superlattices
Jost Adam; University of Southern Denmark, Denmark

Designing new plasmonic nanomaterials with unique physical and chemical characteristics and outstanding optical properties remains a critical task for advanced energy conversion and sensing concepts. Optimizing the material properties to improve their functionality and performance in plasmonic applications is a subsequent challenge to be tackled. This presentation will overview recent advances in the computational design of potential future plasmonic materials, such as transition metals and transparent conducting oxides, and their application in colloidal plasmonic structures. The extraction of complex dispersion characteristics from density functional theory (DFT) calculations allows the integration into subsequent electromagnetic modeling steps, ranging from isolated particles of various shapes and materials to self-assembled plasmonic nanoparticle superlattices, exhibiting collective plasmonic crystal responses.

The talk will furthermore propose a path to minimize the gap between combined quantum- and electromagnetic simulations and experimental characterization of self- or chemically assembled nanostructures, employing a combination of statistical image analysis (based on SEM images of self-assembled clusters), finite-element modeling, and material- and structure optimization. Based on image statistics, we introduce and superimpose various morphological irregularities in our model alongside optimization of particle morphology, potential shell thickness, and particle materials. Our results, corroborated by electromagnetic simulations and complemented by optical characterization and SERS measurements, provide insight into the near-field enhancement of nanospheres, nanorods, and nanotriangles, arranged in sub-wavelength superlattices of macroscopic dimensions.

9:00 AM *EL05.11.04
Growth, Assembly and Transformation of Plasmonic Nanostructures in Confined Spaces Yadong Yin; University of California, Riverside, United States

Growth, assembly, and transformation in confined spaces represent a set of indirect methods for producing colloidal plasmonic nanostructures with highly tunable morphologies and configurable optical properties. We will discuss the basic working mechanisms involved in such synthesis and assembly strategies, their applicability, and the directions of future efforts. We will reveal the unique feature of the space-confinement method in creating thermodynamically unstable nanostructures. Upon removing the confinement, these nanostructures transform into more stable morphologies through reconstruction, providing opportunities for designing new nanostructures with promising applications in sensing, anti-counterfeiting, information encryption, and displays. Further, we will discuss the many opportunities of this synthesis strategy in creating hybrid nanostructures that integrate the plasmonic property with other physical properties

Photocatalysis Enhanced by Plasmonic Nanoparticles Dongling Ma; Institut national de la recherche scientifique (INRS), Canada

Due to their unique, size- and shape-tunable surface plasmon resonance, plasmonic nanostructures have recently been explored for increasing the efficiency of photocatalysis. Essentially they enhance and/or broaden solar photon harvesting via improved light scattering, strong near field effect and/or hot electron injection. In this talk, I will present our recent work on the synthesis of plasmonic nanoparticles and hybrid nanomaterials (the assemblies of plasmonic nanoparticles and semiconductor photocatalysts) as well as their applications in solar fuel and photocatalytic degradation of pollutants in our environments [1-5]. Rational design of hybrid nanomaterials, which is the key to maximize the beneficial plasmonic effects, is highlighted. One example is about developing an in situ ligand method to load cost-effective, plasmonic semiconductor CuS nanoplatelets on rationally selected BiOCL semiconductor nanosheets and nanoplates, with a close interface, monodispersion and relatively large interface. As a result, we achieved the efficient hot hole collection from the CuS nanoplatelets as supported from largely broadened photocatalysis. Theoretical modelling revealed that the transverse mode dominates the hot hole generation and has a greater contribution to photocatalysis than the longitudinal mode. This work demonstrates the feasibility of harvesting hot holes from plasmonic semiconductors and opens a new route for rational design of broadband and cost-effective plasmonic photocatalysts.

1:30 PM EL05.11.02
Optical Coupling of Plasmonic and Surface Lattice Resonances in Gold Nanocube Arrays Marlo Vega[1], Jean-Francois Bryche[1], John Hulse[2], Michel Canva[1], Paul Charette[1] and Li-lin Tay[2,1]; [1]Université de Sherbrooke, Canada; [2]National Res Council Canada, Canada

The ability of localized surface plasmon to confine light to a sub-diffraction-limited mode volume can drive coherence effects in quantum emitter systems that lead to quantum photonic applications. Periodic arrays of plasmonic nanostructures can further sustain photonic lattice resonances (also referred to as surface lattice resonance) that can be tuned to couple with plasmonic resonance. Here, we will demonstrate the varying degrees of optical coupling that arise when periodic arrays of gold nanocubes (AuNC) are grown atop a gold mirror. This architecture allows us to independently control the two distinct optical modes, a plasmonic gap mode between the AuNC and the gold surface and a lattice resonance mode resulting from constructive interference from the scattering of the periodic array. From electromagnetic simulation and reflectance spectroscopy, we will show that these two resonance modes can be tuned and show a varying degree of coupling that is dependent on the nanostructure geometry, lattice pitch and lattice symmetry. A series of periodic arrays of 73 nm of AuNC on top of a 100 nm Au mirror with a 4.6 nm polymethyl methacrylate (PMMA) spacer and with periodicity ranging from 500 nm to 950 nm were fabricated through a Si nanofabrication services. The gaps between the AuNCs are partially filled by SiO2 spacer. Electromagnetic simulation of these structured arrays has shown that the breadth and peak of the lattice resonance mode sharpens and red-shits with increasing periodicity. In the lowest periodicity array, only plasmonic gap modes are observable. When the periodicity reaches 500 nm, two optical modes become visible with the longer wavelength reflectance peak corresponding to the plasmonic gap mode and the shorter wavelength peak associated with the lattice resonance. A visible coupling of the plasmonic gap mode to the surface lattice mode was observed in an AuNC array with 600 nm periodicity which is indicative of mode hybridization. We will also discuss the impact that particle geometry and material have in this presentation.

1:35 PM EL05.11.03
Bimetallic Superatomic Bi-icosahedral Au_xCo_y Clusters for Data Storage Benjamin Raufman, Desmond Smith, Zaid Qureshi, Dariush Aligholizadeh and Mary Sajini Devadas; Towson University, United States

Atomically-precise gold nanostructures have garnered considerable research interest over recent years because of their applications in imaging, catalysis, sensing, medicine, and more. One of the most investigated gold nanostructures is the thiol-capped Au25 nanocluster due to its exceptional stability, facile synthesis, and the ease with which its physiochemical properties can be manipulated. The stability of this nanocluster derives from its “magic-number”, meaning its closed outer-electron shell. Au_{25} also exhibits superatomic properties due to its ultra-small size and construction from an even smaller superatom: the Au_{13} nanocluster. The Au_{25} cluster has been synthesized in two structural varieties: the icosahedron and the bi-icosahedron forms. Recent studies have shown this cluster can be easily doped with other metallic atoms, each offering unique properties and insights, although most of these studies focus on the icosahedron structures. Many of these studies demonstrate some advanced property, such as increased fluorescent quantum yield, increased catalytic effect, or magnetism, which have been taken advantage of for applications in both the biomedical field and advanced chemical research.

Herein, we report a method to synthesize and purify a novel bi-icosahedron cobalt-doped $Au_{25-x}Co_x(PPh)_{10}(SR)_5Cl_2$ cluster for the first time. Although the synthesis is straightforward, the purification is cumbersome. Once purified, UV-vis absorption, fluorescence, NMR, and electrochemical analysis were utilized to characterize the novel cluster. Data gathered using these methods showed results consistent with the expected results based off previous reports on its theoretical icosahedral counterpart, as well as the un-doped bi-icosahedral cluster. The UV-vis spectra of the novel clusters is highly similar to that of the un-doped cluster, with the most notable difference being a splitting of the peak in the NIR region. The fluorescent quantum yield shows a slight decrease from that of the un-doped cluster. Most importantly we see the effect of spin-orbit coupling in the doped clusters. These results suggest a number of future potential applications for these clusters in computers.

“Meta”-Optical Fibers—Integration of Metaphotonics with Fiber Optics Andrew Palmer, Leon Zhang, Stuart Love, Zoey Liu and Ho Wai (Howard) Lee; University of California, Irvine, United States

Optical fiber is a well-established and efficient light-guiding medium. Although optical fiber is efficient for transmitting light, its functionality is limited by the dielectric material of the core, which has poor optoelectronic, magneto-optical, and nonlinear-optical responses and has a dielectric diffraction limit.

Therefore, the optical properties of the optical fiber such as phase, amplitude, polarization, and mode profile, cannot be altered after the fiber drawing fabrication, thus limiting the development of novel in-fiber devices. Integration of new materials and nanostructures into fiber will enhance processing/transmission capabilities and novel functionalities.

In this talk, I will present our recent development of “Meta”-optical fiber, an advanced optical fiber integrated with emerging nanophotonic concepts such as optical metasurfaces, plasmonic nanowires, and zero-index photonics. I will present the development of ultrathin optical metalens which is cascaded on the facet of a photonic crystal fiber that enables light focusing. I will also discuss the first experimental demonstration of zero-index resonance excitation in an optical fiber coated with AZO nanolayer and excitation of plasmonic resonances on holey optical fiber for advanced optical sensing and tip-enhanced Raman spectroscopy. These advanced “meta”-optical fibers open a pathway to revolutionary in-fiber lasers/spectroscopies, optical imaging/sensing, and optical communication devices.

11:00 AM *EL06.01.02
Singularity Engineering and Structured Light by Meta-Optics Ahmed Dorrah and Federico Capasso; Harvard University, United States

Metaoptics offer fresh opportunities for structuring light as well as dark. I will discuss metasurfaces that enable light’s spin and OAM to evolve, simultaneously, from one state to another along the propagation direction[1,2], along with nonlocal supercell designs that demonstrate multiple independent optical functions at arbitrary large deflection angles with high efficiency.[3] In one implementation the incident laser is simultaneously diffracted into Gaussian, helical and Bessel beams over a large angular range and in another one a compact wavelength-tunable external cavity laser with arbitrary beam control capabilities including hologram lasing is demonstrated. We also propose a new class of computer-generated holograms whose far-fields have designer-specified polarization response, dubbed Jones matrix holograms.[3] We provide a simple procedure for their implementation using form-birefringent metasurfaces. In particular, we demonstrate holograms whose far-fields implement parallel polarization analysis and custom waveplate-like behavior. The realization of 2D phase and polarization singularities and the unique applications that they will open will be discussed[4] ·along with recent results on the realization of an equally spaced liner array of 0D phase singularities using inversed designed cylindrically symmetric phase only metasurfaces. Finally, a complete, topologically protected polarization singularity has been reported for the first time; it is located in the 4D space spanned by the three spatial dimensions and the wavelength and is created in the focal region of a lens using a metasurface.[5] The field Jacobian plays a key role in the design of such higher dimensional singularities, which can be extended to multidimensional wave phenomena, and pave the way to novel applications in topological photonics.

Electrochemically Actuated Metasurfaces Jason G. Valentine; Vanderbilt University, United States

In this talk I will explore the hidden potential of electrochemically actuated metasurfaces. Electrochemical actuation is unique in that it provides for control over both the volume expansion of a scatterer as well as the free electron density for permittivity control. I will explore this freedom in dynamic tuning of titanium dioxide and silicon-based metasurfaces, materials already popularized in the field of photonics for their high index and low loss throughout the visible spectrum. Using these materials, we leverage electrochemical intercalation of lithium to initiate phase changes in a continuously tunable, reversible, and bi-stable manner, using bias voltages that are an order of magnitude less than similar devices.

1:30 PM *EL06.02.01
Controlling the Thermal, Optical and Mechanical Properties of Metasurfaces for Applications Towards Laser Sails Victor Brar; University of Wisconsin--Madison, United States

I will discuss how the materials used in metasurface-based laser sails set limits on their thermal stability and the maximum powers that can be used for propulsion. It will be shown that under high optical intensities, non-linear processes and temperature-dependent absorption can create thermal runaway effects in commonly used dielectrics such as silicon. In particular, the combination of two-photon absorption and temperature-dependent bandgap narrowing sets the equilibrium temperature for Si-based metasurfaces in high fluence conditions, and we find the conditions where no equilibrium is achievable. We will also show that the thermal runaway can nucleate near material defects and zodiacal dust, and we demonstrate the time evolution of those processes. Design strategies for mitigating such processes and simultaneously achieving high efficiency will be proposed which include minimizing non-linear materials, and including sacrificial zones on the sail that prevent the spreading of damage. Finally, we will discuss how thermal cooling can be used to impart mechanical stability on the sail, allowing for minimal movement within the drive laser beam.

2:00 PM *EL06.02.02
Nonlinear Optics in Space and Time with Novel Materials Vladimir Shalaev[1], Soham Saha[1], Samuel Peana[1], Mustafa Ozlu[1], Eran Lustig[2], Ohad Segal[3], Alexandra Boltasseva[1] and Mordechai Segev[3]; [1]Purdue University, United States; [2]Stanford University, United States; [3]Technion–Israel Institute of Technology, Israel

The emerging near-zero-index (NZI) materials have recently opened up new chapters of nonlinear optics by enabling strong light-matter interactions in both nanophotonic and hybrid photonic/plasmonic systems as well as greatly enhanced optical phenomena such as negative refraction, time refraction, and photon acceleration. Building up on our work on the extraordinary modulation of the refractive index in transparent conducting oxides (TCOs), we have demonstrated negative refraction in time-varying, strongly coupled optical media. We show large changes in the epsilon-near-zero (ENZ) points in undoped zinc oxide, with 20-ps response time, and utilize the permittivity modulation to enhance the third-harmonic generation, and develop optically controlled polarization switches. We also used the large nonlinearities in NZI TCO films for ultrafast pulse characterizations. Furthermore, we showed that the femtosecond modulation of TCO permittivity can be achieved by a tightly controlled pulse, opening new directions in nonlinear optics where a temporal modulation of permittivity can result in phenomena such as time refraction, reflection, and open bandgaps in the momentum of a photon pulse. This forms the basis of our investigations in photonic time crystals which can pave the way in gain-free lasing, non-reciprocal optics, and many other exciting fields.

2:30 PM EL06.02.03
Chemically and Electrically Driven Geometric Reconfiguration of Soft Polymer Metasurfaces for Dynamic Wavefront Manipulation Siddharth Doshi[1], Anqi Ji[1], Ali I. Mahdi[1], Scott T. Keene[2], Yi-Shiou Duh[1], Philippe Lalanne[3], Eric A. Appel[1], Mark L. Brongersma[1] and Nicholas Melosh[1]; [1]Stanford University, United States; [2]University of Cambridge, United Kingdom; [3]Université Bordeaux, France

The optical transfer functions of engineered metasurfaces are defined by the geometric arrangement and material properties of their constituent meta-atoms. Optical metasurfaces have traditionally been fabricated with rigid inorganic materials and accordingly, have geometries that are fixed upon fabrication. Tuning of dynamic metasurfaces based on inorganic materials typically relies on modulation of their refractive index. While significant progress has been made in tuning with semiconductors (by free carrier generation), TMDC monolayers (by exciton generation) and phase change materials, these devices still face challenges including limited index tuning ranges and low power efficiencies.

In contrast, the geometric dimension of polymer materials can be widely reconfigured by a diverse range of stimuli, providing a powerful lever to control optical responses. For example, some thin polymer films can swell by 2-3 times their original thickness in the presence of different solvents or by electrically induced ion uptake. We leverage this property to create dynamically reconfigurable optical metasurfaces that that offer control over the intensity and phase of reflected light. Our platform consists of a spacer layer of the widely used and commercially available conducting polymer, PEDOT:PSS, situated between a metallic mirror and plasmonic nano-antennae. The degree of swelling of the PEDOT:PSS spacer is reversibly tuned through fluidic application of solvents with varying degrees of solvation energies. We thereby change the distance between the mirror and plasmonic nano-antennae and hence control the phase of light scattered from individual nano-antennae. We use this platform of “Expansion Plasmonics” to demonstrate high diffraction efficiency beam steering and continuous tuning of colour over a full gamut. In contrast to systems relying on changes in the dielectric constant of specific materials over limited spectral ranges, our approach, involving geometric reconfiguration of transparent polymers, could in principle enable full light field control across a broad range of spectral regions, spanning from UV to THz. Finally, we demonstrate the wider applicability of our platform by tuning our metasurface with other stimuli, including electrochemical control of local ion concentrations.

Our work opens the door to the broad integration of a range of polymers, engineered to respond to specific chemical stimuli, into reconfigurable optical elements with applications in bio-sensing, display, and imaging.

Analog Optical Image Processing and Computing with Metastructures Andrea Alu and Michele Cotrufo; City University of New York, United States

In this talk, I will discuss our recent progress in the area of analog signal processing using metasurfaces and metastructures, and the associated opportunity in the context of low-energy, ultra-fast computations using light at the nanoscale. I will also discuss the potential opportunities stemming from using feedback in these structures to realize analog optical computation, and the possible impact for photonic technologies.

3:45 PM *EL06.02.05
Dynamic Wavefront Shaping with High Quality Factor Metasurfaces Jennifer A. Dionne[1], Mark Lawrence[2], Elissa Klopfer[1], Sahil Dagli[1] and Hamish Carr[1]; [1]Stanford University, United States; [2]Washington University in St. Louis, United States

Wavefront shaping and control is essential for advancing optical technologies spanning communication, computation, and sensing. Metasurfaces promise to miniaturize future optical components, like beam steerers and lenses, for lightweight, compact, and on-chip platforms. However, most current metasurface designs are static, unable to flexibly tune their responses to environmental or operational cues once fabricated.

Here, I present the design, fabrication, and characterization of dynamic metasurfaces that efficiently modulate their behavior, based on integration of high quality factor (high-Q) resonances. High-Q resonances have two primary features that augment metasurface tuning mechanisms. First, high-Q resonances are characterized by very sharp spectral features that are extremely sensitive to refractive index variation, allowing even very small perturbations to strongly vary the resulting optical response. Second, high-Q resonances are accompanied by strongly-enhanced near fields, which can improve modulation mechanisms that rely on electromagnetic near-fields, such as nonlinearities.

This presentation describes several novel devices enabled by high-Q metasurfaces. First, we demonstrate tunable high-Q metasurface lenses. Controlling the spectral position of the high-Q resonances via thermal or nonlinear effects enables high-fidelity modulation of the focal characteristics. Second, we demonstrate reconfigurable high-Q beamsplitters and beamsteerers through electro-optic control. The inclusion of lithium niobate and direct control of each nanoantenna resonance in the device opens up full operational control through voltage biasing. Finally, we demonstrate how high-Q metasurfaces enable dynamic detection of molecules and their interactions, with the potential for single-molecule vibrational spectroscopy.

5:00 PM EL06.03.01
Development of Integrated Optofluidic Biosensor to Image Protein-Protein Interactions Yunju Chang and Jiandi Wan; University of California, Davis, United States

Protein-protein interaction plays a pivotal role in most cellular activities, including cell division, proliferation, and signaling. Therefore, studying protein

interactions is essential for understanding the fundamental mechanism of cellular activities, disease diagnosis, and drug development. Conventional approaches to study protein interactions include the enzyme-linked immunosorbent assay (ELISA) and the Forster resonance energy transfer (FRET), but the drawback is that these technologies require optical labeling. Currently, label-free photonic biosensors are getting attention because of their high sensitivity, small footprint, and multiplex assay. However, applications for photonic biosensors are mostly limited to the detection of biomolecules either by trapping the analyte of interest or by immobilizing interacting ligands. Therefore, our goal of this study is to develop label- and immobilization-free optofluidic biosensors that can image freely interacting proteins. The technological gaps are that (*i*) the current approaches to integrate microfluidic channels are not confined to the sensing area which requires larger sample volume than needed and (*ii*) to our best knowledge, there have been no studies reported with surface modification or functionalization which enables proteins to interact freely.
Here, we demonstrate ring-assisted Mach-Zehnder Interferometer (RA-MZI)-based biosensor with microfluidics confined on the sensing area. RA-MZI photonics component measures the change of local refractive index upon protein-protein interaction. Due to the innate characteristic of the resonator, such as high quality factor or large extinction ratio, ring resonator-based sensors show low limit of detection and high sensitivity. To overcome the fabrication variations and further maximize the sensitivity of sensor, we have incorporated microheater on both reference and sensing arms. By manipulating the temperature, we have increased the extinction ratio, and in return, increased the sensitivity. Our next steps will be to coat the microfluidics surface with supported lipid bilayer so that we can image protein interaction while both interacting proteins are relatively freely moving on the lipid membrane. This label- and immobilization-free optofluidic biosensor will allow us to discover novel approaches to early-stage detection by studying the mechanisms and fundamentals of disease-associated protein interactions.

5:00 PM EL06.03.02
Thermally Triggered Multilevel Diffractive Optical Elements Tailored by Shape Memory Polymers for Temperature History Sensors Dokyung Kyeong, Minsu Kim and Moon Kyu Kwak; Kyungpook National University, Korea (the Republic of)

Shape memory polymers (SMPs) have been widely used as sensory material due to capability to induce morphological transition in response to external stimuli. Diffractive optical elements (DOEs) have shown their attractive potential as sensing platforms owing to the high sensitivity provided by the real-time response of far-field diffraction patterns. Many studies have demonstrated a series of reconfigurable DOEs with SMP based on conventional template molding process, which is fast, inexpensive and has no limitation in materials. However, in most cases, simple surface relief structures such as micro-groove grating were chosen as a proof of principle model due to their straightforward relationship between ridge height and diffraction intensity. Thus, they still need to be validated in a much more complex diffraction pattern which facilitates achieving higher information content to provide greater flexibility in device design and operation. Here, by combining the temperature-sensitive characteristic of SMP and the display characteristic of multilevel DOEs, an optical temperature sensing film showing the temperature information as a change of far-field diffraction images is proposed. To achieve this, micropatterns of the DOEs are imprinted on epoxy based SMP film, which can be programmed to hold a temporary optical image and revert to its original image when exposed to a specific temperature. Convolutional neural networks (CNNs) are utilized to detect and measure the optical image transformation depending on temperature. Furthermore, the threshold temperature where the image transformation occurs can be customized by varying the chain flexibility of the SMP. Based on a range of transition points, imprinting the desired combination of SMP-DOEs on a film, a sensor that can record and inform the temperature history is demonstrated. This work can be used for the compact and reliable optical temperature indicator, which can be applied in temperature-sensitive industries such as food and pharmaceutical.

5:00 PM EL06.03.03
Self-Assembled Optofluidic 3D Chemical Sensors Zihao Lin, Chunhui Dai and Jeong-Hyun Cho; University of Minnesota, Twin Cities, United States

Most plasmonic-based sensors are designed on two-dimensional (2D) planar surfaces with an enhanced electromagnetic field close to it. The enhancement effect decays in exponential form as samples move away from the surface. This results in a tiny nanoscale sensing area where long distances between the sensing position and the micro/nano specimen is undesired. Here, we introduce a method that enforces the specimen to be located close to the sensing area (plasmonic structures) using three-dimensional (3D) nano architectures self-assembled with nanoscale precision. A sensor (nanosplit rings) patterned on the inner surface of nano tubular 3D structures allows a strong interaction between the specimen and the optical sensor. The self-assembly process offers great flexibility in scaling tube diameters from 500 nm down to 100 nm. The proposed method also bridges the large gap between nanofluidics and nanoplasmonics. Here, a dynamically optofluidic sensing behavior can be achieved during biomolecular transportation in the tube, at the same time, these biomolecules can be detected via nanosplit rings inducing an electromagnetic field enhancement effect. Different 3D plasmonic structures, including nanocylinders, parallel plates, and prisms, were self-assembled and simulated. The results indicate that nanocylinders have the highest optical enhancement. Tests were first carried out to verify the nanotubes' ability to flow liquid inside them then hemoglobin was used as the target biomolecule and was flowed in the fabricated 3D plasmonic tubular structures. Raman result demonstrates that a 22 times higher enhancement intensity was realized for hemoglobin fingerprints in the 3D structure compared to a 2D planar surface. This result shows the power of utilizing 3D architectures in nanoscale, leading to enhanced physical (optical) properties.

5:00 PM EL06.03.04
Asymmetric Pairing of Cholesteric Liquid Crystal Droplets for Programmable Photonic Cross-communication Sihun Park[1], Sang Seok Lee[2] and Shin-Hyun Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Chiral nematic liquid crystals, or cholesteric liquid crystals (CLCs), are one of the liquid crystal phases that display unique optical properties. The CLCs are typically formulated by the self-assembly of LC molecules in the presence of a chiral dopant. The introduction of chirality into an achiral LC host induces a regular rotation of the director of LC molecules along the helical axis. As the periodic modulation in refractive index between ordinary and extraordinary values occurs due to the helical structures, the CLCs can develop a photonic stopband property, selectively reflecting circularly-polarized light with the same handedness as the helical structure at the stopband region. In particular, structural colors are produced by wavelength-selective diffraction when the stopband lies in the visible spectrum. The position of the stopband in terms of wavelength can be dynamically tuned with external stimuli, such as temperature, light, and electric field. These stimuli-responsive optical properties make the CLCs fascinating as anti-forgery materials, sensors, and optical particles. For specialized applications, the CLCs have been enclosed by curved surfaces, transforming into droplets, shells, microparticles, and microcapsules.
Interestingly, the spherical geometry gives rise to additional optical patterns for the CLC compartment, which are otherwise difficult to obtain in a bulk film format. For identical and contiguous CLC droplets, a color pattern arises by the retroreflection comprising double or triple reflections at the curved surfaces and the direct single reflection on the top surfaces, which is referred to as photonic cross-communication. CLC shells with a thin-top shape or buckled shape can show another pattern of color rings through internal reflection. When multiple CLC compartments are combined to form CLC multishell, additional color patterns develop through internal cross-communication. These diverse kinds of color patterns are particularly promising for optical encryption in anti-forgery applications. However, the encryption of optical codes is extremely dependent on the direct single reflection from the top surfaces of CLC droplets. To exploit various color patterns as optical authenticators, it is essential to formulate the color patterns in a programmable way. In this study, we investigate the photonic cross-communication taking place between two distinct CLC droplets with different sizes and stopband

wavelengths, thereby establishing an optical platform for programming resulting color patterns. The CLC droplets with a size variation and a stopband wavelength variation are prepared using capillary microfluidic devices, which are then positioned in contact to form a set of asymmetric pairs. As discussed, color patterns are generated by double reflections of light at an angle of 45° at each surface. However, when two CLC droplets with distinct stopband wavelengths yet the same size are paired, the optical path for the double reflections is imperfect due to a mismatch in stopbands. That is, it is necessary to construct asymmetric pairs with an optimum size ratio for two different stopband wavelengths to maximize the photonic cross-communication. We have experimentally investigated the relationship between stopband-wavelength ratios and droplet-size ratios for the most effective photonic cross-communication using various sets of droplet pairs and verified the relationship using a mathematical model. Furthermore, we have demonstrated that the wavelength of the photonic cross-communication is affected by refraction at the surfaces of CLC droplets. With the principle of design, we have shown the evolution of bright photonic cross-communication patterns between asymmetric pairs of distinct CLC droplets. We believe that various pairs of CLC droplets with distinct stopband wavelengths and consequent photonic cross-communication patterns will open a new chapter in advanced optical encryption for anti-counterfeiting.

SESSION EL06.04: Adaptive Nanophotonic Materials I

8:30 AM EL06.04.01
Machine Learning Driven Steering of Incoherent Emission from III-V Metasurfaces Saaketh S. Desai[1,2], Prasad Iyer[1,2], Sadhvikas J. Addamane[1,2], Remi Dingreville[1,2] and Igal Brener[1,2]; [1]Center for Integrated Nanotechnologies, United States; [2]Sandia National Labs, United States

Spatiotemporal control of incoherent emission from LEDs and thermal sources remains a critical challenge for state-of-the art beam steering methods designed for coherent sources. Recently, we have shown that photoluminescence (PL) from InAs quantum dots embedded in GaAs metasurfaces can be dynamically steered over 70° using structured optical pumping. This was achieved by creating a dynamic spatially varying resonant phase gradients across the metasurface using an ultrafast (80fs, 1 Khz rep rate, 3mJ/cm^2) 800nm pump which images the pattern from a spatial light modulator (SLM) onto the metasurface. This photoluminescence (beam) steering was done solely based on periodic blaze grating order patterns, which created a periodic refractive index profile using Drude free-carrier refraction, resulting in a spatial phase gradient on the metasurface and ultimately directing the momentum of the light emission. In this work, we solve the inverse problems of steering PL towards a specific direction using generative models and active learning from aperiodic spatial pump patterns. We use a variational autoencoder to generate novel pump patterns beyond human-intuition, and use Bayesian optimization to discover these pump patterns on the SLM that steer the photoluminescence towards specific angles. We find that these pump patterns are 10x more efficient in beam steering compared to the initial periodic blaze grating pump pattern designed using human intuition. Our work provides a novel machine learning driven closed-loop platform to understand and discover the physics of incoherent emission steering from metasurfaces with potential applications for augmented and virtual reality displays.

8:45 AM EL06.04.02
Electrochemically-Gated $La_{1-x}Sr_xCoO_{3-\delta}$ (LSCO) as a Phase-Change Material for Active Metasurfaces Rohan D. Chakraborty, William M. Postiglione, Supriya Ghosh, K. A. Mkhoyan, Chris Leighton and Vivian Ferry; University of Minnesota-Twin Cities, United States

Metamaterials have aided the development of infrared nanophotonics through applications in photonic circuits, telecommunications, thermal imaging, and more. While the optical response of traditional metamaterials is static, recent advances have imparted *tunability* to these metamaterials by pairing them with materials that undergo controllable refractive index changes.

Here, we present ion-gel-gated perovskite $La_{1-x}Sr_xCoO_{3-\delta}$ (LSCO) thin films as a new class of room-temperature, electrically tunable, phase-change materials along with their applications. We will show Kramers-Kronig consistent refractive index models before and after gating of LSCO films at $0.00 < x < 0.70$, ranging from the visible to mid-infrared spectral range, as measured with a combination of spectroscopic ellipsometry and infrared optical spectroscopy. The measured optical properties are correlated with insights from XRD, TEM, and electronic transport.

We find that as-grown perovskite LSCO films are high index insulators at $x < 0.18$ but highly lossy Drude metals at $x > 0.18$, following the percolation-induced insulator-metal transition known to occur in the perovskite phase. When LSCO is implemented in ion-gel-gated transistors, positive gate voltage and resulting oxygen vacancy formation drives electrochemical reduction, in some cases inducing a topotactic transition from the perovskite phase to an oxygen-vacancy-ordered brownmillerite phase, $La_{1-x}Sr_xCoO_{2.5}$. Electrochemical gating of $x > 0.18$ LSCO films reveals a metal-insulator transition from the highly lossy perovskite phase to a high index, low loss insulating phase. LSCO films at $x < 0.18$, despite their nominally insulating character, still undergo remarkable refractive index changes to another lower index, lower loss insulating state. Finally, electromagnetic simulations of a tunable plasmonic absorber show that insulator-insulator contrast in $x = 0$ LSCO can shift the surface plasmon resonance wavelength of a gold nanodisk by $\Delta\lambda > 600$ nm, and metal-insulator transitions in $x = 0.50$ LSCO can achieve single-wavelength reflectance modulation of $\Delta R > 60\%$, even at LSCO film thicknesses as low as 20 nm. Together, these findings frame electrochemically-gated LSCO films as a library of room-temperature phase-change materials for infrared applications including telecommunications and thermal radiation control.

9:00 AM EL06.04.03
Reconfigurable Switches and Color Pixels Based on Metal-Hydrides Systems Micah Karahadian and Jeremy N. Munday; University of California, Davis, United States

Adaptive and reconfigurable photonic devices are critical to a variety of applications from photonic circuits and color pixels to computing and quantum information processing. One promising class of materials are metal-hydrides, which can undergo extreme changes in optical properties via insertion of hydrogen atoms into the metallic lattice, which can be controlled through applied bias or gas pressure. Here we present our recent work on developing reconfigurable optical devices based on switchable metal-hydrides. In addition to optical, mechanical, and chemical characterization [1], we have developed vivid color pixels with wavelength shifts (>100 nm) during hydrogenation of various materials. Through appropriate design, we have produced structures that have five orders of magnitude change in reflectivity, as well as systems for physical encryption and counterfeit detection. We find alloying of these metal films not only improves cyclability, but also leads to higher hydrogen fractions than previously obtained as a result of film stresses and microstructuring [2]. Finally, we will show how novel optical substrates can enhance these effects [3] and how nanostructuring can lead to additional opportunities for adaptive systems with tunable optical behavior.

9:15 AM EL06.04.04
Active Optical Metasurfaces Based on Low Loss Phase Change Materials Fouad Bentata[1,2,3], Lotfi Berguiga[4,2], Xavier Letartre[4,2], Stephane Monfray[1], Patrice Genevet[3] and Sébastien Cueff[2,4]; [1]STMicroelectronics, France; [2]Institut des nanotechnologies de Lyon, France; [3]Centre de Recherche en Héterostructures et Epitaxie et ses Applications, France; [4]Ecole Centrale Lyon, France

Metasurfaces are promising optical components that enable light engineering by controling the phase, amplitude or/and polarization achieving large panel of applications such as optical filtering, focusing, holographic projection, spatial light modulation, lidar and neuromorphic computing. Inherent passive functionality limits full integration into smart devices and multi-functionality on demand. Active metasurfaces are a potential solution for a wide range of applications. Several use cases have been detected based on the level of design complexity. First, the correction of manufacturing aberrations in post-fabrication for mass production and highly sensitive applications. Second, increasing the functionality of fixed features into binary or continuously adjustable features is of great interest. Finally, an on-demand addressable meta-atom would allow arbitrary light control.
Among the different tuning mechanisms, the exploitation of phase change materials (PCMs), such as GeSbTe, GeTe, seems particularly relevant as they possess remarkable optical properties that can be strongly modulated by reversibly changing the crystallinity of the material. This also-called standard PCMs, widely used in non-volatile memories, exhibit high optical losses in the visible and near infrared range, which limits the efficiency of optical devices. A new class of PCMs called low-loss PCMs, such as Sb2Se3, Sb2S3, GeSbSeTe, is more suitable for optical metasurfaces given the low optical losses and phase change properties[1].

In this work, we focus on the design, fabrication and characterization of metasurfaces based on low-loss PCMs, especially Sb2S3. First, an active metasurface based on the Pancharatnam Berry principle is optimized to passively encode the deflection angle information in a given polarization state, and then, depending on the crystallinity state, we switch from one polarization state to the other, realizing a binary beam deflection. Next, an active filter will be presented, allowing both independent passive control of an extremely high Q factor using design-controlled perturbation and active spectral control using the active properties of PCMs. After showing examples of potential designs of the active spectral and spatial light control, we finally present the nanofabrication and characterization challenges that have been addressed.

Programmable Photonics with Metal Insulator Transition Jiachen Li, Tiancheng Zhang, Kaichen Dong, Jie Yao and Junqiao Wu; University of California, Berkeley, United States

Materials with metal insulator transition can provide real-time reconfigurability of photonic devices, which would create new optical functionalities via recompilation of photonic operators. Exploiting the hysteretic phase transition of vanadium dioxide, we achieved an all-solid, rewritable metacanvas on which nearly arbitrary photonic devices can be rapidly and repeatedly written and erased. More recently, we fabricated a reconfigurable twisted bilayer photonic moire superlattice that hosts a localized mode in the mid-infrared spectral range, immune to fluctuations in layer separation and twist angle but subject to the metal insulator transition. The ease and flexibility in fabrication make it a promising platform for probing new physics in moire superlattices.

10:30 AM *EL06.04.06
3D Meta-Optics for Sorting Light by Wavelength, Polarization and Angle of Incidence Andrei Faraon, Gregory Roberts, Conner Ballew and Ian Foo; California Institute of Technology, United States

Modern imaging systems can be enhanced in efficiency, compactness, and range of applications through introduction of multilayer nanopatterned structures for manipulation of light based on its fundamental properties. Metaoptical components can be tailored to respond to these varying electromagnetic properties, but have been mostly explored in single-layer, ultrathin geometries, which limits their capacity for multifunctional behavior. Here we show the design of several pixel-sized scattering structures which sort light efficiently based on its wavelength, polarization state, and spatial mode. The multispectral and polarimetry devices are further fabricated via two-photon lithography and experimentally validated in the mid-infrared.

Picophotonics - Subatomic Optical Localization Beyond Thermal Fluctuations Tongjun Liu[1], Cheng-Hung Chi[1], Bruce Ou[1], Kevin F. MacDonald[1] and Nikolay I. Zheludev[1,2]; [1]University of Southampton, United Kingdom; [2]Nanyang Technological University, Singapore

Despite recent tremendous progress in optical imaging and metrology, the resolution gap between atomic scale transmission electron microscopy and optical techniques has not been closed. Is optical imaging and metrology of nanostructures exhibiting Brownian motion possible with resolution beyond thermal fluctuations? Here we report on an experiment in which the average position of a nanowire with a thermal oscillation amplitude of ~150 pm is resolved in single-shot measurements with accuracy of 39 pm using light at a wavelength of $\lambda = 488$ nm, providing the first example of such sub-Brownian metrology with ~$\lambda/12{,}000$ resolution. To localize the nanowire, we employ a deep learning analysis of the scattering of topologically structured light, which is highly sensitive to the nanowire's position. As a non-invasive optical metrology with sub-Brownian absolute errors, down to a fraction of the typical size of an atom (Si: 220 pm diameter), it opens the exciting field of picophotonics.

2:00 PM *EL06.05.02
Active Metasurface Systems for Angle-Sensitive and Low Intensity Imaging Harry A. Atwater; California Institute of Technology, United States

The ability to dynamically control the optical response in the quasi-static and time-modulated regimes opens a multidimensional design space that can be fully harnessed by developing appropriate nanophotonic structures for arbitrary manipulation of light. Active metasurfaces have potential as building block components of meta-imaging systems, in which each cascadable element enables dynamic, independent, and comprehensive control over all constitutive properties of light in both reflection and transmission. Active metasurfaces can also form the components angle-selective lens-less imaging systems. I will discuss the properties and characteristics of angle-selective active metasurface imaging systems and compare their characteristics to conventional lens-coupled image sensors. I will also describe the use of active metasurfaces as elements of single-photon/pixel imaging systems for low intensity image acquisition using thermal and weak scattered light sources.

Hybrid Photonic Systems for Neuromorphic Processing Wolfram Pernice; Heidelberg University, Germany

Optical computing methods are seeing a resurgence of popularity due to recent advances in integrated photonics and neuromorphic engineering. Photonic systems are very suitable for analog computing approaches with moderate accuracy, yet very high processing speed. These features hold promise for implementing photonic accelerator systems for computationally expensive tasks such as matrix vector multiplications (MVM). Here I will introduce a nanophotonic approach for realizing chip-scale MVM-units by making use of hybrid integration. Using phase-change photonic devices allows for creating parallel processing circuits in which analog multiplications can be carried out at high speed. Hybrid integration of active and passive integrate photonic chips via 3D printed optical interconnects enables the realization of compact neuromorphic architectures for ultrafast information processing. Applications lie in the implementation of photonic convolution processers, as well as the realization of associative photonic memories and ultrafast correlation systems. In combination with the development of novel light sources, such photonic approaches offer new opportunities for creating brain-inspired hardware for artificial intelligence applications.

3:30 PM *EL06.06.02
NEO-PGA—Nonvolatile Electro-Optically Programmable Gate Array Arka Majumdar; University of Washington, Seattle, United States

Reconfiguration of silicon photonic integrated circuits relying on the weak, volatile thermo-optic or electro-optic effect of silicon usually suffers from large footprint and energy consumption. Non-volatile phase change materials, such as Ge2Sb2Te5 (GST) provide an attractive solution to solve this problem. I will talk about our effort on integrating GST with silicon photonics to demonstrate an energy-efficient, compact, non-volatile, reprogrammable platform. By adjusting the energy and number of free-space laser pulses applied to the GST, we characterized the strong broadband attenuation and optical phase modulation effects of the platform, and perform quasi-continuous tuning enabled by the thermo-optically induced phase changes. As a result, a non-volatile optical switch with high extinction ratio as large as 33 dB is demonstrated [1]. We also solved the problem of large absorptive loss in GST by designing a new type of directional coupler, and demonstrated an optical switch with less than 1dB insertion loss, even though the material itself has very high loss [2]. Using silicon p-i-n heater, we demonstrated electrical actuation of the phase transition to create a prototype of electrically controlled reconfigurable switch with ultra-low power consumption [3,4]. Finally, I will discuss new phase change materials[5], and device engineering to create next generation low-loss reconfigurable optical switch and phase-shifters.

4:00 PM *EL06.06.03
Reconfigurable Photonics on Thin Film Lithium Niobate Mengjie Yu; University of Southern California, United States

Lithium niobate (LN) is an excellent nonlinear photonic material due to its large electro-optic (EO) coefficient, second order and Kerr () nonlinearity, along with a wide optical transparency window. Thanks to the recent advances in nanofabrication technology, monolithic LN waveguides with high optical confinement and ultralow linear loss has been achieved, which was critical to the success of the silicon-based platform in the past decade. Highly efficient and controllable light-matter interactions can be achieved using optical, electrical, or mechanical waves at extremely compact footprints. In this talk, I will review our recent developments of thin-film LN nonlinear devices for high power and reconfigurable EO frequency combs, femtosecond pulse synthesis and spectral-shaping of single photons. Combination of multiple nonlinearities of LN unlocks ultrabroadband electromagnetic spectrum from microwave to mid-infrared. Lastly, I will discuss the potential of LN photonic platform for scaling up and accelerating classical and quantum technologies in sensing, photonic computing, and communication networks.

4:30 PM *EL06.06.04
Fast-Tunable and Low-Loss Stress-Optical Microsystems Sunil A. Bhave; Purdue University, United States

Silicon Nitride (SiN) is an outstanding material for on-chip photonic systems because of its extremely low optical loss, outstanding optical power handling and controllable non-linearity. SiN photonic integrated circuits (PICs) are becoming more commonplace in high performance systems including LIDAR, Optical Frequency Combs, Spatial Light Modulators and Photonic Quantum Processors. In such microsystems, low-loss photonics enhances lidar resolution and range, octave-spanning combs for optical clocks, longer-distance free-space communication and higher intensity light incident on detectors in photonics quantum processors.

However, modulation and tuning of SiN has been limited to thermal heaters because it’s a dielectric amorphous material with no electro-optic coefficients. In this presentation I will present architectures based on piezoMEMS technology to demonstrate stress-optical modulation and tuning of silicon nitride optical ring resonators. Specifically, I will demonstrate high speed tuning of self-injection locked lasers for LIDAR and frequency combs and GHz frequency mechanical resonant actuators for implementing magnetic-free optical isolators. If time permits, I will discuss optomechanical inertial sensors and microwave-to-optical quantum converters in our Piezo-on-Nitride technology platform.

This research is in close collaboration with Professor Tobias Kippenberg’s group at EPFL.

SESSION EL06.07: Adaptive Nanophotonic Materials III

Reprogrammable Nanophotonic and Metaphotonic Devices Enabled by Phase-Change Materials Sajjad Abdollahramezani, Hossein Taghinejad, Tianren Fan and Ali Adibi; Georgia Inst of Technology, United States

A new platform for miniaturized programmable nanophotonics through integration of dielectric, semiconductor, and plasmonic materials with nonvolatile phase-change materials will be discussed. This platform enables reconfigurable photonic building blocks with subwavelength features. Two groups of reconfigurable devices based on integrated photonic structures and metasurfaces along with their unique features for state-of-the-art applications will be discussed. Design, fabrication, and application of this platform for state-of-the-art devices and systems will be covered.

8:30 AM EL06.07.01
All-Dielectric, Switchable Metalenses Using Sb2S3 Phase Change Material Siddharth Padmanabha[1], Isaac Oguntoye[2], Jesse Frantz[3], Robert Bekele[4], Anthony Clabeau3[4], Vinh Nguyen[3], Jasbinder Sanghera[3] and Matthew D. Escarra[1]; [1]Tulane University, United States; [2]Intel Corporation, United States; [3]U.S. Naval Research Laboratory, United States; [4]University research Foundation, United States

All-dielectric metasurfaces have recently been shown to be excellent candidates for advanced wavefront manipulation devices in phase delays, beam steerers, metalenses, metaholograms and more. These devices allow for significant size, weight, and cost reduction in comparison to their traditional refractive optic counterparts, while allowing for creative use of non-linear responses of these structured surfaces. One limitation, however, for these devices is the lack of post fabrication tunability. To break this limitation, the fastest and most efficient approach would be utilizing refractive index-tunable materials. Phase change materials (PCMs) are one such category of materials. Huygens metasurface based optics utilizing these PCMs hold the possibility of high transmission and full 2π phase control of incident wavefronts which are tunable post-fabrication. In this work, we present a design and fabrication pathway for reconfigurable cylindrical metalenses in the visible utilizing one such PCM, antimony trisulfide (Sb2S3).
PCMs aid in active optical modulation when switched between their different non-volatile phases. The selected PCM for this study, Sb2S3, exhibits a visible wavelength refractive index contrast of 0.75 with low losses when switched between its amorphous and crystalline phases (hereby called optical states). The metalens design presented here is comprised of an arrangement of pixelated arrays of homogenous nano-antennas. Each pixel is designed as an array of cylindrical nano-antennas in a repeating square lattice. Different geometric parameters are cycled through to generate a pool of Huygens’ meta-atoms to act as building blocks for individual pixels. We choose to discretize the continuous (ideal) 0 to 2π phase profile for a cylindrical lens into an arbitrary N = 4 phase levels. To create the discretized wavefronts necessary in both optical states, a total of N2 = 16 elements are chosen. This selection of elements informs the pixel sizes that are necessary for the wavefront-shaping. To address the inter-element coupling issues inherent in highly resonant Huygens metasurfaces, an inter-pixel gap of 1.5μm is employed, which effectively reduces the crosstalk between adjacent pixels.
Individual nano-antenna arrays are optimized to ensure maximum generalized diffraction efficiency in both optical states of the PCM utilizing a figure of merit (FOM) first presented in [1]. This design FOM allows for a computationally effective and efficient synthesis of the reconfigurable metalens without the need for a full wave electromagnetic simulation of the entire metalens system in both optical states. The resulting compound metasurface acts as a reconfigurable cylindrical metalens with focal lengths of 3.5cm and 5cm depending on the optical state of the PCM The design predicts focusing

efficiencies of 72.9% and 79.7% for the amorphous and crystalline phases, respectively.
Sb2S3 thin films are created by ion sputtering with in situ substrate heating. The patterns are written using the Raith VOYAGER 100 electron-beam lithography tool on a Sb2S3 -PMMA- chromium stack and etched off in a single-etch process by reactive ion etching. This stack is then encapsulated with a layer of SiO2 to form a capping layer. The capping layer is necessary to prevent lateral migration of sulfur during the phase-change process, and to act as a mechanical protection layer for the metalenses. Optimization of nanofabrication, investigation of optically reversible phase changes, and experimental characterization of these metalens are all in progress.

8:45 AM EL06.07.02
Single-Photon Emission from Monolayer 2D Materials Coupled with Chiral Plasmonic Nanoparticles Soon-Jae Lee[1], Jae-Pil So[1], Kwang-Yong Jeong[2], Ryeong Myeong Kim[3], Ki Tae Nam[3] and Hong-Gyu Park[1]; [1]Korea university, Korea (the Republic of); [2]Jeju National University, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

The single-photon emitter carrying spin angular momentum is a key component in quantum information and quantum cryptography, promising highly secure information processing without leakage. Nonreciprocal single-photon configurations and deterministic spin-photon interfaces are possible with chiral quantum optics. Recently, quantum confinement in atomically thin transition metal dichalcogenides (TMDCs) has been investigated for single-photon emission based on naturally or artificially occurring defects. By applying mechanical strains to the TMDCs, it is feasible to precisely control the position and polarization of a single-photon emitter [1]. Strains in TMDCs have been induced using various nanostructures including dielectric pillars and nanogaps. In this work, we demonstrate a new type of single-photon emitter with chirality. Atomically thin tungsten diselenide (WSe_2) is placed on silica-encapsulated plasmonic chiral nanoparticles [2]. As a result of efficient coupling between the single-photon emitter and the chiral plasmonic nanoparticle, Purcell enhancement and increased intensity from the single-photon emitter were observed, showing circular or elliptical polarization directions. In the experiment, we observed that strain-induced single-photon emission with a chiral nanoparticle was >10 times stronger than unstrained WSe_2 photoluminescence. The single-photon characteristics were clarified using the Hanbury-Brown and Twiss (HBT) measurement setup. Furthermore, due to the coupling with the metal nanoparticle, the single-photon emitter had the reduced lifetime (0.8 ns) compared to the uncoupled emitter (20 ns). By measuring the polarization of the emitter coupled with the chiral nanoparticles, a degree of circular polarization of 0.8 was obtained. Last, numerical simulation demonstrated that chiral nanoparticles can generate spin angular momentum. Therefore, our approach will be useful for demonstrating a quantum light source for next-generation photonic integrated circuits.

Vortex and Anti-Vortex Lasing Modes in Disclination States Ha-Reem Kim[1], Min-Soo Hwang[1], Daniel Leykam[2], Yuri Kivshar[3] and Hong-Gyu Park[1]; [1]Korea University, Korea (the Republic of); [2]Centre for Quantum Technologies, National University of Singapore, Singapore; [3]The Australian National University, Australia

In photonics, the ability to control the angular momentum of light has long been of significant interest. For the purpose of creating different degrees of freedom in spatially distinct channels for data transmission, the orbital angular momentum (OAM) is particularly useful. Although the directional output and generation efficiency of OAM beams in previous works are impressive, considerable scattering loss and large energy consumption are unavoidable when constructing ultra-small optical devices due to the absence of mechanisms related to high-quality light confinement. Furthermore, additional work is required to tune the pump beam when the emission chirality of vortex microlasers depends on circularly polarized optical pumping. Realizing ultra-compact laser systems that can self-configure vortex modes with OAM properties and reliably localize resonant modes is therefore still challenging.
A more recent development is the introduction of photonic topological insulators (PTIs), which are attractive tools for the localization of topological states and robust light manipulation. PTI research has expanded to include topological defects such as dislocations and disclinations, which typically break the symmetric geometries of topological crystalline insulators (TCIs) [1,2]. Notably, the presence of a fractional charge in the disclination leads in topological bound states in TCIs. [3]. Disclination defects, however, have not yet been used in the realization of ultra-small light sources with quantized OAM states. Here, we report on two novel topological lasing modes with OAM states found in disclination defect nanocavities: vortex and anti-vortex modes.
The photonic disclination structure was constructed by cutting the crystal into four identical sectors, applying the Frank angle of $\Omega = +90°$, and adding one sector to a square-lattice photonic crystal structure. Different disclination defects were examined by shifting the air holes in the C5 symmetric core and the nearest layer to the core. Numerical simulations using finite-element method (FEM) were performed to optimize the structural parameters. Then, the localized in-gap states were opened at the disclination defect, and vortex and anti-vortex modes appeared in the gap, showing different polarization distributions. For the experimental demonstration of the vortex and anti-vortex nanolasers, we fabricated pentagon-shaped photonic crystal structures based on the FEM simulation results in a InGaAsP slab incorporating three quantum wells. We demonstrated the vortex and anti-vortex lasing modes in the disclination defects of topological photonic crystal structures. The OAM states of these modes were identified by measuring the polarization-dependent spatial intensity profiles and interferences patterns. The realization of the photonic disclination states may open up new opportunities for creating distinctive OAM vector laser beams for the next-generation optical communication.

Optoelectronic Characterization of tunable Luminescent organic molecules Arya Karappilly Rajan, Ryan Brisbin, Sayantani Ghosh and Ryan Baxter; University of California, Merced, United States

Luminescent organic molecules (LOMs) are interesting compounds, as they combine the photo-induced charge carrier generation and recombination of inorganic semiconductors with the lightweight and easy fabrication techniques common to organic materials. LOMs therefore offer the potential to be used in the development of inexpensive, flexible, and tunable organic electronic and optoelectronic devices as alternatives to inorganic semiconductors. Examples of such devices include organic light emitting diodes (LEDs), solar cells, chemical and biochemical sensors, field-effect transistors, and nonlinear optical media for lasing applications.

We present results of a novel class of LOMs, Benzoyl Pyraziniums, whose optical properties can be controlled by tuning the electronic and chemical structure, as well as their concentration and interaction with surrounding materials. Optical characterization of the three differently substituted (methoxy, fluorine and unsubstituted) salts of the LOMs exhibited interesting results. The photoluminescent (PL) emission intensity increased, and the emission spectra shifted to higher energies, with decreasing concentration. The recombination lifetimes of all three salts decreased as the solution concentration was increased from 0.1 to 100 mM. As pyridiniums are capable of intramolecular charge transfer, assuming that the primary concentration dependent non-radiative decay is through this pathway, these results can be explained by a corresponding increase in the number of non-radiative decay pathways with increase in the concentration. Most recently, we have discovered an optical activation pathway in these LOMs, where the absorption and emission spectra changed significantly on UV exposure. These changes are dependent on the energy of the UV excitation, time of irradiation, as well as their concentration. To study the behavior of these LOMs as composites in the mesoscale regime, we further looked at their cumulative emissions in solid state, via spin-casted thin films. While thin films also demonstrate the spectral blue-shift with decreasing concentration, the shift is only on the order of a few nanometers (nm) over the entire range of 0.1 – 100 mM with a significantly narrowed emission.
Further investigations of the electrochemistry of these molecules offer unique perspectives on the charge transfer properties within them, which is used to optimize their optical emission and establish these LOMs as highly suitable candidates for organics LEDs.

Electro-Optics with Quantum Paraelectric Materials Christopher P. Anderson, Giovanni Scuri, Alexander D. White, Daniil Lukin, Erik Szakiel, Josh Yang, Melissa Guidry, Kasper Van Gasse, Wentao Jiang, Amir Safavi-Naeini and Jelena Vuckovic; Stanford University, United States

Tuning optical properties of materials with electric fields is key to many quantum and classical applications. In particular, photonic modulation in cryogenic environments is an outstanding challenge, as traditional tuning mechanisms degrade at low temperature. In this talk, I present SrTiO3 as an attractive cryogenic electro-optic photonic material. Displaying a quantum paraelectric phase at low temperature, this material on the verge of ferroelectric instability results in a massive but stable electric susceptibility and tunability. I will first discuss our measurements of the electro-optic effect in this material near a quantum critical point. I then describe the creation of thin films of patterned SrTiO3 for high quality photonics. Finally, I will review how this material can transform microwave-to-optical quantum transduction, photonic quantum computing, and light-based control of superconducting systems.

Scalable, Milliwatt-Level, Switchable Electrochromic Resonator for Full-Color Generation Joo Hwan Ko, Serim Kim, Hyeon-Ho Jeong and Young Min Song; Gwangju Institute of Science and Engineering, Korea (the Republic of)

Display is an inseparable device for visually conveying information in today's daily life. Although the conventional color-filter-based light emitting devices have made great progress by the world's leading companies, there is still the important problem of power consumption. Alternatively, reflective displays and/or electronic paper utilize ambient light as a light source, thus, it does not consume energy for light emission, resulting in drastically reduced power consumption. Behind these advantages, electronic paper shows the black and white operation method, which has been treated as a limitation for colorful image production. In recent years, state-of-the-art coloration technologies have been introduced including thin-film cavity, plasmonics, and metasurface [1]. These systems have been combined with functional materials such as liquid crystals, phase change materials, or electrochromic polymers to successfully turn on and off these reflective surfaces [2]. Nevertheless, due to the individual RGB sub-pixel configuration, each color can only occupy up to 1/3 of the total gamut, which not only reduces chromaticity but also requires a lot of incident light [3].
Here, we present full-color electrically tunable reflective display (ETRD) with the milliwatt-level power-consumption. The RGB implementation allowed us to present effective displays with a single reflective pixel with multiple colors (monopixels) instead of relying on adjacent pixels with fixed colors. By introducing planar resonant structure, the scalable and full-colored reflective display is presented over wafer lever. Based on the structural design to have sensitive chromatic responsivity, the refractive-index-engineered/porous meta-medium has been introduced on metal film for the resonance promoting, which shows a great chromatic sensitivity to electrochromic materials. For the active modulation, we used polyaniline (PANI), which show great complex refractive index modulation level, resulting in distinct color modulation over RGB range. In this process, we successfully coated the PANI layer on meta-medium with great uniformity, enabling scalable fabrication. Furthermore, the monopixel configuration is adopted as a display unit pixel for prohibiting degradation of chromaticity. In particular, the protonation reaction of PANI enables the fast/low-voltage operation (from - 0.2 to 0.8V) with comparable switching time (~34 ms). Also, the minimized voltage levels lowered the power consumption as milliwatt-level (≈ 1 mW cm−2). In addition, we designed the pixelated reflective display module, which possesses the addressing ability. Finally, the full-color range switchable device shows a great lifetime over 200 cycles without degradation. In conclusion, we presented an electrically tunable reflective display based on electrochromic material for low power consumption and dynamic colorations. The electrically tunable reflective display with planar configuration provides a wide range of color generation in the reflection mode. We also designed the pixelated display module, which is capable of addressing ability. The investigated ETRD can indeed serve as the highly chromatic display with low-energy consumption striving toward wide color purity as electronic papers or affordable display.

Electrically Controlled, High On/Off Ratio Active Tamm Plasmons for Photonic Integrated Circuits Dong Hyun Seo, Joo Hwan Ko and Young Min Song; Gwangju Institute of Science and Technology, Korea (the Republic of)

The forefront of reconfigurable photonics is advancing towards more promising due to fast information transfer and high density multi-spectral operation in data-processing/ telecommunications. With the advent of state-of-the-art material engineering and lithography technologies, recently, a number of progresses have been reported for on-chip switchable devices. Representatively, based on the phase change materials (PCMs) embedded with micro-/nano-heater (i.e., electrothermal Joule heating), electrically reconfigurable photonics have been presented, with Ge2Sb2Te5 (GST). Although the fast response and large refractive index change of PCMs promoted the distinct variation of optical output, the requirement of constant energy consumption in heating process. Furthermore, under the metal-insulator transition, the introduction of free carriers leads to the optical losses. Especially, in the tele-communications frequencies (e.g., C- band around 1550 nm or O-band around 1310 nm), the loss limits not only optical modulation ratio but also the transmission rate. To overcome the limitations, over the last several years, remarkable progress of material engineering for lowering the optical loss of PCMs (e.g., Ge2Sb2Se4Te1 (GSST), Sb2S3, and Sb2Se3) have been presented. Nevertheless, even subtle extinction coefficient of GSST, it still hinders highly efficient light transport. In case of Sb2S3 and Sb2Se3, although they eliminated the optical loss, the tunability is too small.

As an alternative approach, recent works on dynamic photonics have shown that organic conducting polymer can redox reaction under electric field, enabling large complex refractive tuning, including polyaniline (PANI), polypyrrole, and poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS). Among them, PEDOT:PSS, which intrinsically possesses metallic characteristics in the infrared, shows a drastic transition into a nearly perfect dielectric state under -1 V. Nevertheless, the previous works have been focused on its concept functions (beam steering and neuromorphic computing) rather than high contrast optical switching.

The designed photonic integrated circuit shows a high-optical modulation through the active Tamm resonator. The optical state change induced by the metal-to-insulator transition of the polymer(PEDOT:PSS). In the mirror state, the polymer shows insulating properties. Thus, the photonic cell fully reflects input light and satisfies the optical 'ON' state. On the other hand, in the Tamm state, the polymer acts as a metal layer inducing strong absorption of the input light. The nearly unity absorption corresponds to the optical 'OFF' state. We confirmed a high on/off ratio (~74 %, - 8.3 dB) under the favorable range for the CMOS technology (0 ~ 3.3 V).

Interestingly, the high-contrast optical modulator showed a hysteresis property by applying sequential voltages. We investigated the reflectance-voltage (RV) hysteresis of the photonic cell. The two distinct states of the reflectance at the read state (0 V) can be realized due to its large memory window. To prove the stability of the photonic cell, we measured the dynamic variation of reflectance in response to cyclical write and erase state, confirming the high-contrast response without striking degradation.

Here, we presented a high-contrast optical switch by designing it to have strong light-material interaction even introduction of a subtle extinction coefficient. On the other hand, at the reduced state (-1 V), it fully reflects the incident light without any optical loss. Based on this property, we characterized the response tendency corresponding to the pulse stimulation. Furthermore, interestingly, the high- contrast optical modulator showed a hysteresis loop by cyclical write and erase state. Using the function, we showed memory characteristic by alternatingly applying the voltages.

11:15 AM EL06.08.03
Micro Holographic Effects with Sub-7nm Photonic CMOS Transistors for Nonlinear Optoelectronic Processors and Optical Computers James Pan; American Enterprise and License Company, United States

Three dimensional holograms are formed using the optical holography technique. There have been reports on improved performance with Digital Holography and Incoherent Digital Holography. These advanced technologies focus on macroscopic scale holograms. External lasers and digital tools are required. In this report, we will focus on microscopic holographic effects using sub-7nm photonic CMOS transistors. Due to the resonance and coherent holographic process, there are more information in the photonic CMOS output signals, which makes wide-band optical computing a reality.

A hologram contains more information, because it is formed by interference / modulation of split coherent lights. A regular picture is produced by reflection of an incident light from an object. A hologram is produced by interference of an incidence light and its split coherent light affected by an object. As the result, the 3-D features are enhanced and delineated by holography. In some ways holography is similar to a Michaelson Interferometer.

If two lights are coherent, their phases are organized. If the two lights are incoherent, their phases are not related. Although incoherent digital holography has been demonstrated, more complicated setup would be required. In this paper only coherent holography will be presented.
A photonic CMOS transistor includes a laser in the drain area, and another laser in the source area, and photon sensors in the well region. When the MOSFET is on, the lasers and photon sensors are also on. When the MOSFET is off, all devices are off. The MOSFET, lasers, and photon sensors are fabricated as one integral transistor.

A resonance chamber is formed at the center of the CMOS transistor, when the source laser and the drain laser are coherent, and only the drain laser / sensor receives an input light signal. This creates a holographic effect in the resonance channel region. The output light signal will include the holographic messages, which can be transmitted to other transistors for optical processing. The performance is superior due to the more sophisticated interference and modulated split coherent lights.

The CMOS transistor is designed for only the drain laser and drain photon sensors to receive external light signals, as there is a depletion region located only at the drain side. External lights are blocked from the source laser.

We will present data examining the coherence vs. sub-7nm transistor parameters, such as Rch and Rds (channel and source drain resistance). For femtosecond pulsed lasers, we will look into the effects of frequency as a function of the quality of the coherent holographic signals. Device features, and process integration will be discussed for the micro holographic effects. How optical computing can be implemented, taking advantage of the nonlinear optoelectronic CMOS with micro holography will be presented.

The design of an optical processor relies on transmission of optical signals either through an micro optical waveguide or confined free space. Laser communications between photonic transistors in an optical computer become more efficient if the lights are encoded with micro holographic techniques. We will introduce a few examples of logic gate designs (AND, OR, NAND, NOR, XOR, Comparator, OP AMP) and SRAM for optical computing using micro holography.

Finally, we would like to discuss how to enhance the micro holographic effects using nonlinear optical materials in optical waveguides and photonic CMOS, from UV to NIR and Terahertz spectral ranges. The photonic CMOS needs to be configured with nonlinear optical materials, in order to adapt to such nonlinear micro holographic process. A few different approaches will be presented.

11:30 AM EL06.08.04

Photonically Modulated Synaptic Plasticity for Neuromorphic Vision in Zinc-Tin Oxide and Gold Nanoparticles Heterostructure Transistor Li-Chung Shih, Fang-Jui Chu, Ching-Hsiang Yang, Ya-Chi Huang and Jen-Sue Chen; National Cheng Kung University, Taiwan

Inspired by the human brain, neuromorphic computing systems have great advantages of strong fault tolerance and improved power efficiency for complex real-time information processing. In parallel, the biologically inspired computer vision is a growing computing paradigm, aiming at mimicking human visual perception to capture valuable information from images and videos. To integrate the two operations in one, photosynaptic devices with modulation of conductance via applying the optical and electrical spikes will be a prudent approach to emulate photosensitive synaptic plasticity change for the realization of neuromorphic photonics.

Transparent semiconducting oxides have received considerable attention in state-of-the-art neuromorphic image sensor arrays owing to their high light sensitivity, carrier mobility, and low-temperature processability. In this study, we demonstrate a photosynaptic transistor based on zinc-tin oxide (ZTO) with embedded Au NPs heterostructure. The ZTO/Au NP photosynaptic transistor exhibits high-performance capabilities and versatile transistor characteristics that are driven by electrical and optical stimuli. The electron detrapping effect at the ZTO/Au NP interface and localized surface plasmon resonance (LSPR) effect of Au NPs are realized using a negative gate voltage (V_G = -5 V) and at an illumination of 520 nm light, respectively, leading to the increasing drain current (I_D). Intriguingly, the synergistic optoelectrical coupling effect is observed with the simultaneous application of electrical and optical spikes, which is attributed to a greater probability of charge separation between the photogenerated electrons and ionized oxygen vacancies in the ZTO with an external electric field. It is worth noting that this synergistic effect corresponds to the behavior of the biological synapses, that is, the released neurotransmitters can significantly activate glutamate receptors and facilitate synaptic plasticity for learning and memory under light illumination. As a result, the ZTO/Au NP photosynaptic transistor shows the potential to be implemented in sensor networks and pave the way to mimic visual perception for with the minimal power consumption.

Probing the Material Impact of Nanofabrication on Integrated Thin-Film Lithium Niobate Photonic Device Performance David R. Barton, Matthew Yeh, Julia Mundy, Marko Loncar and Evelyn Hu; Harvard University, United States

Thin-film lithium niobate on insulator (TFLN) has emerged as a promising platform for integrated classical and quantum photonics due to its intrinsically large electro-optic effect and wafer-scale availability. The direct connection between driving electric fields and refractive index in this platform has enabled new schemes for creating pulsed lasers on chip, high-bandwidth and energy-efficient modulators, and devices for integrated nonlinear photonics. However, it is generally recognized throughout the community that the reliability of thin-film lithium niobate modulators is subject to unstable electro-optic response at low frequencies, and undesired photorefractive index changes due to defect absorption at high optical powers. Post-processing methods such as annealing have been developed to reduce these deleterious effects, but their microscopic origins remain unclear. It is also not known if these effects relate to fundamental materials issues, might be exacerbated for materials in thin-film form with possible strain inhomogeneities, and indeed might arise from thin-film preparation, which involves ion implantation, and chemical-mechanical polishing.

Here, we employ a combination of X-ray photoelectron spectroscopy (XPS) and atom probe tomography (APT) to analyze a commercial x-cut congruently-grown lithium niobate on insulator wafer, and thereby illuminate the surface and bulk composition as a function of nanofabrication process conditions. First, we show through XPS that the etch conditions and standard acid cleans used in our thin-film processing dramatically impact the surface, either by removing lithium from the surface or by locally reducing Nb^{5+} to Nb^{4+}. Specific chemical cleans remove the damaged layer, while annealing at moderate temperatures in an oxygen environment restores the surface Li:Nb ratio to its unprocessed status. We gained additional insight by using APT to map out the material composition in 3D. Surprisingly, we found that the lithium composition within the unprocessed material varies substantially over length scales on the order of 10 nanometers, suggesting that local defect structures such as the small polaron (reduced Nb antisite defect: $\mathrm{Nb}^{\cdot\cdot\cdot\cdot}_{\mathrm{Li}}$) may exist in appreciable concentrations that could give rise to photorefraction. Annealing our samples temporarily increases quality factors and reduces photorefraction, indicating that diffusion of mobile species such as Lithium may indeed play a role in long-term stability of our devices. These results suggest that simple fabrication modifications can help reduce the leaky dielectric nature of our integrated films, while posing questions about the fundamental limits of this platform for integrated photonics.

Bioinspired Artificial Photonic Synapses Based on Polycrystalline *β*-Ga_2O_3 for Neuromorphic Applications Youngbin Yoon, Yongki Kim, Wansik Hwang and Myunghun Shin; Korea Aerospace University, Korea (the Republic of)

Recently, artificial intelligence technology that mimics the efficient information processing mechanism of the human brain has emerged as a core technology for big data processing. In particular, a neuromorphic computing chip can directly implement the human brain structure and computational process in hardware, enabling efficient low-power intelligent computation at high speeds. This enormous potential of neuromorphic computing has prompted a worldwide increase in research to realize the technology. More recently, complex biological activities and perceptions, such as memory and forgetting processes, classically conditioned learning experiments, and artificial sensory functions, have been emulated using neuromorphic artificial synaptic devices, including memristors and field-effect transistors (FETs). The biological nervous system represents associative learning through sensory systems. To comprehensively mimic brain functions, artificial synaptic devices integrating sensing and processing functions must be developed. Vision plays a vital role in organisms' reactions to the external environment, primarily because more than 80% of the information acquired through the sensory organs is obtained through vision. In addition to visible light, various animal species contain photoreceptor cells that can absorb ultraviolet (UV) light in the retina and transduce it into cellular signals. For example, bees can be trained to search for sugar water because of their UV-sensitive visual and nervous systems. In the dim Arctic twilight, reindeer use their ability to sense contrast in the UV to locate plants, including lichen and moss, and effectively evade predators (wolves and polar bears). Since humans cannot perceive UV light, the development of UV neuromorphic sensors complements our understanding of UV light and can be utilized in a variety of applications, such as chemical/biological sensors, on-chip optical communications, ultraviolet astronomy, and early warning systems. In particular, the incorporation of light into the operation of synaptic FETs can expand the bandwidth and effectively improve the interconnection problem of synaptic devices. Synaptic devices of oxide semiconductors are stimulated by deep UV signals because of their large optical bandgaps. Among them, gallium oxide (Ga_2O_3), which has an ultra-wide bandgap of 4.9 eV is particularly noteworthy. The ultra-wide bandgap provides a controllable number of large memory (storage) states. Moreover, Ga_2O_3 is suitable for optical device applications because of its almost direct bandgap properties and can also be utilized in synaptic devices that respond to optical stimuli. In this study, β-Ga_2O_3-based synaptic phototransistors were fabricated for the first time. Optical and electrical spikes stimulated the Sn-doped 100-nm thick polycrystalline β-Ga_2O_3 synaptic FETs. The device mimicked crucial synaptic functions, such as EPSCs, IPSCs, PPF, SNDP, SRDP, and STDP using two types of stimuli (optical and electrical). With light stimulation, a linear increase in synaptic weight (current) was confirmed owing to the PPC effect in the device that was fabricated with a back-gate structure. Synaptic reinforcement and inhibition were achieved by gate dielectric (SiO_2) interfacial states induced by gate voltage control. We confirmed the modulation of weights through the synergistic effect of excitatory and inhibitory synapses and mimicked the associative learning process, an expected neurological behavior. Moreover, convolutional neural network (CNN) simulation was used to perform National Institute of Standards and Technology (MNIST) handwritten digit images pattern recognition to further demonstrate the applicability of the synaptic β-Ga_2O_3 phototransistor in the neuromorphic field and achieved using the proposed optimized training method.

Emerging Glassy and Phase-Change Chalcogenide Thin Films with Unconventional Bonding Mechanism for Adaptive Photonic Devices Anthony Albanese[1], Jean-Baptiste Dory[1], Jean-Yves Raty[2], Martina Tomelleri[1], Meryem Ibnoussina[3], Jean-Baptiste Jager[4], Anthonin Verdy[1], Francesco d'Acapito[5], Magali Tessaire[1], Aurélien Coillet[3], Benoît Cluzel[1] and Pierre Noé[1]; [1]Univ. Grenoble Alpes, CEA, LETI, France; [2]CESAM-Physics of Solids, Interfaces and Nanostructures, Belgium; [3]ICB, UMR CNRS 6303, Univ. Bourgogne Franche-Comté, France; [4]Univ. Grenoble Alpes, CEA, IRIG, France; [5]CNR-IOM-OGG c/o ESRF – The European Synchrotron, France

Chalcogenide materials have attracted much attention over the years due to their wide range of applications. Among them, some compounds such as Ge-Sb-Te based alloys exhibit a unique portfolio of properties, which has led to their wide use for non-volatile memory applications such as optical data storage or more recently resistive phase-change memory [1,2]. In addition to a high IR transparency window and high optical nonlinearities [3], some chalcogenide glasses such as Se-based compounds exhibit an unusual conductivity behavior under high electric field, called ovonic threshold switching (OTS) effect [4]. Recently, we showed that some As-free $GeSb_wS_xSe_yTe_z$ chalcogenide compounds exhibit outstanding reconfigurable linear and nonlinear properties when deposited in thin films. All films were obtained by industrial magnetron co-sputtering deposition.
First, the linear and non-linear optical properties of innovative $GeSe_{1-x}Te_x$ thin films in the amorphous phase as-deposited as well as after annealing crystallization are studied. These alloys belong to the GeSe-GeTe pseudo-binary line located between the covalent GeSe compound and the "metavalent" GeTe phase-change material (PCM). They are considered very promising candidates for high temperature non-volatile resistive memories [5], emerging all-optical neuromorphic circuits and IR photonic applications. These new PCM compounds offer promising properties for optical switch applications requiring high refractive index contrast upon crystallization with limited optical losses, especially at 1.55 µm. In addition, the amorphous films exhibit good thermal stability up to crystallization occurring above 300 °C [5], as well as a high nonlinear refractive index offering promising opportunities for nonlinear NIR-MIR on-chip devices. Second, exceptional n_2 values are obtained for all as-deposited $GeSb_wS_xSe_yTe_z$ films in the NIR-MIR range. These values are 2 to 3 orders of magnitude higher than those found in SiN_x thin films, which are considered today as the reference material for on-chip nonlinear NIR photonic applications. A dramatic change in the Kerr index as a function of the composition of the $GeSb_wS_xSe_yTe_z$ chalcogenide alloys is also observed and related to changes in the amorphous structure. The origin of the very high local electronic polarizability, related to highly polarizable structural motifs in the amorphous lattice, can be linked to the enhanced optical nonlinearities of the material [6]. These highly polarizable patterns are reminiscent of "metavalent" bonding, the unique bonding mechanism that causes the huge optical and electrical contrast between the amorphous and crystalline states of phase change materials.
In summary, some innovative As-free $GeSb_wS_xSe_yTe_z$ chalcogenide compounds exhibit outstanding linear and nonlinear optical properties that are behind their promising potential for reconfigurable and on-chip NIR-MIR applications. This results from the formation of particular structural patterns leading to a specific bonding mechanism that gives rise to their huge polarizability. These results pave the way to control and enhance the unique optical properties of chalcogenides in thin films.

Broadband Total Absorption of Light Nina Vaidya[1], Eric Plum[1], Anton N. Vetlugin[2] and Nikolay I. Zheludev[1,2]; [1]University of Southampton, United Kingdom; [2]Nanyang Technological University, Singapore

We report a new light absorption device that - in principle - can absorb light completely across the entire electromagnetic spectrum by utilizing its spatial coherence and we provide proof-of-concept experimental demonstration of such a device. Complete absorption of broadband light is key for several technologies including photovoltaics, energy conversion, quantum and stealth technologies.

We demonstrated *broadband* coherent perfect absorption through experimental results. Constructive interference of counterpropagating waves on a thin film with appropriate optical properties (e.g. chromium or graphene film of appropriate thickness with 50% absorption) enables complete (deterministic) absorption of light, down to the single-photon level. We, recently, succeeded in demonstrating experimentally how this discovery can be utilized to realize a compact device that perfectly absorbs broadband spectrum of light simultaneously- by broadband constructive interference of light we achieved perfect absorption in nanometer scale thin films. When the optical path lengths were not matched, the reflectivity spectrum oscillated between coherent absorption and coherent transmission. With alignment, the bandwidth of coherent absorption increased, and became very large when the path lengths were matched. In this case, we observed only 9% reflectivity across the studied wavelength range of 1540 to 1620 nm, implying >90% absorption. Changing one effective optical path length by about half a wavelength switched between coherent absorption and coherent transmission of the Cr film, i.e., between a perfect absorber and a mirror. We also note that perfect absorption of s-polarization coincides with perfect transmission of p-polarization and vice versa.

The thin film can be made photoactive (using 2D transition-metal dichalcogenides, semiconductors thin films, or organic-inorganic mixed films like perovskites) so that it not only absorbs all the light but also produces electricity/detects. Several permutations of optical designs including 2D and 3D structures, tessellated arrays, scaling, broadband light sources, polarizers, and various absorbing thin film materials are being investigated to develop the demonstration further and to optimize the concept for specific applications.

The recent results are noteworthy as the first demonstration in the field – of *broadband* coherent perfect absorption in a single compact device. This demonstration will help pave the way forward to go beyond the ergodic light trapping limit and the Shockley–Queisser limit to create highly efficient ultrathin absorbers, solar cells, and detectors; and forms building blocks for future adaptive nanophotonics as well.

2:15 PM EL06.09.04
Tunable Infrared Metasurface of Quasi-Metal Transparent Conductive Oxide for Thermal Management Applications Thu H. Le[1] and Ngoc Lam Huong Hoang[2]; [1]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [2]Vietnam National University, Hanoi University of Science, Viet Nam

This study reports a novel class of transparent conductive oxide (TCO) of TiO_2:Nb that exhibits the carrier density comparable to metals for infrared plasmonic applications. Recently, TCOs have emerged as alternative plasmonic materials to replace noble metals, owning to their CMOS compatibility, tunability of optical and structural properties, etc. The plasmonic properties of TCOs are determined by their carrier densities, however, most of the studies, so far, reported the carrier densities (~10^{20}/cm^2) much lower than those in nobel metals (~10^{22}/cm^2). It consequently limits the realization and improvement of plasmonic properties in TCOs. In this study, we demonstrate a new method to significantly increase the carrier density in transparent conductive oxides by doping of a small amount of silver (Ag) into conductive oxide thin film (TiO_2:Nb), while maintaining the crystalline structure and the visible transparency of TiO_2 film. The tunability of optical properties of Ag-Nb co-doped TiO_2 in mid-infrared regime was charaterized by ultrafast transient infrared spectroscopy. Thin films were fabricated by co-sputtering Ag and TiO_2:Nb (9% Nb) targets at appropriate ratios. After deposition, the amorphous films underwent the annealing process at 350-400^{o}C in vacuum. This thermal treatment induced the diffusion and the ion exchange of Ag during the crystallization of Nb-doped TiO_2, resulting in the co-doping of Ag of Nb into the anatase structures of TiO_2. The doping of Ag improves the carrier density while has subtle effect on the visible transparency TiO_2 films. The Hall measurement results of 100 nm-thick Ag-Nb co-doped TiO_2 films show carrier density at 2.1×10^{22}/cm^2. This value is two-order larger than reported TCOs and at the same level with nobel metals. The film exhibits the transparency of 85% in the visible regime, which is comparable to TiO_2:Nb without Ag doping. The plasmonic properties of Ag-Nb co-doped TiO_2 were investigated by fabricating metasurface of nanostructures on thin films and characterizing their optical properties. For example, nanorod structures fabricated on a 100 nm-thick Ag-Nb co-doped TiO_2 thin film, with different rod sizes. The corresponding transmittance spectra reveal distinct plasmon dips in the infrared regime, and the decreasing resonant wavenumbers with larger rods, that clearly indicates the plasmonic property in Ag-Nb co-doped TiO_2. Moreover, the plasmon resonance can also be tuned by the doping level of Ag. The achieved plasmonic property can be attributed to the extremely high carrier density and its controllability by Ag doping levels. We also demonstrated the dynamic tuning and switching of optical properties of Ag-Nb co-doped TiO_2 metasurface by thermal and electrical triggers. We observe redshifts of localized surface plasmon resonances arising from a change of the plasma frequency of Ag-Nb co-doped TiO_2, which is governed by the conduction band non-parabolicity. Herein we have demonstrated a simple method of Ag doping for TCOs thin film and demonstrated a novel class of quasi-metal TCOs that exhibit distinquished plasmon properties and tunability in mid-infrared regime. The tunability of optical properties in mid-infrared promises their wide applications for effective usage of solar energy, such as smart windows that allow us adjust light and thermal at ultra-low energy consumption. This work also demonstrates a new scheme to control infrared plasmons for optical switching, telecommunications and sensing.

All-Dielectric High-Q Thermo-Optically Tunable Transmissive Metasurfaces Ruzan Sokhoyan, Claudio Hail, Morgan D. Foley, Meir y. Grajower and Harry A. Atwater; California Institute of Technology, United States

We theoretically demonstrate all-dielectric low-loss active metasurfaces, which can dynamically manipulate the wavefront of the transmitted light in the near-infrared wavelength range. Our active metasurfaces feature an array of amorphous silicon (a-Si) pillars on a silica (SiO_2) substate, which support supercavity resonances with quality factors (Q-factors) as high as 9800, as well as lower-Q resonances. We show that the considered supercavity mode is also supported by an isolated pillar with the highest achievable quality factor of 676. We observe that the quality factor of the supercavity mode increases by a factor of 14 when the metasurface elements are arranged in a metasurface array.
Next, we propose a metasurface geometry and a realistic interconnect architecture, which enable thermo-optic dynamic beam steering and dynamic beam switching with switching times as low as 7.3 μs. In the proposed metasurface implementation, the top and bottom 50 nm of Si are n-doped with a carrier density of 6×10^{18} while the carrier density of the lightly doped Si core is 3.2×10^{17} cm^{-3}. By applying voltage between the top and bottom doped Si layers, we flow a current between the doped layers through the lightly doped a-Si layer. The induced current raises the temperature a-Si pillars by means of Joule heating, resulting in a modified refractive index of a-Si. To realize dynamic beam switching or beam steering in transmission, we utilize modest refractive index modulation of amorphous Si ranging between $\Delta n = 0.0026$ to $\Delta n = 0.006$, depending on the specific implementation. In our proposed metasurface structures, we benefit from both relatively low-Q modes as well as high-Q supercavity mode supported by an individual a-Si pillar. We use full wave optimization to obtain high directivity steered beam using the particle swarm optimization algorithm. We show that that that our full wave optimization approach increases the directivity of the steered beam as compared with the case when the intuitive forward design approach is used.
We observe that both the high-Q and lower-Q modes can steer the beam for two orthogonal incoming polarization directions at two different wavelengths, indicating that with an appropriate interconnect design, the proposed metasurface can potentially be used for two-dimensional beam steering.
It is also worth mentioning that, so far, most of the active metasurfaces enabling dynamic wavefront shaping operate in reflection. On the other hand, active metasurfaces operating in transmission can readily be integrated with chip-scale light sources, yielding ultra-compact wavefront shaping devices.

3:45 PM EL06.09.06
Filterless Narrowband Si/organic Integrated Photodetector for Sensitive Near-Infrared Detection Zhuhua Xu and Guodan Wei; Tsinghua-Berkeley Shenzhen Institute, China

Narrowband photodetector (PD) has attracted intensive attention for full-color imaging and visible-blind near-infrared (NIR) detection in image sensing, optical communication .They requires a strongly peaked response centered around a certain “design wavelength” since the wavelength selective light detection could increase the sensitivity, color separation and resolution of image sensors. However, it always remains a great challenge to reach narrowband PDs for commercialzed Si photodetectors due to its absorption limition. For narrowband photodetection application in night-vision imaging and security, Si photodetectors have to integrated complex **optical filters**, resulting increased manufacturing cost and architectural complexity. Even the quality of imaging sensing could be affected. Numerous efforts have been explored with limited success on searching solutions for narrowband NIR detection. Herein, we have explored unique silicon nanograting structure on top of the regular Si substrate in combination of very thin organic layer, obtaining filterless NIR narrowband photodetectors as narrow as **26 nm**. The ultrafast response time could be reached in micro seconds. This unique Si nanograting/organic bulk heterojunction has facilitated the charge collection narrowing of the external quantum efficiency of the NIR photodetectors. To our best knowedge, this has been the **very first narrowest** NIR Si photodetectors, which could open up a new window for commerciated application for multicolor imaging and autonomous mobiles.
The narrowband detection capability of the PD can be attributed to the following reasons: 1) The periodic neat nanograting Si structure can generate optical diffraction and a wide reflection peak; 2) The organic film have a transmission spectrum that strongly overlaps with the absorption spectrum of the

nanograting Si underneath, which could ensure the wavelength onset of the resonant enhancement absorption peak; 3) The as-obtained organic layer forms a nanograting structure for strongly localized optical field and the strong optical interference that has greatly contributed to the narrow NIR photoresponse; 4) The effective potential barrier could be formed after introducing the appropriate organic layer, which greatly suppresses dark current; 5) The interface of the nanograting Si and the organic layer has provided energy favorable sites for effective charge transfer, enhanced charge collection efficiency, and therefore 40-fold higher photoresponse than that of the nanograting Si PD.

Optically-Controlled Dielectric Metasurfaces for Dynamical Dual-Mode Modulations on Terahertz Waves Lei Zhou; Fudan Univ, China

Dynamically controlling terahertz (THz) waves with an ultra-compact device is highly desired, but previously realized tunable devices are bulky in sizes and/or exhibit limited light-tuning functionalities. Here, we experimentally demonstrate ultra-fast dynamical light modulations with a dielectric metasurface in mode-selective or mode-unselective manners, through optically pumping the system at different wavelength. Coupled-mode-theory analyses, in good agreement with both experiments and simulations, reveal that the physics is governed by distinct wavefunction overlapping between resonance modes and field patterns of pumping light penetrating inside the system at different wavelength. We then design/fabricate a dielectric metasurface and experimentally demonstrate that it can dynamically control the polarization state of incident THz wave, dictated by the strength and wavelength of the pumping light. Our studies reveal that the pump wavelength can be a new external knob to dynamically control THz waves, which may inspire the realizations of many tunable meta-devices with diversified functionalities. As an illustration, we finally numerically demonstrate the pump-wavelength-controlled optical information encryption based on a carefully designed dielectric metasurface.

Plasmon-Empowered Electrically Tunable Metasurfaces Sergey I. Bozhevolnyi; University of Southern Denmark, Denmark

Optical metasurfaces (OMSs) represent subwavelength-dense planar arrays of nanostructured elements designed to control local phases and amplitudes of scattered optical fields, thus being able to manipulate radiation wavefronts at a subwavelength scale. In the past decade, many configurations involving different physical mechanisms have been developed, and numerous diverse applications have been demonstrated, including free-space wavefront shaping, versatile polarization transformations, optical vortex generation, optical holography and many others [1]. However, to date, most reported OMSs are static, featuring well-defined optical responses determined by OMS configurations that are set during fabrication, although, for more intelligent and adaptive systems, dynamic OMSs with externally controlled functionalities are in high demand. Realization of dynamic adaptive OMSs is, at the same time, very challenging because of the high density of array nm-sized elements that are also arranged in nm-thin planar configurations, circumstances that limit severely the interaction volumes.

In this talk, I present recent results that we obtained with two different configurations for realizing electrically controlled OMSs operating in reflection: piezoelectric micro-electro-mechanical systems (MEMS) integrated with gap surface-plasmon (GSP) based OMSs [2] or Fabry-Perot resonant OMSs [3] and resonant configurations based on thin electro-optic crystal layers sandwiched between nanostructured electrodes [4,5]. Their operational principles are described, and the main experimental results obtained are presented. Furthermore, new developments and functionalities demonstrated will be presented at the conference.

Direct Coupling for Compact Integrated All-Optical Reservoir Computing Ivan Boikov[1], Daniel Brunner[2] and Alfredo de Rossi[1]; [1]Thales Research & Technology, France; [2]CNRS & University Bourgogne Franche-Comté, France

We propose a highly compact Reservoir Computer (RC) implementation on integrated platform based on evanescently coupled nonlinear optical microresonators acting as neurons. We discuss how basic parameters of system impact RC properties, suitability of microresonator types and semiconductor platforms and scalability of reservoir with number of neurons. We compare impact of two-photon absorption, free electron dispersion and Kerr effect on RC properties. Finally, we demonstrate RC operation on a common benchmark of Mackey-Glass prediction task and an applied task of optical data recovery. Such RC was capable of performing autonomous computation at GHz frequency range in real-time, while requiring several mW of optical power and footprint on the order of 0.001 mm^2, excluding readout. We found that all three nonlinearities positively contributed to computing performance.

9:30 AM *EL06.08.01
Active THz Topological Photonics for 6G and Beyond Ranjan Singh; Nanyang Technological University, Singapore

Global digitalization and the recent rise of artificial intelligence-based data-driven applications have directed their vectors towards terabits per second (Tbps) communication links. The fast-evolving 5G communication network cannot fulfill this demand due to several technological challenges, including bandwidth scarcity, which has stimulated innovative technologies with a vision of 6G communication. Semiconductor and emerging quantum material-driven Terahertz (THz) micro-nanotechnologies have been identified as a critical candidate for the emerging 6G communication with the potential to provide ubiquitous connectivity and remove the barrier between the physical, digital, and biological worlds. Nonetheless, the existing THz photonic on-chip communication devices suffer from backscattering, bending loss, limited data speed, and lack of active tunability. Here, I will describe active on-chip THz photonic topological devices consisting of low-loss, broadband single channel 160 Gbit/s interconnect devices and critically coupled high-*Q* cavities built on Silicon Valley-Hall Photonic Crystal. Silicon topological photonics will pave the path for augmentation of CMOS-compatible hybrid electronic-photonic driven terahertz technologies, vital for accelerating the development of 6G and 7G communications.

Abstract Presented (ON-DEMAND ONLY) Controllable Doping of Noble Metals in Disordered Inorganic Solids—An Alternative Way for Tunable Nanophotonics Cheng-Wei Qiu and Zhiyuan Yan; National University of Singapore, Singapore

Phase transitions among amorphous, quasicrystals and crystals states are ubiquitous in nanoscale and bulky materials, manifested in alloys, 2D materials, phase change materials, thermoelectric and semiconductors. Here we report a phase-transition-assisted gradient and reversible doping approach for solid thin films that enables the dopants to be gradually doped into the host and reverted to their pristine positions. We demonstrate thermally tunable high-resolution and large-scale colour images on Si wafer within 1 minute using this approach. Our findings provide a distinct post-production modification of optical, electrical, mechanical, and thermal properties of inorganic solids, and that would be useful for dynamic and tunable nanophotonics.

11:00 AM *EL06.11.02
Learning from Failure—Improving Cycling Endurance of Optical Phase Change Materials Juejun Hu; Massachusetts Institute of Technology, United States

Chalcogenide phase change materials (PCMs) are truly remarkable compounds whose unique switchable optical and electronic properties have fueled an explosion of emerging applications in electronics and photonics. Key to any application is the ability of PCMs to reliably switch between crystalline and amorphous states over a large number of cycles. While this issue has been extensively studied in the case of electronic memories, current PCM-based optical devices show limited endurance. To understand the failure mechanisms limiting endurance of PCMs specifically in photonic devices, we have developed an on-chip micro-heater platform and an automatic multi-modal characterization system to analyze cycling performance of optical PCMs. Our work revealed directional elemental segregation over extended cycles, and identified morphological instability as a new premature failure mode unique to photonic devices. Reversible switching of large-area PCM devices over 10,000 cycles was demonstrated.

Low Pressure Dusty Plasmas Synthesis of Silicon Nanocrystals for Photonic Applications Uwe R. Kortshagen; University of Minnesota, United States

Chemically reactive nonthermal plasmas at low pressure are an interesting medium for the growth of nanocrystals. Molecular precursors are dissociated by electron impact reactions and the resulting molecular fragments and radicals, many of them charged, nucleate to form clusters and nanocrystals. Energetic surface reactions can heat these initial clusters to temperatures that exceed the gas temperature by hundreds of Kelvin. This enables plasmas to form crystalline nanoparticles even of materials with very high melting points. The unipolar negative charging of nanoparticles in the plasma virtually eliminates particle aggregation, leading to very monodisperse size distributions. Furthermore, plasma synthesis is an all-gas-phase method that does not require solvents or ligands and is thus a relatively sustainable synthesis method. In this presentation, we will discuss the plasma synthesis of silicon quantum dots with diameters on the order of ~3 nm for luminescent applications as well as the synthesis of larger silicon nanocrystals, 60-200 nm in diameter, that show interesting scattering behaviors.

Plasma-synthesized silicon quantum dots have shown good luminescence properties with photoluminescence quantum yields of up to 60%. To attain such high quantum yields, passivation of surface defects is required that has traditionally been achieved by hydrosilylation reactions. However, hydrosilylation requires organic solvents which partly offsets the sustainability advantage of plasma synthesis. Here, we report on recent progress in performing the surface functionalization in the gas phase right after the synthesis step. We discuss various methods to attach organic ligands to the surfaces of silicon quantum dots while in flight in the afterglow of the synthesis plasma.

One application of luminescent silicon quantum dots is in luminescent solar concentrators (LSCs). These are semitransparent waveguides that are doped with silicon quantum dots. The silicon dots absorb solar radiation primarily in the blue range of the spectrum and reemit it in the near-infrared. Waveguiding concentrates this radiation on small solar cells that can be edge or surface mounted. We discuss results of a numerical model that investigates the application of silicon LSCs to greenhouses and demonstrate that LSC roof panels have the ability to enable net-zero-energy greenhouses in certain climates.

In the final part of the presentation, we discuss recent progress in the plasma synthesis of larger, highly monodisperse silicon nanocrystals with diameters of 60-200 nm. These nanocrystals exhibit intriguing optical scattering through overlapping electric and magnetic dipole modes. We show that ensembles of silicon nanocrystals produced by plasmas show scattering behavior that is essentially consistent with single particle scattering models due to their very narrow size distribution.

Ge-Based Nanowires of Metastable Composition: Hyper-Doping and Alloy Formation Sven Barth[1], Raphael Behrle[2], Masiar Sistani[2], Jos Haverkort[3] and Michael Seifner[4]; [1]Goethe University Frankfurt, Germany; [2]TU Wien, Austria; [3]TU Eindhoven, Netherlands; [4]Lund University, Sweden

This contribution will address the formation of nanowires and nanorods of metastable composition and demonstrate the significant changes in physical properties associated with their composition.[1] All the growth studies are carried out either in solution or by gas phase techniques using the metal to be incorporated in the Ge host lattice as a growth seed. This approach allowed the formation of highly crystalline, metastable Ge$_{1-y}$Ga$_y$ (y~0.03%) as well as Ge$_{1-x}$Sn$_x$ (x=0.13-0.28) nanowires and nanorods at low temperatures.[2-4] The materials have been characterized by different analytical methods including TEM, EDX, Raman spectroscopy as well as XRD. Generally, a homogeneous incorporation of unusually high contents of Sn and Ga in the Ge lattice has been observed. The high incorporation efficiency also alters the physical properties significantly. While hyperdoped Ge$_{0.97}$Ga$_{0.03}$ shows quasi-metallic behavior in temperature dependent transfer characteristics, Ge$_{0.81}$Sn$_{0.19}$ reveals still semiconducting behavior in equivalent experiments. Moreover, the formation of Ge$_{1-x}$Sn$_x$ with x>0.09 causes the transformation to a direct bandgap material, while the solid solubility limit according to the binary phase diagram (~ 1 at% Sn in Ge) has to be overcome. The efficient absorption and emission in the mid-IR range (<~0.55 eV) makes Ge$_{1-x}$Sn$_x$ very attractive for CMOS-compatible optoelectronics based purely on group IV elements. The high crystal quality of CVD-grown, epitaxial Ge$_{0.81}$Sn$_{0.19}$ nanowires can be illustrated.

Vanadium-Related Electro-Luminescence from Vertical 4H-SiC PiN-Diode at Elevated Temperature Koichi Murata[1], Shin-Ichiro Sato[2], Satoshi Asada[1], Seiichi Saiki[2], Yuta Masuyama[2], Takeshi Ohshima[2] and Hidekazu Tsuchida[1]; [1]Central Research Institute of Electric Power Industry, Japan; [2]National Institutes for Quantum Science and Technology, Japan

Introduction

Quantum-sensing technology has gained increasing appeal to detect magnetic and electric fields and measure temperature with high sensitivity in a range of fields, including biomedical and space applications. The negatively charged nitrogen-vacancy defects in a diamond are the most well-known spin defects and widely studied. Although silicon carbide (SiC) has great potential for quantum sensing, several spin defect candidates have been reported [1]. These include vanadium (V^{4+}) in its neutral state in 4H-SiC, which shows photoluminescence (PL) and a wavelength of 1.3 μm in the optical telecom O-band (original band) [2, 3]. In addition, V-doped 4H-SiC materials exhibit high thermal stability against thermal post-processes up to 1973 K [2], although current-driven electroluminescence (EL) of V-doped 4H-SiC has not yet been studied. In this report, we will present EL from a vertical PiN-diode with a V-doped n-layer above room temperature.

Experiment

A V-doped 4H-SiC epitaxial layer was grown in a CVD reactor using liquid VCl$_4$ as the V dopant source [2]. A 120 μm-thick V-doped n-layer (N: 1 × 10^{15} cm^{-3}, V: 2 × 10^{14} cm^{-3}) was grown on a commercial n$^+$ SiC (0001) substrate, while a 1.5 μm-thick aluminum-doped p-type layer was grown on the n-type layer to form a vertical PiN diode structure. The comb-shaped electrode was fabricated on the p-anode and the EL was recorded under a forward bias. Deep level transient spectroscopy (DLTS) was employed to study V-related trap levels in the diode.

Results & discussion

Applying a forward current saw a clear EL appear, with peaking at 1.28 μm (hν = 0.97 eV) and a spectral shape showing positive agreement with the PL spectra obtained from V-doped n-type epilayers [2, 3]. It corresponds to the intra-3d-shell transition of V^{4+}. The EL intensity intensified as the forward current was increased, while the luminescence profile remained unchanged. The EL is also observable, even at temperature over 523 K, with no significant shift in the luminescence peak. These results demonstrate the potential of V-doped 4H-SiC based PiN diodes to function as infrared emitters at elevated temperature. The EL mechanism was also considered. Incorporated V atoms act as amphoteric defects and form two trap levels of $V^{3+/4+}$ acceptor (Ec - 0.97 eV) and $V^{4+/5+}$ donor (Ec - ~ 1.5 eV) in the 4H-SiC band gap. Within this device, the $V^{3+/4+}$ peak was confirmed on a DLTS spectrum taken under reverse bias. The $V^{3+/4+}$ peak originates from the transition between negatively charged V^{3+} and neutral V^{4+} by thermal emission. The Fermi level in the n-type layer is located well above the $V^{3+/4+}$ trap level, indicating the V^{3+} is a steady state in the n-type layer in the PiN diode at the temperature range of this study. Accordingly, the transition from V^{3+} to V^{4+} is essential and has two possible origins: (i) hole-capturing at V^{3+} and (ii) excitation of trapped-electron in V^{3+} by the energy from an electron-hole pair recombination of 4H-SiC. Given that the $V^{3+/4+}$ trap level acts as an effective carrier recombination center and minority carrier lifetimes in V-doped n-type layers are determined by V concentration [2], the origin (i) would be enhanced under a forward bias. Besides, extra excitation energy of > 0.97 eV is necessary for the intra-3d-shell transition of V^{4+}. The possible energy source for this process would originate from the electron-hole pair recombination of 4H-SiC. The luminescence mechanism discussed above supports V-doped 4H-SiC has a potential as infrared emitters operating at elevated temperature. Furthermore, electrical control of the charge states of V could be useful for quantum-sensing.

Hexagonal SiGe Phase Revealed by Nano-XRF and XLD XAS Madeleine Han[1], Jaime Segura-Ruiz[1,1], Gema Martinez-Criado[1] and Erik Bakkers[2]; [1]European Synchrotron Radiation Facility, France; [2]Technische Universiteit Eindhoven, Netherlands

Highly crystalline hexagonal $Si_{1-x}Ge_x$ nanowires (NWs) are tunable light emitting semiconductors that opens the silicon technology to photoelectronic applications. Under perpendicular crystallographic orientations, by using a hard X-ray nanobeam it is possible to probe axial vs radial coordination environment and detect any preferential order modulation that impacts the anisotropic optical response. This proposal aims to record XEOL-detected X-ray linear dichroism (XLD) microscopy around Ge atoms in $Si_{1-x}Ge_x$ alloyed NWs to illustrate 2D projections of the optical anisotropies that relies on different short-range structural orders.
Although silicon is a critical material in semiconductor industry, its indirect electronic band gap structure makes silicon an inefficient light emitter, limiting its applications. Cubic Si has the lowest conduction-band minimum close to the high-symmetry X-point and a second-lowest minimum at the L-point. On the other hand, cubic Ge also has an indirect bandgap, but its lowest conduction-band minimum is located at the L-point. Thus, by modifying the crystal structure from cubic to hexagonal, the symmetry along the <111> crystal direction can be changed. As a consequence, for hexagonal Ge the band-folding effect results in a direct bandgap at the Γ-point with a magnitude close to 0.3 eV. However, the goal of achieving efficient light emission from group-IV materials in silicon technology has been elusive for decades. Recently, Fadaly et al. demonstrated efficient light emission from direct bandgap hexagonal Ge and SiGe NWs[1]. These findings were possible thanks to the growth of Ge-rich $Si_{1–x}Ge_x$ alloys around a thin (about 35 nm in diameter) wurtzite gold-catalysed GaAs NW that is lattice-matched to Ge. These NWs have shown a sub-nanosecond, temperature-insensitive radiative recombination lifetime and an emission yield similar to that of direct-bandgap III–V semiconductors. Moreover, by controlling the composition of the hexagonal $Si_{1–x}Ge_x$ alloy, the emission wavelength can be continuously tuned over a broad range, while preserving the direct bandgap structure. Therefore, such results represent a huge step in the silicon technology and a thorough investigation could provide further insights into their singular physical properties. However, it is hard to filter out the SiGe phase from GaAs phase by XRD technique. They are expected to present the same hexagonal structure and close lattice parameters due to the close element number of Ga (31) and As (33) compared with Ge (32). So far , nanoXRF and nanoXAS have proven to be a valuable tool to image different types of semi-conductor alloy NWs[2,3]. Here in we propose to combine the power of these two approaches with elemental and polarization selectivity via X-ray linear dichroism (XLD) at the Ge K-edge to explore in details the property-function relationships in these novel SiGex alloyed NWs.

Photon Up-Converting Silicon Quantum Dots via Gas-Phase Synthesis and Grafting Joseph Schwan[1], Kefu Wang[2], MingLee Tang[2] and Lorenzo Mangolini[1]; [1]University of California, Riverside, United States; [2]The University of Utah, United States

Due to their non-toxic composition and high performance, upconverting silicon quantum dots (SiQDs) are becoming interesting for applications ranging from photovoltaics to bioimaging.[1] This study utilizes a one-step gas-phase method of silicon nanocrystal synthesis and surface-grafting of alkyl ligands to produce monodisperse silicon with uniform partial surface functionalization. The novel technique employed is a non-thermal plasma for SiQD synthesis, followed by functionalization within the plasma afterglow through the introduction of ligand saturated hydrogen.[2,3] This method allows for precise control over the SiQD size as well as the ligand species and amount being grafted to the surface. Partial surface functionalization with alkyl ligands allows for indirect control over subsequent 9-ethylanthracene (9EA) transmitter group surface coverage. Upon 9EA quantification through absorption measurements, transmitter molecule surface coverage effects are directly studied. Further analysis by FTIR enabled the quantification of alkyne surface coverage relative to unoccupied SiQD surface sites, allowing investigation into alkyne-length solubility relations. Meanwhile, emission measurements provided relations between ligand length, SiQD size, and transmitter coverage to photoluminescence and upconversion quantum yield. We have carried out experiments with 1-hexene, 1-octene, and 1-dodecene, demonstrating differences in surface coverage required for colloidal stability and the effects this coverage has on subsequent 9EA attachment and photon upconversion. Additional experiments optimizing SiQD size and alkyl surface coverage for upconversion were also conducted. Conditions enabling upconversion quantum efficiencies reaching 17% were thus achieved under minimal 1-dodecene grafting to maintain solubility, allowing for 3 9EA per SiQD.

Surface Functionalization of Silicon—Introducing Spectroscopic Labels, Monolayer Control for Ultra-Shallow Doping, and Providing Surface Passivation for Atomically-Precise Processes Andrew Teplyakov; University of Delaware, United States

Over the last several decades, chemistry for surface functionalization of silicon went through a number of directional changes that were largely dictated by the technology development. Some of the recent work in our group has been targeting modification of silicon surfaces that could be done in solution or in high vacuum, meaning that the silicon surfaces used should be sufficiently robust to withstand chemical modification conditions. Hydrogen and halogen terminations have been well documented for single crystalline surfaces, such as Si(100) and Si(111). However, if Si(111) has demonstrated overall well-ordered and chemically defined surface structures, Si(100), which is the surface mostly used in applications, has always been difficult to prepare and characterize. This presentation will cover the solution reactions of boron trichloride, boric acid and 4-fluorophenylboronic acid studied in order to understand the interaction of these molecules with hydrogen- and chlorine terminated Si(100) surfaces. These reactions will also be compared with the chemistry of nitrogen containing molecules (such as ammonia and hydrazine) in solution and at gas/solid interface. Parallels and major differences between the chemistry of (100) and (111) crystal faces of silicon will be examined. The reactions of the same surfaces with metalorganic precursor molecules will be presented to evaluate the role of minority sites (defects) in atomically-precise processing. Selected chemical modification pathways will be compared between flat silicon surfaces and nanomaterials.

2:00 PM *EL07.02.02
Tailoring Silicon Quantum Dot Photophysics Using Surface Chemistry and Doping Enabled by Gas-Phase PECVD Growth Nathan R. Neale; National Renewable Energy Laboratory, United States

We have been exploring the effects of surface chemistry and doping on the photophysics of silicon quantum dots (QDs) prepared by nonthermal plasma-enhanced chemical vapor deposition (PECVD) growth. In this presentation, we will describe the PECVD synthesis of silicon quantum dots (Si QDs) that provides the ability to incorporate high concentrations (~10^{20} cm^{-3}) of either p-type (B:Si) or n-type (P:Si) dopants. We also can use this synthetic technique to prepare co-doped QDs containing *both* P and B atoms in the same PB:Si QD. Whereas the optical absorption of singly P:Si and B:Si QDs exhibit plasmonic features characteristic of a high concentration of dopants, the co-doped PB:Si QDs instead exhibit photophysics that resemble those of intrinsic Si QDs, for example emission lifetimes of ~100 ms, but with size-dependent optical transitions that are tunable even *below* the energy of bulk Si (1.12 eV). We also will describe surface chemistry strategies made possible by the highly reactive hydride-terminated surfaces of these QDs that provide further tunability of their photophysics that could potentially enable their use in novel optoelectronic devices.

2:30 PM EL07.02.03
Silicon Quantum Dot-Molecular Hybrid System with C-C and Si-Si Binding Bridges for Efficient Photon Upconversion Kefu Wang[1], Nguyen Nhien[2], Joseph Schwan[3], Minglee Tang[4], Lorenzo Mangolini[3] and Timothy Su[3]; [1]University of Utah, United States; [2]University of california, Riverside, United States; [3]University of California, Riverside, United States; [4]The University of Utah, United States

Si quantum dots (QDs) holds great applicative potential in optoelectronic devices and bio-fluorescent agents due to their biocompatibility compared to conventional toxic Group II-VI and III-V metal-based quantum dots. [1] Recently, Si QDs have shown excellent photon upconversion property and a high photon upconversion efficiency of 7% was obtained for Si QD - 9-ethylanthracene (Si:9EA) system. [2] In addition, it has been reported that sigma Si-Si bonds exhibited comparable electron/ hole conductivity compared to C=C bonds. [3] This motivated us to investigate the binding group between Si QDs and molecular transmitters to facilitate triplet energy transfer so as to improve photon upconversion efficiency. In this work, we successfully attached silyl anthracene transmitter to Si QD surface with Si-Si bond employing di-tert-butyl peroxide as the radical initiator. Si-anthracene system with three different binding group (-CH$_2$-CH$_2$-; -Si(Me)$_2$-Si(Me)$_2$-; -Si(Me)$_2$-Si(TMS)$_2$-) between Si QDs and anthracene molecules were compared to investigate how they affect triplet energy transfer and photon upconversion. We found all three Si-anthracene systems showed high photon upconversion exceeding 5%, indicating the efficient triplet energy transfer between Si QD and anthracene transmitter for these binding bridges. Compared to Si-anthracene system with C-C binding bridge, Si-anthracene system with Si-Si binding bridge exhibited a red-shift and broader triplet excited states absorption. Overall, this work shows efficient triplet energy transfer and photon upconversion efficiency in silicon quantum dot-molecular hybrid system for both C-C or Si-Si binding bridges, which might shed light on controlling energy or charge transfer at nanoscale interfaces for optoelectronic applications.

3:15 PM *EL07.02.05
Friend or Foe—Unraveling the SiO Evolution Reaction Jonathan Veinot; Univ of Alberta, Canada

Silicon and silica-based materials are ubiquitous in 21st century technology. Whether as nanoparticles or integrated circuits, these systems are essential to a wide array of modern semiconductor applications. While the Si-SiO$_2$ interface is often presumed to be stable, the Veinot group recently encountered a previously overlooked/underappreciated reaction while exploring a widely employed silicon nanoparticle preparation. At high temperatures, silica can be reduced by silicon, resulting in the evolution of silicon monoxide (SiO) gas. Under appropriate conditions, this competing reaction eliminates all silicon nanoparticles from the synthesis. To better understand and exploit this reaction, we investigated the SiO evolution reaction and its impact on silicon nanoparticle synthesis. As our understanding of silicon monoxide improved, we were inspired to explore this reaction as a new pathway for Si-SiO$_2$ interface manipulation. This presentation will outline the insights gained during our studies and outline the challenges and opportunities presented by the silicon monoxide evolution in the context of Si nanomaterial design and preparation.

Wet Chemical Processing to Form Nanotrenches along Step Edges on a Vicinal Si(111) Surface Composed of Terraces and Atomic Steps Kenta Arima, Zhida Ma, Tetsuro Takeuchi, Ryuto Hashimoto, Rongyan Sun and Kazuya Yamamura; Osaka University, Japan

We aim at forming ultrathin Si ribbons from a silicon-on-insulator (SOI) layer possessing a vicinal surface by total wet chemical processing. To test this concept, we used a p-type Si(111) wafer of which surface is misoriented in the <11-2> direction at an angle of 0.2°. After a cut sample was wet cleaned, it was immersed in water with an ultralow level of dissolved O_2 molecules, which is referred to as the first LOW (Low dissolved-Oxygen Water) treatment. LOW was obtained by adding the deoxygenation agent ammonium sulfite monohydrate to deionized water [1] in which the O_2 concentration was less than 2 ppb. The first LOW treatment formed a Si(111) surface composed of flat terraces and biatomic steps. Then it was immersed in LOW containing Ag^+ ions at a concentration of 5 ppm, which is referred to as the second LOW treatment. We have found that Ag atoms were selectively reduced at the edges of atomic steps on Si(111) to form Ag nanowires, as reported by another group [2]. Finally, the Si sample with Ag nanowires was immersed into a mixture of HF and H_2O_2. An atomic force microscopy (AFM) image reveals that the self-assembled Ag nanowires after the second LOW treatment were replaced by almost continuous nanotrenches [3]. This is probably because the Ag nanowires acted as a catalyst to enhance chemical etching of the Si surface underneath. The height and width of the trenches were in the range of 1.1–1.4 nm and 16–19 nm. By applying this sequence for a thin SOI layer, we expect to form Si ribbons of which width and thickness are both controlled in a self-assembled manner. We also present very recent results to form and image a staircase Si structure on an SOI layer at the boundary of a buried SiO_2 and the SOI.

Non-Hydrogen Peroxide Plasma Activated Water—An Efficient Way of Surface Modification of Semiconductor Nanostructures Pavel Galar, Filip Matejka and Katerina Kusova; Czech Academy of Sciences, Czechia

The development and application of nanomaterials is one of the most impacted trends in the current science and also industry. The reason of its attractiveness is the possibility to significantly tune the properties of bulk materials by limiting their dimensions and using various surface termination or encapsulation strategies. Silicon nanocrystals (SiNCs) are one group of materials which gain significant interest. Even though Si is an indirect semiconductor, SiNCs show relatively high light emission efficiency with size tunable spectral position, good stress resistance and also surface reactivity. A wider application of SiNCs is, however, limited by the absence of a cheap and simple method for their surface termination and modification together with significantly low water dispersibility.

We have recently shown that non-thermal plasma can be effectively used for tuning of the SiNCs surface chemistry through plasma activated liquids (PAL).[1] The liquid activation is realized through treating a liquid by an electric discharge, resulting in the generation of reactive species in the liquid based on the chemical composition of the liquid, surrounding atmosphere and also properties of the used discharge. The most common PAL is plasma activated water (PAW), which is a well-known agent in medicine, agriculture and related field, because of its antibacterial, antifungal and disinfection properties. The limiting parameter of common PAW for nano-semiconductor surface treatment is the presence of a high concentration of hydrogen peroxide, which not only damages the nanocrystals, but also blocks any other surface termination except for oxidation. To overcome this effect, we have developed a technique for the preparation of PAW very low in hydrogen peroxide and containing a high concentration of nitrogen radicals (HiN:PAW). The technique is based on the application of transient spark discharge and semi-closed atmosphere at ambient conditions. Using a specific ratio between the electric pulse period and the peak current, the discharge is able to generate plasma containing a high concentration of nitrogen atoms in air, resulting in the suppression of peroxide generation in favor of nitrites and nitrates in HiN:PAW. The treatment of SiNCs by HiN:PAW for about 30 minutes resulted in nitrogen-based surface termination, manifested by a significant increase in their photoluminescence quantum yield (more than 10 times) and an increase in their dispersibility in water. The modification is stable for more than a month. While the first effect increases the prospective utilization of SiNCs in light conversion and generation and imagining technology, the latter makes them interesting for further applications in hybrid technologies, where water-based chemical processes are involved, such as the preparation of electrodes for lithium batteries. Analogical treatment can also be effectively applied to other kinds of semiconductor nanoparticles, which makes HiN:PAW a novel, cheap, easy and effective way of surface termination of semiconductor nanoparticles.

4:15 PM EL07.02.08
Interfacial Strain Fields for Nano-Carrier-Confinement and Efficient Bandgap Emission in Silicon Under 980-nm Laser Excitation Sufian Abedrabbo[1], El Mostafa Benchafia[1], Ali Abdulla[1], Anthony T. Fiory[2] and Nuggehalli M. Ravindra[2]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]Integron Solutions LLC, United States

Ordinary Czochralski silicon (CZ-Si) is known to be inferior in radiative recombination at the bandgap. Interfacing CZ-Si with sol-gel based silica coatings improves the bandgap emission significantly by introducing random strain fields; such results have been reported in several publications and presentations in the literature. In all previous work, the emission band can be modeled by a combination of uncorrelated electron-hole and phonon three particle process. In this work, we report an enhancement in carrier recombination from p-Si photoluminescence that is unorthodoxly dominated by excitonic carrier recombination. The nano-region carrier-confinement results in photons of energy hn with intensity of spectral form $e^{1/2}$ associated with correlated carrier recombination, where e = hn - E_B + E_{exc} + E_{TO}, E_B is the band gap, E_{exc} is the exciton binding energy, and E_{TO} is the transverse optical phonon energy.

8:30 AM *EL07.03.02
Luminescent Silicon Nanocrystals—From Single Quantum Dot to Light-Converting Applications Ilya Sychugov; KTH Royal Institute of Technology, Sweden

Fundamental photophysical properties of Si quantum dots (QDs) were investigated on a single-particle level to understand the mechanism of light conversion [1-3]. Emission, absorption and lifetime data were obtained for individual silicon nanocrystals with either oxide or ligand passivation. In comparison with theory we found that core-related luminescence from Si QDs emanates from an indirect-bandgap state for all practical size range of Si QDs. Small intermixing of direct-bandgap character due to quantum confinement effect takes place, but relevant only for higher energy states pertinent to the light absorption process. Quantum size effect from Si bandgap (1.1 eV) up to 2 eV has been clearly demonstrated by observation of sharp emission linewidths in a broad energy range [3].

Despite partly forbidden character of the recombination process, luminescence from Si QDs may still possess high quantum efficiency when a defect-free core with proper surface passivation realized. We have demonstrated a new synthesis method, which can reduce pre-cursor cost by an order of magnitude from the established HSQ-based method [4]. Si QDs prepared in this way have near-unity internal and > 50% external (quantum yield) quantum efficiency. They also possess a large Stokes shift, which suppresses re-absorption of the emitted light of importance in a number of applications.

One such application is a semi-transparent photovoltaics for glazing in building-integration. It is based on a luminescent solar concentrator concept, where high efficiency and a large Stokes shift are necessary requirements for nanophosphors [5-6]. In this configuration absorbed solar light is re-emitted and a large fraction of it is guided by total internal reflection to the edges for collection by standard solar cells. As a proof-of-concept we fabricated 20x20 cm^2 prototypes, where Si QD-doped polymer layer is sandwiched between glass plates in a triplex geometry. Such "solar windows" feature high transparency (>80%), low haze (<3%), high color rendering index (~ 88) and, at the same time, deliver up to 0.6 W of electrical peak power under one sun [7-8]. Another application is in bio-labeling, where long lifetime of Si QD emission (~ us) makes them sensitive to surface chemistry. It was shown previously that the presence of nitrogen moieties on nanocrystal surface may introduce a fast, ~ ns, recombination channel, which can take over carrier recombination from the QD core. Here we used this effect to monitor amino acids in the cell, where their binding of Si QDs manifested in shifted luminescence from near-infrared to blue and drastically reduced the lifetime, acting as an efficient amino acid probe in live cells [9].

Designing Hybrid Silicon Interfaces for Photon Up- and Down-Conversion Sean T. Roberts; The University of Texas at Austin, United States

Organic compounds that undergo singlet fission or its inverse process, triplet fusion, have emerged as promising materials for designing systems that efficiently convert light of one color into another by redistributing the energy of individual photons. However, to achieve these functions, these materials need to be partnered with a long wavelength light absorber. Due to its prominent role in microelectronics, photodetection, and solar energy harvesting, silicon is a natural target material to partner with organic singlet fission and triplet fusion compounds. In this presentation, I will describe work by my group done in collaboration with others to prepare heterojunctions wherein covalent bonds are used to anchor organic singlet fission and triplet fusion compounds to silicon to enable energy exchange between these materials. In particular, I will showcase recent work wherein we have achieved strong-coupling between acene molecules and silicon. This strong coupling produces excitonic states with mixed molecule:silicon character that straddle their interface and can serve as effective doorways for shuttling energy between silicon and its environment. We have used these states to prepare silicon nanocrystals that fuel photon upconversion, converting green photons to blue ones with better than 17% efficiency as well as silicon surfaces wherein spatially separated acene molecules form spatially-delocalized 2D excitonic states via intermolecular interactions that are fueled by coupling to the underlying silicon lattice.

EL07.03.04 Universality of Photoluminescence Lifetimes in Slowly Emitting Silicon Quantum Dots Katerina Kusova[1], Tomas Popelar[1], Pavel Galar[1], Filip Matejka[1] and Paola Ceroni[2]; [1]Czech Academy of Sciences, Czechia; [2]University of Bologna, Italy

Silicon quantum dots (SiQDs) are a class of light-emitting materials with very low inherent toxicity and broad spectral tunability. SiQDs are being developed for several decades and a wide range of synthesis techniques are available now. Generally speaking, several modes of light emission from SiQDs have been reported in the literature, covering an extremely wide range of photoluminescence lifetimes from hundreds of microseconds to ten nanoseconds. In this contribution, we focus on the "traditional", first-reported mode of light emission featuring slow (tens to hundreds of microseconds) emission tunable from the red to the near infrared spectral range, originating in the lowest excited transition of the quantum-confined states in the QD. Using our characterization of SiQD samples prepared by various techniques and a wide compilation of literature data, we observe striking similarities in the lifetimes of differently prepared samples and propose that all these fabrication techniques yield SiQDs with fundamentally similar properties. Our analysis provides us with a tool for the determination of radiative and slow non-radiative lifetimes of these samples, which is, unlike complicated measurements of internal quantum efficiency yielding the same quantity, extremely easy to apply. We also differentiate between fast and slow non-radiative pathways and discuss the importance of the radiative and both the fast and the slow non-radiative pathways in the assessment of the overall emission properties of slowly emitting SiQDs.

9:45 AM EL07.03.05
Nanograin Network Memory with Reconfigurable Percolation Paths for Synaptic Interactions Hoo-cheol Lee[1], Jungkil Kim[2], Ha-reem Kim[1], Kyung-Ho Kim[3], Kyung-Jun Park[1] and Hong-Gyu Park[1]; [1]korea University, Korea (the Republic of); [2]jeju national university, Korea (the Republic of); [3]Chungbuk National University, Korea (the Republic of)

The development of memory devices with functions that simultaneously process and store data is required for efficient computation. To achieve this, artificial synaptic devices have been proposed because they can construct hybrid networks with biological neurons and perform neuromorphic computation.

However, irreversible aging of these electrical devices causes unavoidable performance degradation. Although several photonic approaches have been suggested to control the currents, photonic suppression of current levels and switching of analog conductance remain challenging. Here, we present a nanograin network memory using reconfigurable percolation paths in a single Si nanowire consisting of solid core/porous shell segments. The unique electrical and photonic control of current percolation paths in the Si nanograin networks enabled the analog and reversible adjustment of the persistent current level, exhibiting memory behavior and current suppression in this single nanowire device. In addition, the synaptic behaviors of memory and erasure were demonstrated through potentiation and habituation processes. Notably, photonic habituation was achieved using laser illumination on the porous shell, with a linear decrease in the postsynaptic current. Furthermore, synaptic elimination was emulated using two adjacent devices interconnected on a single nanowire. Therefore, electrical and photonic reconfiguration of the conductive paths in Si nanograin networks will pave the way for next-generation nanodevice technologies.

Lead-Free Infrared Photodetectors with III-V and IV Materials Pan Xia, Margherita Biondi, Tong Zhu, Bin Sun and Edward H. Sargent; University of Toronto, Canada

Infrared photodetectors are vital for multi-detection applications, including cameras, security systems, and LiDAR. Low-toxicity, lead-free infrared photodetectors have significant applications in consumer electronics and industry. III-V and IV group materials stand out due to their ability to absorb visible to mid-infrared light, being heavy-metal free, and their high carrier mobility. This work introduces the investigation of III-V and IV group materials in infrared photodetectors in two aspects: 1) photophysical study of III-V group colloidal quantum dots (CQD), and the optimization of their photodetectors; 2) application of hybrid III-V and IV group materials in photodetectors.
In recent years, several synthesis and passivation approaches for typical III-V group-InAs quantum dots (QDs) have been explored. InAs CQD-based photodetectors have been reported to achieve good detectivity and fast response at room temperature [1,2]. This work reports that improvement of the surface passivation of InAs CQD enables photodetectors with low dark current and good detectivity across a spectrum of wavelengths. In addition, the hybrid of IV with III-V materials as photodetectors is being studied for better detectivity and a wider detection range.

Photoinduced Disordering and Recovery in Colloidal Silicon Nanocrystals Richard D. Schaller[1,2]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States

Low toxicity silicon nanocrystals offer potential for use in applications that range from bio-labeling to solar energy conversion and LEDs. Small particles present reduced melting points and highly active surfaces that raise possibilities of loss of crystalline structure upon excitation as phonons are generated. We probe behavior of few-nanometer colloidal silicon particles and in particular focus on how the lattice responds to controlled fluence optical excitation. Using transient X-ray diffraction using optical excitation enabled by Beamline 11-ID-D at Argonne's Advanced Photon Source, we correlate development of transient signals with number of photons absorbed to arrive at excitation densities that demonstrably disorder the initially crystalline lattices. Electronic consequences of this disordering are examined.

High Hole Mobility in Two-Dimensional Germanane Thin Films Yumiko Katayama, Daiki Kobayashi, Yuhsuke Yasutake, Susumu Fukatsu and Kazunori Ueno; The University of Tokyo, Japan

Germanane (GeH) is a hydrogen-terminated layered crystal of germanium and is expected to be a direct bandgap semiconductor with high electron mobility [1]. Our group reported an electric double-layer transistor on a GeH thin film with the ambipolar transport characteristics and the Hall mobilities of electrons and holes at 120 K, 6500 cm^{2}V^{-1}s^{-1}, and 570 cm^{2}V^{-1}s^{-1}, respectively [2]. However, due to the high contact resistance between electrode and GeH, the transport properties below 120 K remained unexplored. In this study, we report unexpectedly high hole mobilities of GeH thin films exceeding 67 000 cm^{2}V^{-1}s^{-1} at 15 K, which was achieved by optimizing the electrode materials and crystal growth conditions.
The GeH thin films were prepared by the topotactic transformation of epitaxial CaGe$_2$ films on a Ge (111) grown by solid-source molecular beam epitaxy (MBE) with a base pressure better than 2x10^{-8} Pa. A Ge buffer layer and a Zintl-phase CaGe$_2$ film were grown on the nominally undoped Ge (111) substrate. The GeH films were obtained by immersing the CaGe$_2$ films in concentrated aqueous HCl for 1~4 days at -18 °C, and then by rinsing in isopropanol at room temperature. Pt electrodes, in a Hall-bar configuration, were formed by sputtering through a stencil mask. The transport properties were measured on a Quantum Design physical properties measurement system.
The sheet resistance, Rs, of the GeH film showed a peak approximately at 250 K. Below 250 K, Rs decreased with decreasing temperature from ~1.5 kΩ at 250 K to ~50 Ω at 30 K, which indicates metallic conduction, whereas it showed semiconducting behaviors above 250 K. From the Hall measurement, the majority carriers were confirmed to be holes at low temperature while they were electrons at high temperatures above 250 K. Rs above 250 K was likely to be dominated by conduction through the Ge substrate and the buffer layer. At 200 K, the Hall resistance showed nonlinear dependence on the magnetic field, which can be understood in terms of two-carrier transport including the holes from the GeH film and the electrons from the Ge layer. Because the magnetic-field dependence of the Hall resistance becomes linear at low temperature, the contribution of the Ge layers can be ignored below 200 K. That the carriers are holes at low temperatures was also confirmed by the Seebeck coefficients. The hole concentration decreased with decreasing temperature from 2×10^{17} cm^{-3} at 200 K to 3×10^{16} cm^{-3} at 15 K. Meanwhile, the Hall mobility increased with decreasing temperature from 2×10^3 cm^{2}V^{-1}s^{-1} at 200 K to 6.7×10^4 cm^{2}V^{-1}s^{-1} at 15 K. At 15 K, the magnetoresistance ratio reached 6,500 % at 7 T and Shubnikov-de Haas oscillation was observed. The sheet carrier density by assuming a spherical Fermi surface was estimated to 2.8×10^{11} cm^{-2}, which is in good agreement with the Hall carrier density of 3.0×10^{11} cm^{-2} at 15 K. These results indicate the possibility of single-band conduction originating from the light-hole band in GeH.
Our results showed that two-dimensional hydrogen-terminated layered germanium prepared by topotactic reaction exhibits unprecedented high hole mobility and well-resolved Landau levels at 15 K. Further attempts at even lower temperatures would allow the first observation of the quantum Hall effect in this novel layered system.

Self-Switching Diode Effect in Electrostatically Gated Silicon Nanowire Geometric Diodes Kelly White, Gordon Rogelberg, James Custer and James Cahoon; The University of North Carolina at Chapel Hill, United States

High frequency rectifying diodes are essential for microwave and terahertz detection systems, with important applications in security, healthcare, and high-speed communication. Geometric diodes are an emerging class of electrical diodes that have unique advantages as high frequency rectifiers, without a dependence on minority carriers and with simpler device fabrication using lower cost materials. They operate on the principle of ratcheting by converting a fluctuating, unbiased force into unidirectional electron motion. Silicon nanowire geometric diodes are morphologically asymmetric silicon nanostructures that function as electron ratchets at room temperature and have been shown to rectify frequencies up to 40 GHz, with a theoretical cut-off frequency above 1 THz. While these devices are considered quasi-ballistic rectifiers, their electrostatic effects, particularly at the nanowire surface, have a significant impact on diode performance and are largely unexplored. Here, we synthesize silicon nanowire geometric diodes using dopant-encoded VLS growth and dopant-selective etching and fabricate wrap-around gated single-nanowire devices to precisely control nanowire surface charge. Electrical characterization of single-nanowire devices demonstrates tunability of diode polarity, current magnitude from 1 nA to 10 µA, and DC asymmetry from 1 to 400 with gate voltage. Through finite-element modeling, we clarify the asymmetric bias-induced barrier lowering mechanism that enables electron ratcheting in these gated nanostructures and is indicative of self-switching diode devices. Notably, we observe this same mechanism and similar current and DC asymmetry results in simulations of ungated silicon nanowire geometric diode devices with sufficiently large trap densities at the nanowire surface. When we consider the surface trap states, the resulting surface charge acts like a wrap-around gate with a fixed voltage. These results demonstrate the creation of a novel silicon nanowire-based self-switching diode and the possibility for simplifying fabrication through surface modification to tune nanowire surface trap density.

Strong Coupling Physics and Nanoscale Photoreactivity Joel D. Eaves[1,2], R. P. Cline[1,2,3], Sean T. Roberts[4], Lorenzo Mangolini[5] and Ming Lee Tang[6]; [1]University of Colorado, United States; [2]University of Colorado Boulder, United States; [3]National Renewable Energy Laboratory, United States; [4]The University of Texas at Austin, United States; [5]University of California, Riverside, United States; [6]The University of Utah, United States

Recently, experimentalists have built new interfaces consisting of organic molecules covalently bound to inorganic solids. Covalent bonding between the molecule and the solid allows for stronger and more tunable electronic coupling between the localized electronic states, typical of the molecule, and the delocalized states of the solid. These systems can exhibit much stronger coupling than is typical in either the molecule or solid alone, and that coupling can be controlled using simple linking chemistries. In this talk, I will discuss how strong electronic coupling allows one to tune the onset of the absorption maximum and how coherences between molecules at the surface, mediated by strongly coupled bulk electronic states, can influence photoreactivity. Preliminary results suggest that these strong coupling physics might be a vital step in the development of new multielectron redox catalysts.

3:00 PM EL07.04.04
Theory of Optically Detected Magnetic Resonance of a Silicon Vacancy in SiC Nanoparticles—A Quantum Sensor of Magnetic Fields David Fehr and Michael Flatté; University of Iowa, United States

Magnetometers are used in virtually every aspect of our lives: from navigation, the detection of submarines and underwater debris, archaeological and geological surveys, to our mobile phones and in the exploration of our solar system [1-2]. Recently, solid-state magnetometers have stimulated particular interest due to their smaller size, weight, and power (SWaP) compared to existing magnetometers [3], and their potential to self-calibrate [4]; two attractive features which improve the efficiency of any device carrying a magnetometer, especially spacecraft. However, extensive research must be completed to optimize this new technology for widespread commercial use, and a detailed theory is the first step in this process.

Silicon Carbide nanoparticles containing defects with optically addressable spin states are available in a variety of sizes and crystal structures [5-8]. This creates the perfect playground for optimizing the spin-photon interaction for the purpose of quantum sensing of magnetic fields. In this work we model optically detected magnetic resonance (ODMR) of the silicon vacancy (V_{Si}) in silicon carbide,
a budding candidate for solid-state quantum magnetometry, using Lindblad master equations. The silicon vacancy can be thought of as a $S = 3/2$ synthetic atom, and its spin states are sensitive to magnetic fields via the Zeeman effect. In ODMR, magnetic resonances of the Zeeman field are detected by extrema in the normalized photoluminescence signal when a transverse microwave field is applied. The photoluminescence is calculated from the steady-state density matrix populations and compared to recent experimental results [9-11].

We acknowledge support from NSF DMR-1921877.

Cross-Correlated Quantum Thermometry Using Diamond Containing Dual-Defect Centers Madhav Gupta, Tongtong Zhang and Zhiqin Chu; The University of Hong Kong, Hong Kong

The contactless temperature measurement at micro/nanoscale is vital to a broad range of fields in modern science and technology. The nitrogen vacancy (NV) center, a kind of diamond defect with unique spin-dependent photoluminescence, has been recognized as one of the most promising nanothermometers. However, this quantum thermometry technique has been prone to a number of possible perturbations, which will unavoidably degrade its actual temperature sensitivity. Here, for the first time, we have developed a cross-validated optical thermometry method using diamond containing both NV centers and Silicon Vacancy (SiV) centers. Particularly, the latter has been intrinsically immune to those influencing perturbations for the spin-based approach, hence serving as a real-time self-calibration system. As a proof-of-the-concept demonstration, we have shown a trustworthy temperature measurement under the influence of the randomly changing magnetic fields. This multi-modality approach allows a synchronized cross-validation of the measured temperature, which will be meaningful for micro/nano scale measurements in complicated biosensing environments such as inside a living cell. Additionally, we propose to build on our previously developed method[1] of using high quality salt-assisted air-oxidized (SAAO) nanodiamonds (NDs)[2] as CVD seeds to grow diamond particles, for synthesizing nanodiamond crystals having a co-existence of NV and SiV defect centers. This will provide a high performance all-optical thermometer as an independent temperature validation/self-calibration mechanism with nanoscale spatial resolution. This has a wide variety of practical applications requiring high spatial resolution, such as performing quantum thermometry in living cells.

Understanding Stability in Ge-Sn Surfaces and Nanoparticles with First-Principles Calculations Katelyn P. Nelson, Mattea Miller, Deep M. Patel and Luke T. Roling; Iowa State University, United States

Group IV semiconductors have demonstrated promise as candidates for next-generation low-temperature optical computing and communications technologies due to their promising optoelectronic properties. In particular, the bandgap of Ge can be tuned and made direct through the incorporation of Sn, motivating the study of Ge(Si)Sn nanomaterials and surfaces. However, the development of practical devices utilizing these elements is limited by the incorporation of Sn in high quality and uniform synthesizable materials. In this presentation, we will share our recent computational insights into fundamental properties governing the stability of Sn in Ge surfaces and nanoparticles.

Using density functional theory (DFT) calculations, we show that the stability of GeSn systems changes non-monotonically with Sn content. The incorporation of Sn depends strongly on morphology, considering both {111} and {100} crystal orientations; structure, considering extended surfaces and nanoparticle models of varying sizes; surface termination, considering a range of terminating species including H, halogens, and alkyl groups; and atomic-scale arrangements of Sn and Ge atoms. Our calculations predict improved Sn incorporation in {100}-terminated nanocrystals compared to {111}-terminated structures, enabled by the increased geometric freedom imparted to the larger Sn atoms at the more open {100} surfaces. The nature of the surface termination strongly influences atomic arrangements at the surface, with stronger-binding species (e.g., -Cl) exhibiting significantly different stabilization of Ge and Sn and thereby affecting the preferred segregation of components within surfaces and nanoparticles. Our results also suggest that the relative stability of nanoparticles depends on the nanoparticle size, though the nature of the size effects depend on surface termination (species and geometry). We finally show the effects of applied strain on the stability of Sn in surfaces, including in the presence of adsorbates. These fundamental insights suggest possible routes toward the synthesis of GeSn materials with tunable and high Sn content.

SESSION EL07.05: Poster Session

5:00 PM EL07.05.01
Surface Termination of Plasma Synthesized Silicon Nanocrystals using Plasma-Activated Liquids Filip Matejka[1,2], Pavel Galar[1,2], Josef Khun[2] and Katerina Kusova[1]; [1]Czech Academy of Sciences, Czechia; [2]University of Chemistry and Technology, Czechia

In the last decades, nanoparticles of a broad variety of materials, mainly semiconductors, made a breakthrough impact on science and industrial development. The main glamor of nanostructured materials is due to the alteration of their original bulk properties. Nano-scaled materials report a higher surface-to-volume ratio, leading to a crucial impact on the surface effects. Moreover, with sizes less than a dozen of nanometres, the quantum confinement of the wavefunctions is manifested. In the case silicon in the form of nanocrystals (SiNCs), these effects lead to the lighting up of the normally dull bulk material. The relatively high light emission efficiency of SiNCs is accompanied by wide spectral tunability from visible to near-infrared (IR)spectral regions. The peak emission and intensity of photoluminescence (PL) is dependent on the size, defects, and surface termination. However, the limitations of further applications of the SiNCs are their methods of synthesis and methods of surface termination. So far, especially the existing termination methods are low yield, expensive, complex, and not environmentally friendly.

In this work, we apply non-thermal plasma (NTP) for both the synthesis and the subsequent surface modification. In the case of the synthesis, the NTP low-pressure method generates SiNCs with a highly reactive hydrogen-terminated surface; due to the synthesis from silane gas, with a low number of defects, leading to initial high PL intensity. Additionally, the mean size of the NCs and therefore their PL peak emission is finely tuneable from 700 nm to 950 nm. The yield of this method is high, in micrograms per minute.

The reactive hydrogen surface can be modified by several methods. The most common method for carbon termination creating C:SiNCs is hydrosilylation, which is costly on time, (reaction time up to 12 hours) and on energy, due to the long reaction time and high boiling points of organic liquids. Hence, we introduce an innovative approach of the NTP treatment of liquids, the so-called plasma activation (PAL). The NTP treatment provides a gentle interaction with the liquid, using reactive species generated by the discharge from the surrounding atmosphere (can be applied in air, or in a closed-space inert atmosphere), using by two needle electrodes. The reactive species then react with the molecules of the liquid, creating a reactive environment for the SiNCs with enough energy to exchange the surface bonds. In our study, we focused on organic liquids (PAOL), whose molecules report dipoles, leading to a better interaction of the discharge with the liquid phase (e.g., Ethanol, Acetic Acid, Octanol, etc.). For the PAOL treatment, the closed chamber reactor constantly flushed with Ar was designed to prevent the the interaction with humid air, suppress flammability, and establish stable discharge conditions. Despite that, the overall PAOL process can be done in less than an hour of reaction time. The PAOL treatment produced a stable (for more than 72 days) enhancement of the quantum yield (QY) and PL properties (intensity increment more than 25 times and slight blue-shift) and better dispersibility (proven by DLS measurements). The surface bonding was studied by IR spectroscopy and PL measurements.

An analogical PAL treatment can be also applied to inorganic liquids. In our recent work, we showed that plasma activated water (PAW) can successfully enrich the surface termination of SiNCs with nitrogen-based species. In this on-air process, the creation of the intermediary phase above water is needed, therefore the settings of the shape of the reactor, volume of water, and discharge are crucial to generate PAW without hydrogen peroxide, which kills the SiNCs PL, simultaneously exhibiting a high concentration of nitrogen species. This treatment leads to stable enhancement of QY (up to 10 times) and water dispersibility of SiNCs, making them more attractive for further applications.

Improving the Dispersion of Silicon/Silicon Dioxide Quantum Dots Adriana Chapa[1,2], Kristine Q. Loh[1], Vivian Ferry[1] and Uwe Kortshagen[1]; [1]University of Minnesota, United States; [2]The University of Texas Rio Grande Valley, United States

Through the years there has been a growing need for renewable energy sources. Luminescent Solar Concentrators (LSCs) are semitransparent devices that generate renewable electricity. LSCs are composed of a transparent polymer waveguide with embedded luminescent nanocrystals. Silicon Quantum Dots (Si QDs) are semiconductor nanocrystals that broadly absorb UV light and photoluminese near-infrared light. Si QDs are suitable for LSC applications as they are nontoxic and made from an abundant element.

This work focuses on developing a method to disperse core/shell Si/SiO2 QDs in a solvent. Various aspects of the dispersion were studied by experimenting with different ligands, pH levels, and solvents. We tested two different ligands, (3-Glycidyloxypropyl) trimethoxy silane (GPTMS) and polyethylene glycol, two different pH level additives, ammonium hydroxide (NH4OH) and hydrochloric acid, and different solvents including ethanol, H2O, and toluene.

The dispersions were characterized using Fourier transform infrared (FTIR), UV-Visible, and photoluminescence (PL) spectroscopies. First, the ligands GPTMS and polyethylene glycol (PEG)-silane were tested. The solution contained 100 µL of HCl, 1.5 mL of ethanol and 0.3 mL of H2O. The dispersion of the Si/SiO2 with GPTMS and HCl settled faster than the Si/SiO2 with PEG-silane and HCl dispersion. Using UV-Vis, the Si/SiO2 with GPTMS absorbance is higher than the absorbance of the Si/SiO2 with PEG-silane due to scattering from the larger agglomerates that settled. The samples in HCl were more stable than ones using ammonium hydroxide. FTIR measurements confirmed that the Si/SiO2 QDs were coated with PEG-Silane.

Lastly the dispersions were characterized using photoluminescence spectroscopy. The Si/SiO2 QDs in toluene and Si/SiO2 QDs in PEG-silane show that the solutions can have similar photoluminescence intensities even though the toluene dispersion sample agglomerates. Si/SiO2 QDs in H2O agglomerate faster relative to the QDs in ethanol. In conclusion, using PEG-silane as a ligand in an acidic environment with a polar solvent led to a stable, homogeneous mixture with a high photoluminescence intensity.

5:00 PM EL07.05.03

Fast Photoluminescence and Energy Transfer in Silicon Quantum Dots Tomas Popelar[1], Katerina Kusova[1] and Paola Ceroni[2]; [1]FZU - Institute of Physics of the Czech Academy of Sciences, Czechia; [2]Università di Bologna, Italy

Si nanocrystals (SiNC) can be relatively efficient light emitters despite their indirect bandgap. Their attributes (e. g. light-emission efficiency) depend heavily on surface passivation. Various schemes were exploited over the years, however, the functionalization with diphenylanthracene (DPA) is quite new in the SiNC field. To investigate the role of DPA we compared the samples with DPA covalently attached to SiNCs (SiDPA), samples passivated with dodecane (SiDDE) and also the mix of SiDDE with various concentrations of DPA. This enabled us to properly characterize the energy transfer between the DPA molecules and SiNCs.

Apart from the classical methods of optical spectroscopy like absorption and time-resolved photoluminescence (PL) measurements, we also used the seldom utilized two-photon excitation to investigate the energy transitions in our samples in detail. This excitation theme interacts with the samples differently compared to the common one-photon excitation due to the different absorption coefficients of two-photon absorption. The samples exhibit typical two-part PL consisting of the fast (ns) blue band and slow (us) red band. By using the two-photon excitation, we observed the enhanced red PL compared to the blue PL and also completely different dynamics even in the case where the same energy transition was excited, i.e. the two-photon excitation scheme used the twice as long wavelength compared to the one-photon excitation. These new effects were observed even in the "classical" SiDDE sample showing that there are still issues to be resolved, particularly in the blue band area. Our usage of a femtosecond laser and optical parametric amplifier (output pulses with wavelengths between 315 - 2000 nm and time-length 150 fs) with streak camera with ps time-resolution for detection enabled us to analyze the individual decay channels and determine the "transition energy" connected to the switching PL dynamics among other effects.

5:00 PM EL07.05.04

Study of Ignition Condition of Non-Thermal Plasma Synthesized Silicon Nanoparticles Jakub Kopenec[1,2], Pavel Galar[1,2], Katerina Kusova[1] and Martin Muller[1]; [1]Institute of Physics the Czech Academy of Sciences, Czechia; [2]University of Chemistry and Technology Prague, Czechia

Silicon (Si) proved to be one of the essential elements of current electronics, energetics and of many other technological fields. When in the form of a nanostructure, e. g. as silicon nanoparticles (SiNPs) Si properties are altered by a complex synergy between quantum effects and an influence of high surface to volume ratio. In comparison with bulk Si, SiNPs show high surface reactivity, mechanical resistance and, despite being an indirect semiconductor, also effective light emission. The combination of Si original and nano-gained properties is beneficial for many optoelectronic, electronic, or biological applications. In addition to these applications, in Li-Ion technology is of special interest here, because silicon possesses the highest theoretical gravimetric (specific) capacity of all elements and in the form of a nanostructure, it is able to withstand extreme volume changes during the lithiation and delithiation proces.

In this study, we demonstrate the potential of SiNCs being used as an energy-storage material. One of the most perspective ways of high-gain synthesis of SiNPs is the utilization of non-thermal plasma. However, at specific synthesis conditions, the plasma-prepared SiNPs (nanoparticles in general) can be highly flammable. They can be ignited even by a weak laser with light intensity of units of mW/mm^2 or by temperatures above approximately 90°C. The origin of this effect is based on the presence of hydrogen in the synthesis chamber and its following efficient integration onto the SiNPs surface. Thus, after synthesis, SiNPs store significant amounts of energy (up to 7000 cal/g), which they release after being ignited. We observed a significant dependence of the ignition conditions on the crystallinity and size of SiNPs and also on the amount of additional hydrogen in the synthesis chamber. Infrared spectroscopy proved that it is the type of the bond ($Si\text{-}H$, $Si\text{-}H_2$, $Si\text{-}H_3$) that plays an important role in the stability/flammability of SiNPs. In particular, SiNPs containing SiH_3 structures on its surface were easier ignited in contrast to the ones containing SiH which were highly stable. The microscopic interpretation of this effect is presented. These findings are potentially important not only for applications in explosives, but they also point towards the possibility of using SiNPs as a hydrogen/energy-storing material.

5:00 PM EL07.05.05

Millimeter Wave to Terahertz Sub-5nm Nonlinear Optoelectronic CMOS Technolog—Performance Advantages Over Traditional CMOS-Based ASICs, SoC and Silicon Photonics James Pan; AELC, United States

Negative resistance millimeter wave semiconductor devices (including Tunnel, Gunn, IMPATT and, BARITT diodes) can generate high frequency microwave signals approaching the terahertz infrared regime for commercial telecommunications and military applications. These devices can be included in the drain or source regions of a MOSFET as one integral device to form Millimeter Wave to Terahertz Optoelectronic CMOS Transistors. Here, we will discuss the performance advantages of this novel technology: how it may even outperform traditional CMOS-Based RF ASICs, System on Chip (SoC), or Silicon Photonics due to reduced series resistance and capacitance. Critical RF parameters, such as cutoff frequency (ft and fmax), are improved due to the switching speed improvements from the photonic and millimeter wave generation process. The integrated device produces less heat and can be thermally more stable. Also, photonic millimeter-wave devices can be designed to handle pulsed laser and millimeter-wave signals simultaneously. Low operating voltages are possible due to the nature of the tunneling process and the close proximity of the components in the integrated device. We also show a path toward monolithic integration in a CMOS fabrication sequence. IMPATT and BARITT are reverse-biased diodes. Laser and LED are forward-biased diodes. The source or drain junction of a MOSFET is a reverse-biased diode. Photon and microwave generating diodes can be included in the drain or source regions of a MOSFET. Photon sensors can be fabricated in the substrate, well or drain regions. Millimeter wave diodes, laser or LED, Photon Sensors, and MOSFET are fabricated as one integral device to form the Millimeter-wave Photonic CMOS Transistors. A millimeter wave tunnel diode can be operated at a very low voltage, due to the tunneling process without thermal diffusion. Photonic Microwave CMOS functions with electric fields (it is a field effective device) compared with diode lasers, which rely on thermal diffusion and produce more thermal noises. With improved device models and circuit designs, nonlinear laser and millimeter wave communications can be a reality. The manufacturing costs for 3D All-Around-Gate FETs and Sub-5nm FINFETs can be very high.

The Milliwave Optoelectronic CMOS is 100% compatible to sub-5nm CMOS technology nodes, as the Laser, LED, and Microwave diodes are in the MOSFET or FINFET drain region - the gate and channel regions are not affected. The manufacturing cost for sub-5nm Millimeter Wave Optoelectronic CMOS is much lower, and the performance can be much higher.

Terahertz operations can be achieved using the Millimeter Wave Optoelectronic CMOS, with Microwave Diodes and Mid- or Far- Infrared QCL (Quantum Cascade Laser) in the CMOS drain regions.

The Transferred Electron Tunnel Millimeter Wave and Gunn Diodes present unique "Negative Resistance" characteristics under a certain bias conditions and internal electric fields, which may reduce the Rsd (series resistance), ft / fmax (cutoff frequency) and are suitable for high clock-speed operations.

In this report we will discuss the performance advantages and cost benefits of the technology. We will also look into various Microwave diodes, how they can be added to the sub-5nm CMOS, and what are the operating conditions, as one integral transistor.

Local Bandgap Measurement of Core/Shell Ge/GeSn Nanowires Employing Electron Energy Loss Spectroscopy in Scanning Transmission Electron Microscopy Milenka Andelic[1], Alexandre Pofelski[1], Sebastian Koelling[2], Simone Assali[2], Lu Luo[2], Oussama Moutanabbir[2] and Gianluigi Botton[1]; [1]McMaster University, Canada; [2]Polytechnique Montréal, Canada

Group IV $Ge_{1-x}Sn_x$ alloyed semiconductors have attracted a lot of attention because of their numerous applications in the field of monolithically integrated optoelectronic and photonic devices compatible for use on the Si platforms. Such applications include free-space data communications, night-vision sensors, biosensors, and materials for thermal imaging, which dominate in the short-wave infrared (SWIR: 1.5-3 um) and mid-wave infrared (MWIR: 3-8 um) and long-wave infrared (LWIR: 8-14 um) wavelength ranges [1], [2].

Core/shell Ge/GeSn structured nanowires (NWs) exhibit high tunability of electronic properties by varying two parameters, Sn content and lattice strain. Furthermore, these free-standing core/shell Ge/GeSn NWs grown on Si wafers tend to accommodate more elastic strain which is relaxed at the sidewall facets of the wires. In this research, a GeSn shell has been grown around the colloidal-nucleated Ge core using the chemical vapour deposition (CVD) technique. The variation in Sn content incorporated in GeSn alloy strongly affects the electronic bandgap energy and optical transitions, such as the plasmonic oscillations and interband transitions. By increasing the Sn content in the $Ge_{1-x}Sn_x$ shell, the bandgap is expected to experience a transition from indirect to direct bandgap, progressively narrowing down. For high enough Sn concentration, the electronic structure would eventually exhibit an effective negative bandgap, essentially an indirect semimetal behaviour [3].

Here we investigate the behaviour of electronic band structure and bandgap energy demonstrating the potential of high-resolution electron energy loss spectroscopy (EELS) in a monochromated scanning transmission electron microscope (STEM). Spatial locality is essential in the bandgap measurement of these NWs as EELS can provide a wealth of information on various features in the low-energy range, showing the effect of localized defect states that may be present in the bandgap energy onset. Other transitions, such as collective plasmon oscillations and single-electron transitions that depend upon the position of electronic levels within the band structure, are observed and will be discussed. [4]

Microwave-Assisted Solution Synthesized Germanium Nanocrystals Susan M. Kauzlarich; University of California, Davis, United States

Ge is one of the quintessential semiconductors being considered in nanoform for optoelectronic applications. Ge alloys have been shown to have potential for energy storage as a Li ion battery anode and energy conversion as a catalyst. Ge has several advantages over Si or SiGe alloys including superior charge carrier mobilities, low dopant activation temperatures, and a smaller band gap. We have recently employed a two-step microwave-assisted reduction of GeI_4 in oleylamine to prepare monodispersed Ge NCs from 10 -20 nm in diameter. The as-synthesized Ge NCs showed high crystallinity with single crystal nature as indicated by powder X-ray diffraction, selected area electron diffraction, and high-resolution transmission electron microscopy. Solutions involved in this two-step reaction were investigated with ^{1}H NMR spectroscopy and high-resolution mass spectrometry to better understand the reaction pathway. I will present new insights gained from this chemical route that may impact the nanoparticle synthesis of other covalently bonding semiconductors.

9:00 AM *EL07.06.02
Functional Silicon Nanoparticles with Sizes Ranging from Single Nanometers to Sub-Micrometers Hiroshi Sugimoto; Kobe University, Japan

Si forms not only the backbone of microelectronics technology but also gains in significance for photonics when its size is down to nanoscale. Depending on its size (1-1000 nm), Si nanostructures exhibit different optical responses. In this presentation, we show the optical properties of Si nanoparticles with two different size regimes. For sub-10 nm in size, so-called quantum dots (QDs), the quantum confinement effect enables the efficient photoluminescence (PL) and facilitate the applications as light emitters. The properties can be also controlled by doping impurities. Here we present a comprehensive study on colloidal Si QDs codoped with boron (B) and phosphorus (P).[1,2] We show the detailed structural and optical characterization and demonstrate that the codopants modify the electronic structures of Si QDs and introduce donor and acceptor levels in the band gap of Si QDs. This enables the optical transition with the energy below bulk Si bandgap (~1.1 eV). We will demonstrate the potential applications of codoped Si QDs in photonics and biomedical fields. The second part of the presentation focuses on Si nanoparticles with 100-250 nm in diameter that exhibit electric and magnetic Mie resonance in the visible to near-IR range due to the high refractive index of Si, which can be utilized as optically resonant antennas. We develop monodispersed Si nanoparticles in solution and show the structural colors by size-dependent Mie resonances. We also discuss optical functionalities and Mie-resonance-enhanced light matter interactions in different materials such as emitting lanthanoid ions and two-dimensional materials.

9:30 AM EL07.06.03
Tunable, High Intensity Photoluminescence from Si/SiO_2 Core/Shell Quantum Dots *via* High-Pressure Water Vapor Annealing Kristine Q. Loh, Vivian Ferry and Uwe Kortshagen; University of Minnesota, United States

As non-toxic, abundant, and low-cost luminophores, silicon quantum dots (Si QDs) can suit myriad applications, from luminescent devices to biological imaging. Nonthermal plasma-assisted decomposition of silane gas is an efficient, sustainable, and controllable method for synthesizing Si QDs. However, as-synthesized, Si QDs have a high dangling bond defect density and require additional passivation for widespread utilization. Liquid-based passivation methods, such as thermal hydrosilylation, can organically cap Si QDs but cannot prevent oxidation upon exposure to ambient air. Native oxidation can passivate the Si QDs through the formation of a silica (SiO_2) shell and ensure long-term air stability but occurs over at least one month. Therefore, we use high-pressure water vapor annealing (HWA) to quickly obtain Si/SiO_2 core/shell quantum dots with tunable, high-intensity photoluminescence (PL) that results in long PL lifetimes and comparable PL quantum yields (PLQY).

HWA is a scalable method that was used to oxidize plasma-synthesized Si QDs with high-pressure steam within a few hours, including heating and cooling time. A high-pressure vessel with both pressure and temperature gauges was loaded with the Si QDs and a controlled amount of deionized water that tuned the pressure of the saturated steam. The vessel was heated between 250 and 300 °C using a thermal sand bath. After ten minutes at its equilibrated pressure, the vessel was vented to atmospheric levels. The vessel was then left to cool to room temperature. The dry Si/SiO_2 QDs were extracted and dispersed in toluene for characterization.

We first show the influence of additional hydrogen gas injection in synthesizing the Si QDs and demonstrate that contrary to previous reports, no additional gas injection in the plasma afterglow led to more stable silica shells. In varying the hydrogen gas flow rate from 0 to 100 sccm, the more hydrogen gas injection, the lower the intensity of the more thermally stable, network-structure silica peak in the measured Fourier-transform infrared (FTIR) spectra. The Si QDs synthesized without hydrogen gas had the highest PL intensity as well.

Then, we show that varying the applied pressure to oxidize Si QDs made using only argon and silane gas can tune the PLQY. We measure both steady-state and time-resolved PL (TRPL) to find that increasing the pressure from seven to 17 bar leads to blue-shifted PL and a 10% reduction in the PLQY. A stretched exponential function was used to fit the TRPL decay and extract lifetimes and dispersion factors. The lifetime also decreases with increasing pressure by 70 µs, but the dispersion factor increases from 0.81 to 0.87. When higher pressures are applied, the silica shells are also fully thermally relaxed. FTIR spectra show the presence of characteristic peaks for Si QDs oxidized in a humid environment. Furthermore, with increasing applied pressure, the peak wavenumber of the Si-O-Si bond increases as well. At an applied pressure of 17 bar, the peak wavenumber reaches 1080 cm^{-1}, which exceeds that of thermally grown silica.

Lastly, we report the influence of silica shell thickness. Thicker shells made using larger Si QDs oxidized with optimized HWA conditions led to a stable PLQY of over 40%. After three months of storage in room air, the PLQY plateaued at 35%. Si/SiO_2 QDs with thicker silica shells also had longer lifetimes (240 µs) and higher dispersion factors (0.85 – 0.9). Compared to other passivation methods, HWA can effectively passivate Si QDs within a much shorter time span and only using water. Using HWA, the PL of Si/SiO_2 QDs can be tuned to meet various design requirements by controlling the applied pressure.

9:45 AM EL07.06.04
Group IV Nanosheets with Surface and Composition Tunable Optical Properties Matthew G. Panthani; Iowa State University, United States

We present our recent efforts in synthesizing 2D Group IV nanosheets derived from layered Zintl phases. This presentation will focus on synthesis of layered/2D silicon (often referred to as silicane, siloxene, or layered polysilanes), as well as other 2D Group IV (comprised of Ge, and Si_XGe_{1-X})[1,2] nanosheets, with precise control over their size and surface chemistry. Using NMR, IR spectroscopy, and atomic pair distribution function analysis we gain insight in their local coordination and long-range order. The optical properties of the nanosheets are sensitive to the structure and interfacial chemistry, which we explain using DFT simulations of electronic band structures. Using ultrafast spectroscopy, we find evidence of a "fast" (few ns) optical transition in 2D Si nanosheets, with a temperature dependence may imply that we observve direct bandgap photoluminescence. Finally, we show the thermal stability of 2D silicon nanosheets, demonstrating their structure and photoluminescence are stable to temperatures beyond what they would experience in real applications.

Functionalized Silicon Nanoparticles—Gram-scale Synthesis and Optical Properties Han Zuilhof; Wageningen University, Netherlands

Silicon nanoparticles (Si NPs) are highly attractive materials for typical quantum dots functions, such as in light-emitting and bioimaging applications, owing to silicon's intrinsic merits of minimal toxicity, low cost, high abundance, and easy and highly stable functionalization. Especially non-oxidized Si NPs with a covalently bound coating serve well in these respects, given the minimization of surface defects upon hydrosilylation of H-terminated Si NPs. However, to date, methods to obtain such H-terminated Si NPs is still not easy. Herein, we report a new synthetic method to produce size-tunable robust, highly crystalline H-terminated Si NPs (4 – 9 nm) using microwave irradiation within 5 min at temperatures between 25 – 200 degrees C, and their further covalent functionalization. The key step to obtain highly fluorescent (quantum yield of 7 – 16%) green-red Si NPs in one simple step is the reduction of triethoxysilane and (+)-sodium L-ascorbate, yielding routinely ~1 g H-Si NPs via a highly scalable route in 5-15 min. Subsequent functionalization via hydrosilylation yielded Si NPs with an emission quantum yield of 12-14%. This approach can be used to easily produce high-quality H-Si NPs in gram-scale quantities, which brings the application of functionalized Si NPs significantly closer.

11:00 AM EL07.06.06
Si-Ge-Sn Alloys Grown by CVD for Applications in Optics, Electronics and Thermoelectrics Omar Concepción Díaz, Prateek Kaul, Oliver Krause, Jin-Hee Bae, Thorsten Brazda, Andreas Tiedemann, Qing-Tai Zhao, Detlev Grützmacher and Dan M. Buca; Forschungszentrum Juelich, Germany

The experimental demonstration of an Sn-based optically pumped laser grown on Silicon by chemical vapor deposition (CVD)[1], the research of group-IV Sn-based semiconductors has exponentially increased. Direct bandgap GeSn alloys offers a unique solution for monolithic integration of photonics in the current CMOS technology. The impediment in reaching room temperature electrically pumped laser based on SiGeSn/GeSn alloys is the low capacity of dissipation of heat[2], reason why new designs are investigated to date. At the same time, the poor heat dissipation has aroused the interest of the scientific community in the field of thermoelectric. Studies have shown that group-IV Sn-based materials can be tailored to offer very low thermal conductivity[3]. In the field of electronics, the high mobility associated with the direct bandgap of Si-Ge-Sn alloys boosts the present field-effect transistor (FET) devices' performance[4].

The content of Sn in the alloy is directly defining the material properties and through this the specific application. While Sn contents above 14 at.% are best used in photonics and thermoelectric, lower Sn contents, <10 at.%, are sufficient to improve nanowire FET devices. However, due to the low solid solubility of Sn of below 1% and the large lattice mismatch between the lattice constants of these elements, such high Sn concentrations are a challenge[6]. Its application to the design of layered heterostructures with multiple Sn contents is even more challenging considering also the low thermal stability of Sn alloys.

In this work, a simple and novel methodology to control the incorporation of Sn in the alloy is discussed. Starting for a reference growth conditions that offer high crystalline quality, keeping the process temperature and the reactor pressure constant, as well as the flow of the gas precursors, the total flow of the carrier gas (N_2 or H_2) is varied. In this way, the gas velocity and the partial pressure of the precursors changes, thus gas phase reactions are modified with impact on the surface kinetics allowing to control the Sn concentration in the films, offering a simple path towards high-quality GeSn/SiGeSn heterostructures. The method is applied for a precise control of the Sn concentration in different heterostructures. Examples of structures used for applications in electronics (MOSFETs,), photonics (Lasers), and thermoelectric (lattice thermal conductivity) are presented and discussed.

11:15 AM EL07.06.07
Near-Field Ultrafast Nanoscopy of Carrier Dynamics in Semiconductor Nanowires Jingang Li, Rundi Yang and Costas Grigoropoulos; University of California, Berkeley, United States

Carrier distribution and dynamics in semiconductor materials often govern their physical properties that are critical to functionalities and performance in industrial applications. Many techniques have been developed to resolve the charge transport and carrier dynamics in semiconductor nanostructures for the design of future electronic and photonic devices. Conventional pump-probe microscopy has limited spatial resolution due to optical diffraction. Recently, ultrafast infrared-terahertz nano-spectroscopy was developed through the integration of scanning near-field optical microscopy and pump-probe optics. However, given the limited photon energy, the efforts have been primarily focused on studying carrier dynamics in narrow bandgap semiconductors or graphene plasmons.
Here, we report near-field ultrafast optical nanoscopy in the visible-near-infrared spectral region to access the carrier dynamics in silicon, one of the most prevalent materials in current semiconductor technology. Our pump beam has a wavelength of 400 nm (3.1 eV), which is sufficient to excite carriers in common optoelectronic semiconductors, including silicon (bandgap of 1.12 eV) and GaAs (bandgap of 1.42 eV). By combining ultrafast nanoscale measurements and theoretical modeling, we unravel the local photocarrier recombination dynamics in silicon nanowires. Moreover, we demonstrate the spatial mapping of carrier lifetime in silicon with a sub-50 nm resolution. Our results provide the capability to probe carrier behaviors in nanoscale materials and devices, which is of great significance to understanding the optoelectronic properties and practical functionality of semiconductor nanostructures.

EL07-virtual

10:30 AM *EL07.07.01
Silicon Photocatalysts for Solar-Driven Hydrogen Production Isabel Curtis, Sarrah Putwa and Mita Dasog; Dalhousie University, Canada

Hydrogen is an important feedstock for various chemical processes and a promising green energy source. Sustainable and affordable production of hydrogen is extremely important for extensive commercialization of fuel cells and to reduce our reliance on steam-methane reforming which has a high carbon footprint. Technoeconomic analyses have shown that solar driven water-splitting using suspended particulate photocatalyst is a simple and cost-effective way to produce hydrogen. Nanoscale Si is an attractive photocatalyst for this process given its abundance, biocompatibility, favorable conduction band edge position for water reduction, and their solar light absorption properties. High surface area Si nanoparticles can be prepared using magnesiothermic reduction reaction. In the last five years, our research group has identified that the magnesiothermic reduction reaction parameters strongly influence the physical properties of the resulting Si particles and their catalytic performance. This presentation will summarize which Si properties are important for photocatalysis and how the reaction conditions can be chosen to maximize the hydrogen evolution rates under solar illumination. Further, the influence of photocatalysis setup and its effect on hydrogen production rates will also be discussed.

11:00 AM EL07.07.02
Colloidal Synthesis, Energy Gap Tuning and Carrier Dynamics of Ge-Si-Sn Nanoalloys with Visible to Near IR Photoluminescence Drew Spera, Griffin Spence, David Pate, Corentin Villot, Umit Ozgur, Ka Un Lao and Indika U. Arachchige; Virginia Commonwealth University, United States

Group IV semiconductor quantum dots have gained noteworthy interest in optoelectronic applications due to their high natural abundance, low-cost of elemental components, and low-to-non-toxicity. A number of chemical syntheses for colloidal Si and Ge quantum dots have been reported and new methods continue to appear. However, these methods generally lack the wide tunability of nanocrystal size and consequently absorption and emission energies resulting in minimal exploration of photophysical properties. To address this issue, we have recently studied the incorporation of elemental Si and Sn into Ge nanocrystals to produce homogeneous $Ge_{1-x-y}Si_ySn_x$ ternary alloy and quantum dots that exhibit size and composition-tunable absorption and emission across visible to near-infrared spectrum. Herein, the physical characterization of the quantum-confined and non-quantum-confined $Ge_{1-x-y}Si_ySn_x$ alloys using powder X-ray diffraction, transmission and scanning electron microscopy, energy dispersive spectroscopy, steady-state and time-resolved absorption and emission spectroscopy, and computational electronic structure calculations will be presented. The effect of synthetic parameters on nanocrystal size, shape, composition, absorption and emission energy, and carrier dynamics will be discussed in light of their application in silicon-based visible to near-infrared optoelectronics.

11:15 AM *EL07.07.03
Light Management in Si Nanocrystal-Based Solar Concentrators Vivian Ferry; University of Minnesota, United States

Luminescent solar concentrators, semi-transparent panels that harvest diffuse, high-energy sunlight, shift the spectrum to more optimal wavelengths, and focus that emitted light onto small-area solar cells. I will discuss the design of luminescent solar concentrators for both architectural and agrivoltaic applications, the fabrication of nanocrystal composites with excellent optical properties, and the use of photonic strategies to direct light within the concentrator to overcome losses.

One recent design I will discuss is the bilayer luminescent solar concentrator, which combines CdSe/CdS core/shell nanocrystals in one layer with Si nanocrystals in a bottom layer. While either layer can act directly as an LSC, combining them both broadens spectral coverage and allows the CdSe/CdS layer to sensitize the Si nanocrystal absorption: light emitted by the CdSe/CdS layer is reabsorbed and emitted by the Si nanocrystals, where it propagates to the edge of the concentrator with minimal parasitic losses. Variation of the relative concentrations of these nanocrystals in the concentrator tunes the transmission spectrum. Integration of various photonic structures into the LSC design is also beneficial for reducing escape cone losses and ensuring that the luminescent light reaches the edge, or that the transmitted light is appropriately outcoupled from the concentrator.

SESSION EL08.01: Bioinspired and Biomaterials for Triboelectric Nanogenerator
Session Chairs: Jun Chen and Xudong Wang
Tuesday Morning, April 11, 2023
Moscone West, Level 3, Room 3008

10:30 AM *EL08.01.01
Biomaterials-Based Wearable Triboelectric Sensors Wenzhuo Wu; Purdue University, United States

The capability of sensor systems to efficiently scavenge their operational power from stray, weak environmental energies through sustainable pathways could enable viable schemes for self powered health diagnostics and therapeutics. Triboelectric nanogenerators (TENG) can effectively transform otherwise wasted environmental mechanical energy into electrical power. However, obstacles hindering the development of efficient triboelectric devices based on biocompatible materials continue to prevail. I will discuss our recent progress in designing and engineering biomaterials for biocompatible, wearable triboelectric devices. Such wearable devices are conformable to human skins and can sustainably perform non-invasive functions by harvesting the operation power from the human body. The gained fundamental understanding and demonstrated capabilities enable the rational design and holistic engineering of novel materials for more capable biocompatible triboelectric devices that can continuously monitor vital physiological signals for creating unprecedented diagnostic tools for diagnosis, interpretation, and prediction of human status in ubiquitous resource-constrained conditions.

11:00 AM EL08.01.02
Soft Triboelectric Pressure Sensor with Spiking Calibration Signal Chankyu Han, Jungrak Choi and Inkyu Park; KAIST, Korea (the Republic of)

Soft triboelectric pressure sensors are growing interest due to increasing demand for various sensors for human-machine interaction and growing global energy concerns. However, signals of triboelectric sensors are significantly affected by miscellaneous factors such as environment and user motion. It is because the surface charge density of triboelectric layers depends on those factors. Although there have been a few attempts to compensate for the change in surface charge density, they were either limited to the change by a specific factor or had considerably limited pressure resolution. None of them could directly calculate current surface charge density to eliminate diverse factors including humidity, time decay and warm-up time while providing continuous pressure information. Here, we propose a triboelectric self-powered pressure sensor with a unique spiking calibration system to directly calculate and compensate for the change in surface charge density.
The sensor generates two output signals: open-circuit voltage and spiking calibration voltage. While open-circuit voltage provides continuous pressure information, it is affected by the change in surface charge density just as in conventional triboelectric sensors. Contrarily, the spiking calibration voltage conveys discrete pressure information without the influence from the change in surface charge density. The spiking calibration voltage is generated based on geometrically switchable operation. A mechanical beam and a parallel-line patterned electrode were designed and fabricated to work as an electrical switch such that the connection depends only on the geometrical state of the sensor. Since closing the switch results in abrupt current spike to flow, a series of voltage spikes are observed with respect to applied pressure. The magnitudes of spikes were not affected by the speed of motion from 0.1mm/s to 5mm/s, and the direction of spikes indicates the direction of pressure change. For triboelectric layers, porous polyurethane and porous ethylene vinyl acetate were utilized due to their softness, high triboelectric performance and cheap price.
Simultaneous analysis of the two signals gives an estimation of current surface charge density in real-time. By comparing the change in the open-circuit voltages between two consecutive spiked moments, current surface charge density can be calculated, which can be further utilized to compensate its change. Triboelectric sensor signals varied by a factor of over two for same pressure due to change in humidity (from relative humidity of 20% to 80% at 22°C) or applying successively higher pressure (up to 13kPa). Nevertheless, our sensor system could successfully eliminate the effect of the change in surface charge density by directly calculating and calibrating it.
Furthermore, the sensor was integrated to a robotic arm to harvest crops in their own optimal growing environmental conditions to demonstrate its possible usage in smart farming robots. As demonstration, a gripper on the robotic arm was feedback controlled to harvest, transport and release a cherry tomato and lettuce with optimal relative humidity of 50% and 75% at 24°C, respectively. While both crops were grabbed with a same target pressure, the open-circuit voltages at the target pressure differed due to different optimal growing humidity conditions. Although conventional triboelectric sensors would have failed to pick them up due to either overestimation or underestimation of pressure, our sensor system could successfully harvest both crops due to its accurate pressure measurements based on the spiking calibration system.

11:15 AM *EL08.01.03
Bioinspired Triboelectric Surface with the Improvement of Nanogenerator Durability for Gait Analysis Zong-Hong Lin[1,2]; [1]National Taiwan University, Taiwan; [2]National Tsing Hua University, Taiwan

Real-time gait analysis is crucial for diagnosis and rehabilitation monitoring of neuromuscular ailments. However, the existing wearable sensors for gait analysis suffer from the drawbacks of bulky, short-term stability and professional operator requirement, which restrict their applicability outside clinical settings. Here, a solid-liquid contact-based triboelectric nanogenerator is developed with soft, flexible and stretchable properties. The device is mainly composed of liquid metal and Ecoflex with biomimic shark skin microstructured surface. The unique surface property prevents the adhesion of liquid metal during sensing and facilitates real-time monitoring of signals and long-term operation stability. The as-designed low-cost, highly scalable self-powered sensor, which is also compatible with diverse detection strategies, provides an on-demand user-friendly point-of-care gait detection and rehabilitation monitoring system with significant applications in personalized health care and sports science.

11:45 AM EL08.01.04
Bio-Triboelectric Wearable Sensors with Enhanced Tribo-Negativity Pedro Henrique de Souza Barbosa[1,2], Robert Ccorahua Santo[1,2] and Wenzhuo Wu[1,2,3]; [1]Purdue University, United States; [2]Flex Lab, United States; [3]Regenstrief Center for Healthcare Engineering, United States

Herein, we have engineered a simple, low-cost, and scalable process to manufacture a biobased triboelectric sensor with enhanced electrical outputs. Our method, based on blade coating, allows us to uniformly modify the thickness of the dielectric layer, which allow us to correlate the processing parameters and performance of our device. Our triboelectric sensor is made from a blend of all-natural compounds and lignin biomass, resulting in an increased tribo-negativity and biodegradability. Recent advances in bio-derived triboelectric sensors are limited by the tribo-positive characteristics of the related materials with respect to human skin. Our lignin-based triboelectric sensors exhibit improved charge transfer when used against the skin, making it sensitive even to subtle mechanical stimuli. We further demonstrated the application of our self-powered wearable device to continuously monitor physiological signs, such as the pulse wave, with high fidelity. Such capability enables the decoding of cardiovascular information around-the-clock sustainably for continuous diagnostics of health status.

SESSION EL08.02: Bio-Related Applications of Nanogenerators

Session Chairs: Sihong Wang and Wenzhuo Wu
Tuesday Afternoon, April 11, 2023
Moscone West, Level 3, Room 3008

1:45 PM *EL08.02.01
Stretchable and Self-Powered Bioelectronics for Achieving Sustainable Interfacing with the Human Body Sihong Wang; University of Chicago, United States

The vast amount of biological mysteries and biomedical challenges faced by humans provide a prominent drive for seamlessly merging electronics with biological living systems (e.g. human bodies) to achieve long-term stable functions. Towards this trend, one of the key requirements for electronics is to possess biomimetic form-factors in various aspects and continuous energy supply for achieving long-term compatible and sustainable operations. This goal conjunctionally relies on two aspects. First, the entire electronic systems (including the power sources) are desired to have similar mechanical (i.e., soft and stretchable) properties with the skin and biological tissues, so as to improve the wearing comfort, suppress invasive reactions, and enhance the signal quality. Second, the power sources of the electronics, which have been conventionally served by rigid batteries, should be sustainable and maintenance-free, ideally with an unlimited lifetime. In this talk, I will introduce our innovative use of polymer chemistry and engineering for achieving stretchable triboelectric nanogenerators that can efficiently harvest energy from human body movements, as well as our developments of stretchable electronic devices, sensors, and light-emitting devices, for ultimately producing fully integrated systems for human-body interfacing.

2:15 PM EL08.02.02
Tellurene-Based Wearable Biosensor for Real-Time Longitudinal Monitoring of Neurotransmitters in Human Sweat Ruifang Zhang[1,2] and Wenzhuo Wu[1,2,3]; [1]Purdue University, United States; [2]Flex Laboratory, United States; [3]Regenstrief Center for Healthcare Engineering, United States

Metabolic biomarkers provide direct indicators of physical and mental health status. However, the state-of-the-art tools for measuring metabolites in body fluids are expensive, time-consuming, and often require invasive procedures to collect the samples. Non-invasive wearable sensors for measuring metabolites in sweat, the most accessible human secretion, are promising alternatives to costly diagnostic tools. Moreover, existing wearable sensors have limited sensitivity, selectivity, and lifetime for measuring disease-specific metabolic markers (e.g., neurotransmitters) from human sweat. Wearable sweat sensors that can monitor the dynamics of neurotransmitters directly from human sweat have yet to be developed. Here we report a novel wearable biosensor based on tellurene for selective and sensitive detection of dopamine (DA) and norepinephrine (NE) in human sweat for the first time. We demonstrated for the first time the successful sensing and quantification of DA and NE concentrations in real human sweat samples using tellurene sensors. We also evaluated and validated the concentrations of neurotransmitters in human sweat using high-performance liquid chromatography/mass spectrometry (HPLC/MS) for the first time. Our technology could create unprecedented diagnostic tools for improving the experience and outcomes of patient care. The development of non-invasive wearable sensors capable of longitudinal measurement of disease-specific metabolic markers from sweat will positively impact erroneous or delayed diagnoses, enable affordable and ubiquitous diagnostic tools, and foster data-driven precise mobile health monitoring with translational applications in patient care and beyond.

2:30 PM EL08.02.04
Frequency-Dependent Performance of Biocompatible Triboelectric Nanogenerators for Ultrasound-Powered Implantable Devices Kalliope Margaronis; University of Cambridge, United Kingdom

Triboelectric generators rely on contact-generated surface charge transfer between materials with different electron affinities, converting mechanical energy into useful electricity. They could potentially be used as power sources for implantable medical devices, which currently mostly run on batteries. Implantable medical devices are an important area of modern medicine, with tens of millions of people living with an implanted medical device, such as cochlear implants and pacemakers. Replacing batteries in implanted medical devices with triboelectric energy harvesters could negate the need for battery replacement surgeries, and could also provide a more convenient, efficient and reliable way of powering such devices.
Two of the main hurdles to consider before replacing batteries with triboelectric nanogenerators (TENGs) are power output and biocompatibility. In order to optimise the performance of a TENG, materials with high surface charge density must be used. Nanostructuring the surface of a material increases its surface area, allowing for greater charge density and therefore larger electrical output. With these considerations poly-L-lactic acid (PLLA) and polytetrafluoroethylene (PTFE) have been investigated as possible biocompatible materials to use in an implanted TENG. We have recently shown that tribopositive PLLA nanotubes grown by melt-press template wetting can be fabricated and optimised for higher triboelectric output through control of polymer crystallinity [1]. As a counter material for TENG applications, PTFE is a highly tribonegative material which, like PLLA, is already widely used as a biocompatible material in the biomedical industry. We therefore investigate the performance of TENGs based on combinations of nanostructured PLLA and PTFE. Importantly, as TENG devices can be actuated at different frequencies, the frequency response of these devices is also presented in this work, with a view to power implantable devices using ultrasound, which represents a low-loss form of energy transfer through human tissue.

Biomolecule-Based Piezoelectric Nanomaterials and Their Energy Harvesting Application Rusen Yang; Xidian University, United States

Biomolecule-based materials can enable technological innovations by virtue of their intrinsic bioactivity and physical properties. Since the discovery of the quantum dots made out of diphenylalanine (FF) peptides, biomaterials have long been explored as biological semiconductors. Their insulating nature with ultra-wide gaps limited their study to mainly optical properties and a conventional electronic device is still to be seen. Piezoelectricity was found in FF peptides and many other biomolecular materials such as virus, amino acids, wood, silk, hair, cornea, tendon, and bone. Relatively low piezoelectric constants and the difficulty of achieve uniform polarization are common in biomaterials. Designing tailored biomaterials is essential to better understand these materials, achieve desired properties, and fulfill their application potential. Herein, the electronic structures, dielectric, piezoelectric and elastic properties of biomaterials is revealed by the first-principle calculation. We demonstrate a physical property-enhanced strategy by taking advantage of the hydrogen-bonding networks of double-layer amino acid crystals with their molecular side chains. We based on the Stranski-Krastanov (S-K) growth mode and propose a mechanism for the growth of ordered amino acid array structures via physical vapor deposition. The growth mode not only explains the formation of uniform and controllable morphology of amino acid structures but also leads to the significant enhancement of their piezoelectric properties. The biomaterials with excellent thermostability and piezoelectricity are employed in nanogenerators with much improved performance, demonstrating their potential for eco-friendly energy harvesting devices.

4:00 PM EL08.03.02
Orientation-Controlled Crystallization of γ-Glycine Films with Enhanced Piezoelectricity Jiajie Sui[1], Jun Li[1], Long Gu[1], Connor A. Schmidt[2,3], Ziyi Zhang[1], Pupa Gilbert[2,3] and Xudong Wang[1]; [1]University of Wisconsin, Madison, United States; [2]University of Wisconsin–Madison, United States; [3]Lawrence Berkeley National Laboratory, United States

Glycine, the simplest amino acid, is considered a promising functional biomaterial owing to its excellent biocompatibility and strong piezoelectricity comparable to conventional soft piezoelectric materials. Practical applications require great flexibility and strong out-of-plane piezoelectricity in glycine films, in which the piezoelectric polar <001> direction aligned with the film thickness direction. Based on the recently-developed solidification approach of aqueous polyvinyl alcohol (PVA) and glycine solution, in this work, we demonstrate that the crystal packing direction of as-synthesized film is determined by glycine crystal nuclei orientation. This alignment was possible because crystal orientation follows those of the nuclei, which is determined by the surface curvature at the nucleation site, which was confirmed by the contact angle-related crystal orientation tuning. From cleavage features in cross-sectional SEM images, the films synthesized on each substrate have different incline angles responding to their contact angle. Typically, larger surface curvature from a larger contact angle leads to greater out-of-plane piezoelectric performance. Inspired by this, we further confined the local nucleation kinetics by introducing a wall around the liquid precursor film thereby the surface curvature along the edge was inverted from positive to negative. Changes in surface curvature suppressed the nucleation at the edge area and forced initial nucleation to the middle of the film, where the surface was flat. Therefore, the (001) surface of glycine nuclei became parallel to the film surface, so as the entire film grown thereafter. Tuning the piezoelectric <001> polar direction of γ-glycine crystal to the thickness direction enhanced the out-of-plane bulk piezoelectricity, with an average d_{33} of ~ 6.13±1.13 pC/N. This value was more than 20% higher than the d_{33} of films nucleated from the edge, where their <001> directions were tilted away from the normal direction. This work demonstrated a promising approach to improving the bulk piezoelectricity of glycine films by nucleation kinetics control. This strategy may inspire crystal orientation control in advanced manufacturing processes of amino acid- or polypeptide-based bio-crystals with enhanced properties.

Vacuum and Plasma Synthesis and Processing of Surfaces, Multifunctional Thin Films and 3D Nanoarchitectures—A Platform for the Development of Energy Harvesting Systems Xabier Garcia-Casas, Javier Castillo-Seoane, Laura Montes, Jaime Del Moral, Francisco Aparicio, Ali Ghaffarinejad, Lidia Contreras-Bernal, Jorge Gil-Rostra, Jorge Budagosky, Carmen Lopez-Santos, Juan Sanchez-Valencia, Angel Barranco and Ana Borras; ICMSE (CSIC-US), Spain

Plasma processing and synthetic routes are called to be a game-changer in the realization of environmentally friendly, low-energy consuming, and scalable key enables technologies for nanomaterials development and their practical implementation in devices. In this presentation, we will demonstrate the application of vacuum and plasma-assisted deposition techniques to process surfaces and thin films and to develop complex nanowires (NWs) and nanotubes (NTs) with a core@multishell morphology where each shell adds functionality or multifunctionality to the system. The steps required for the implementation of these nanomaterials as supported or in-device applications will be presented. The universal character of vacuum and plasma methods allows for the deposition of an unprecedented variety of possibilities, including, organic (small-molecules, organic nanocomposites, polymeric layers), inorganic (metal and metal oxides), hybrid (hybrid perovskite) materials acting as conducting, semiconducting, dielectric, photo-absorbent, piezoelectric or plasmonic components in a radial configuration. Clues to foster reliable and robust low-dimensional materials will be presented. Finally, we will share the results and advances accomplished during the last years in the field of energy harvesting (solar cells,[1-4] piezoelectric and triboelectric nanogenerators[5,6]), photoelectrocatalysis, superwettable surfaces [7], anti-icing,[8-10] and the development of semitransparent nanoelectrodes[11].

9:00 AM EL08.04.02
Ferroelectricity-Modulated Flexible Lead-free Halide Perovskite-based Tribovoltaic Nanogenerator for Mechanical Energy Harvesting Feng Jiang[1,2], Yihui Zhang[3] and Pooi See Lee[2]; [1]Institute of Flexible Electronics Technology of Tsinghua, Zhejiang, China; [2]Nanyang Technological University, Singapore; [3]Applied Mechanics Laboratory, Center for Flexible Electronics Technology, Tsinghua University, China

With the emergence of artificial intelligence, Internet of Things (IoT), and big data, the requirements for device miniaturization, self-powered smart sensors, as well as distributed and wearable power sources, have proliferated dramatically. Tribo- and piezo-electric nanogenerators (TENG and PENG), serving as efficient, low-cost, and distributed energy techniques, enable the energy conversion from low-frequency mechanical energy to electricity, and provide us an opportunity to harvest wasted mechanical energy from the environment or human motion. However, these two technologies are still limited by their large impedance, pulsed electrical signals, as well as the low current output. To solve these potential challenges, a new strategy, tribovoltaic nanogenerator (TVNG), has been proposed, which can directly convert the mechanical energy into direct current (DC) electricity. The DC signals stem from the dynamic Schottky or P-N junctions where the non-equilibrium carriers will continuously diffuse and drift at the conductor/semiconductor or semiconductor/semiconductor interface under the built-in electric field. This new approach not only generates continuous DC output, but also exhibits unique advantages such as high current density, low matching impedance, and continuous power output, providing a new strategy for the future development of sustainable and self-powered energy technology.

In our work, a lead-free (DF-CBA)$_2$CuCl$_4$ halide perovskite was adopted to construct an Al/(DF-CBA)$_2$CuCl$_4$ Schottky junction DC TVNG. Compared to other semiconductor materials, halide perovskites display promising advantages, such as solution-based preparation method, tunable bandgap, photovoltaic as well as ferroelectric properties, which promote the electrical performance of TVNGs. In addition, this copper-based halide perovskite is more eco-friendly, safer than the lead/cadmium/chromium-based perovskites and more stable than the tin/ germanium-based ones, which is significant for their potential applications in the sustainable power sources and wearable materials. Most importantly, the (DF-CBA)$_2$CuCl$_4$ exhibits unique multiaxial ferroelectricity and low coercive field, so its surface charge and work function can be tuned via the external poling process, enabling the TVNG device with excellent electric performance modulation. This work not only offers an insight into the unique coupling between ferroelectric polarization and tribovoltaic effect, but also proposes a ferroelectricity-induced strategy that can modulate the electric output performance of TVNG devices, paving a new avenue for the development of high-performance TVNG devices.

9:15 AM EL08.04.03
Imidazolium-functionalized Ionic Polyurethanes based Self-Healable Triboelectric Nanogenerator with Enhanced Performances Hyeonseo Joo and Ju-Hyuck Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Triboelectric nanogenerator (TENG) is one of the promising energy harvesting technologies which converts ambient mechanical energy to electrical energy. In order to advance in next-generation soft electronic devices, the TENG is required to be flexible, stretchable, and biocompatible. In addition, the ability of autonomously self-healing after mechanical damage is highly desired for durability and stable production of electrical energy. Thermoplastic polyurethane (TPU), a multi-block copolymer composed of hard and soft segments, can control its electrical and mechanical properties through chemical modification. Also, TPU has advantages such as elasticity, flexibility, and mechanical strength. Therefore, a lot of research on self-healing polyurethane TENG based on disulfide bond, and borate bond has been reported so far. However, research on materials that can simultaneously increase output as well as self-healing is still needed. So, in this study, we synthesized imidazolium-based ionic polyurethane to fabricate high output performance and self-healable TENG. Imidazolium-based ionic polyurethane was intended to have biocompatible properties using polycaprolactone diol and hexamethylene diisocyanate. In addition, using imidazolium ionic liquids diol, an ionic polymer composed of a polymer backbone and an ionic liquid (IL) species was prepared for each repeating unit. As a result, the IL moieties consisting of loosely bound bulky cations and anions can form the electrostatic interaction to form self-healing TENGs. If there is a small scratch on the TENG, it will heal and return to its original state after about an hour. Even in an entirely cut state, it can be fully healed after 24 hours at a temperature of 50 degrees and has the same mechanical properties as before. IL not only affects self-healing, but also greatly affects TENG output performance. ILs could form the electrical double layer (EDL) by their high capacitance and mobile ions. So, we checked the output change while gradually increasing the proportion of imidazolium ionic liquids. As a result, it was confirmed that (1,1) has the highest output. In addition, we confirmed that when the molecular weight of PCL was lowered, and a fluorine unit was included under the (1,1) condition, the output was dramatically increased, resulting in a maximum 650 V and 47 μA output. Finally, the power density is 13.5 times greater than when imidazolium ionic liquids are not included, resulting in 1243 $\mu W/cm^2$. So, this imidazolium-based ionic polyurethane TENG demonstrated a possibility of high output performance and self-healable TENG for electronic devices.

9:30 AM EL08.04.04
Liquid-Metal Nanogenerator Fiber for Harvesting Mechanical and Electromagnetic Energy and as Self-Powered Sensors Ying-Chih Lai; National Chung Hsing University, Taiwan

Future wearable technolgies and personal electronics can be benefit from e-textiles that simultaneously possess high elasticity and multiple capabilities such as energy harvesting and sensing. In this talk, we will present an intrinsically stretchable liquid-metal nanogenerator fiber that can harvest both mechanical energy (e.g. from the body) and electromagnetic energy (e.g. from nearby electronics such as laptops, cell phones, transformers). Furthermore, to the best of our knowledge, this is the first single energy-harvesting fiber that simultaneously possesses inherent elasticity and extraordinary stretchability with the ability to harvest two sources of energy (that are mechanical and electromagnetic Energy). This is also the first report of fibers that convert dielectric-loss from electronic devices to electricity. In addition to converting multiple sources of waste energy into electricity, the fibers can act as self-powered tactile and biomechanical sensors. The fibers consist of hollow elastomeric fiber filled with liquid metal. The fibers harvest energy by the combination of triboelectricity (160 V/m, 5 μA/m, and ~360 μW/m) and induced electrification of the liquid metal (8 V/m (60 Hz), 1.4 μA/m, and ~8 μW/m). We characterize the fibers and demonstrate their utility for powering electronics and sensing biomechanical information. These fibers are further demonstrated as completely soft and stretchable components for human-machine interfaces, including keypads and wireless music controllers. The findings of this work provide new advancements in stretchable/wearable energy and sensing technologies, which are both timely and could advance a wide range of emerging wearable technologies and personal electronics.

9:45 AM EL08.04.05
Scalably Manufactured Tellurium Nanowires for Wearable Piezoelectric Devices Meng Hao Lee and Wenzhuo Wu; Purdue University, United States

Scalable synthesis of low-dimensional nanomaterials provides a route for practically using these emerging materials. We demonstrate scalable solution synthesis of tellurium nanowires (TeNW) and explored their application for wearable piezoelectric devices. The process can achieve thin TeNW with a small diameter and uniform distribution (avg. diameter ~8±3 nm). We further demonstrated the integration of the wearable TeNW-based devices for pulse sensor with excellent sensitivity. Our result presents a facile approach of large-scale, high throughput synthesis of piezoelectric nanomaterials for wearable applications.

Additive Manufacturing of Tribovoltaic Direct-Current Generator for Self-Powered Sensing Jun Liu; University at Buffalo, The State University of New York, United States

Tactile sensing is crucial for implementing future intelligent devices for the applications of wearable electronics, biomedical implant, and future robotics. Particularly, the ability to measure and distinguish real-time multidirectional mechanical stimuli remain as a challenge for slip detection and self-adaptive manipulation of unknown objects in robotic applications. Tribovoltaic direct-current (DC) generator is emerging as a promising solution for high-efficient mechanical energy harvesting due to its unique advantage of high current density compared to traditional triboelectric or piezoelectric approaches. Meanwhile, the DC generation itself can be utilized as an effective mechanism for high-performance sensing. In this talk, I will discuss our recent progress in designing and additive manufacturing of tribovoltaic direct-current generator (e.g., 3D printed, woven, etc.) for self-powered sensing applications, and provide perspective about the main challenges and future direction for implementing the technique for future applications.

11:00 AM *EL08.05.05
Self-Powered Flexible Devices: Piezo-Sensor and MicroLED Keon J. Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

This seminar introduces two recent progresses of self-powered flexible devices; piezo-sensors and microLED.

The first part will introduce flexible inorganic piezoelectric membrane that can detect the minute vibration of membrane or human skin that expands the application of self-powered acoustic sensor and blood pressure monitor. Speaker recognition has received spotlight as a next big thing of voice user interface such as personalized voice-controlled assistant, smart home appliance, biometric authentication. The conventional speaker recognition was realized by a condenser type microphone, which detects sound by measuring the capacitance value between two conducting layers. The condenser type microphone, however, has critical demerits such as low sensitivity, high power consumption, and an unstable circuit due to the large gain amplification. Speaker recognition also suffers from a low recognition rate, caused by limited voice information and optimal algorithms for a simple and accurate process. Herein, we reported a machine learning-based acoustic sensor by mimicking the basilar membrane of human cochlear. Highly sensitive self-powered flexible piezoelectric acoustic sensor (f-PAS) with a multi-resonant frequency band was employed for voice recognition. The speech waveforms were recorded by the multi-channel f-PAS and converted into frequency domain signals by using Fast Fourier Transform to obtain the characteristics of voice frequency. Convolutional Neural Network (CNN) were utilized for speaker recognition, resulted in a 97.5% speaker recognition rate with the 75% reduction of error rate compared to that of the reference MEMS microphone.

Analytical and Numerical Models of Zinc Oxide Nanowire-Based Nanogenerators Guylaine Poulin-Vittrant, Emmanuel Dumons, Kevin Nadaud and Louis P. Tran-Huu-Hue; GREMAN CNRS UMR 7347, France

Piezoelectric nanogenerators integrating piezoelectric-semiconducting nanowires are multilayer and composite devices [1], making their theoretical study a challenge. The active piezoelectric layer is similar to a 1-3 composite piezoelectric transducer [2], which offers the advantage to enhance the electromechanical coupling compared to a full piezoelectric layer from the same material. This composite consists of a piezoelectric nanostructured layer surrounded by an insulating and soft polymer matrix, which is destined to isolate electrically the nanowires from each other, and to protect them from damage or ageing. As nanogenerators are designed to harvest mechanical energy from human movements, or forces in natural environment (water, wind), or industrial vibrations, the mechanical excitation is rarely purely sinusoidal. This seminar will introduce the simulation tools, which are analytical [3,4], numerical [5,6], or mixed [3,7], that have been developed to estimate the electrical power harvested by a zinc oxide (ZnO) based nanogenerator, for a given dynamic applied force. Moreover, the different physical phenomena influencing the conversion efficiency will be presented, for instance the surface (acceptor) traps which compensate the negative effect of the free charge carriers. Finally, the sensitivity of the harvested energy will be explained relative to the different model parameters, which may be geometrical or physical properties. Some design trends will be proposed, regarding the strategic parameters to optimize in order to enhance the nanogenerator performance.

2:00 PM EL08.06.02
Strain-Correlated Piezoelectricity in Quasi-Two-Dimensional Zinc-Oxide Corey Carlos, Ziyi Zhang, Yizhan Wang and Xudong Wang; University of Wisconsin--Madison, United States

Flexible, wearable, and human-compatible electronics are helping shape a future of integrated nanotechnologies. As such, piezoelectric and semiconducting materials have drawn intense interest by many research groups for the excellent potential to advance the field of wearable devices. Moreover, two-dimensional (2D) nanomaterials, valued for their enhanced mechanical, electronic, and structural properties, have moved to the forefront of compliant electronic devices. Therefore, a thorough understanding of the interfacial charge distribution is required when utilizing flexible piezoelectric semiconductors, such as zinc-oxide (ZnO). We present a method for monitoring the piezoelectric response of nanometer-thick 2D ZNO nanosheets (NS) grown via Ionic Layer Epitaxy (ILE). The direct piezoelectric effect, and the coupling of electronic dipole polarization to lattice strain within ZnO-NSs, is monitored *in situ* via piezo force microscopy (PFM). Using PFM we illustrate the effects of modulating strain in piezoelectric nanomaterials and its role in the polarization charge distribution across the surface of the 2D ZnO-NS. Subsequently, we show that the strain configuration (either tensile or compressive) can dramatically influence the measured piezoelectric coefficient (d_{33}) of the 2D ZnO-NS. Our results illustrate the critical need for understanding the interdependent roles of static piezoelectric charges, semiconducting properties, and strain, for future flexible devices.

2:15 PM EL08.06.03
High-Performance Piezoelectrocatalytic Sensing of Uric Acid using Wurtzite Zinc Oxide Nanorods Jing Jiang[1] and Wenzhuo Wu[1,1,2]; [1]Purdue University, United States; [2]Regenstrief Center for Healthcare Engineering, United States

Piezoelectricity in nanostructured semiconductors provides a novel way to efficiently engineer the catalytical performance for applications in biotechnological, agricultural, and pharmaceutical areas. Here, a low-cost, high-performance piezoelectrocatalytic sensor for the detection of uric acid (UA), an important pathophysiological signal molecule in the human body, is designed and demonstrated based on the principles of piezoelectrocatalysis. Vertical wurtzite ZnO nanorods (ZnO NRs) are grown on graphene oxide (GO) to realize the piezo-electrochemical detection of UA. The electrocatalytic efficiency is significantly boosted by the lowering of the electron transfer barrier at the ZnO NRs-electrolyte interfacedue to the piezoelectric polarizations. The enhancing mechanism of the piezo-potential during the electrochemical oxidation of UA on the ZnO NRs surface is unveiled and discussed. Such low-temperature, facile preparation of the ZnO NRs welcomes a cost-efficient mass production and a direct integration into human electrochemical wearables, whose performance can be modulated readily with a low mechanical budget generated from the human body.

2:30 PM EL08.06.04
Investigation into Ultra-Low-Power Capacitive Piezo-tronic Force Sensor Yu-Liang Hsiao, Chen Jang, Yi-Miao Lin, Chao-Hung Wang and Chuan-Pu Liu; National Cheng Kung University, Taiwan

With the rapid rise of the Artificial Intelligence and Internet of Things (AIoT), developing ultra-low-power devices is essential to future advanced technology. State-of-the-art piezo-tronic force sensors rely on the current changes manipulated by the piezo-potential built at the Schottky interface, which enables fast response and high sensitivity characteristics. However, a relatively high reading bias is necessary for achieving high performances, normally larger than 0.5 volts depending on the threshold voltage of the Schottky diode. In this study, we demonstrate a novel capacitive piezo-tronic force sensor that allow to operate at an ultra-low reading bias or even nearly 0 bias condition. The capacitive piezo-tronic force sensor directly detects the capacitance changes induced by the piezo-charges, instead of current changes. The changes of the capacitance directly reflect the perturbation of the effective depletion width, rather than the built-in potential, and it shows a consistent trend in wide operation voltage ranges including V_{op}~0V. This enables the ultra-low-power capability because it circumvents the necessity of turning on the diode. To deeply investigate the working mechanism, a force-dependent capacitance-voltage (C-V) characteristic was performed to explore the effective depletion width changes induced by piezo-charges. In addition, a dynamic response of the capacitive piezo-tronic force sensor also exhibits ultra-low-power capability, which is free of triboelectric interference. Based on this experimental study, it provides a design guideline for ultra-low-power thin-film-based capacitive piezo-tronic/piezo-phototronic devices in the future.

2:45 PM EL08.06.05
Piezo-Gated Thin Film Transistor—A Novel Device to Develop a Unique Multi-Axial Smart Strain Sensor and the Synergistic Interaction of Piezo-Gating Effect and Thermoelectric Effect Jit Dutta and Chuan-Pu Liu; National Cheng Kung University, Taiwan

The piezo-gating effect plays a pivotal role to develop piezotronic devices exclusively based on carrier modulation inside the piezoelectric semiconducting material. In earlier studies, the piezotronic devices were extensively developed based on the Schottky barrier height modulation at the interface with the electrode. Therefore, we have created an ohmic junction-based piezo-gated thin film transistor (PGTFT) using ZnO as a model material to eliminate the Schottky barrier height modulation and show the dual mode (depletion and accumulation) function of a PGTFT device for the first time. To obtain the dual mode operation, two configurations of the PGTFTs with Top and Bottom electrode subjected to the compressive force shows the opposite trends in I-V signals, which was further validated by analytical modeling and simulation data. This technique further evaluates and distinguishes the piezoresistive effect from the piezo-gating effect for the first time.Furthermore, utilizing this phenomenon we have developed a double-sided four-electrode-based flexible PGTFT, allowing to not only detect the total amount of strains but also distinguish between bending force (upward/downward) and normal force (tensile/compressive). Thus, we were able to first develop such a smart strain sensor using the piezo-gating effect to capture more information in one single device. Foremost, we also combine the piezo-gating effect with the thermoelectric effect to investigate the carrier dynamics of such effects and obtain a synergistic effect where the thermoelectric power factor was largely enhanced via incorporation of the piezo-gating effect. To examine such behavior, we have used the same PGTFT configuration and exerted a thermal gradient to the source and drain electrode interfaces to initiate the hot electron/hole flow and modulate that via strain-induced piezo-potential inside the channel.

What is the Difference between Contact and Sliding? Tangential Forces are Important for Triboelectricity Karl Olson and Laurence D. Marks; Northwestern University, United States

Despite increasing research interest in triboelectricity, the electric charge transfer that occurs when two materials contact each other, the fundamental understanding of the subject is still limited, especially when at least one of the materials involved is insulating. When surface asperities of the rubbing materials contact each other, they deform, resulting in electromechanical effects that are large enough to cause charge transfer. Especially important is flexoelectricity, the coupling between electric polarization and the strain gradient, which can be very large due to the small size of the asperities [1].

Previously, we have modeled the electromechanics of simple single-asperity metal-semiconductor contacts [2]. Here, we extend this analysis to consider tangential forces as well as normal forces. Macroscopically, this roughly corresponds to sliding instead of simple contact and release.

Intuitively, one might suspect that sliding a balloon on hair causes more charge transfer than contacting and separating. Indeed, the results of our work suggest that in some cases, sliding forces can be more impactful than normal forces. The relative importance of normal forces and tangential forces to the electromechanics of contacting asperities is dependent on material parameters. This fundamental insight into the importance of the geometry of the contact force may be useful both in cases where charge transfer should be prevented to reduce dangerous sparks or where it is desired to power triboelectric nanogenerators.

Coupling Triboelectric and Thermomagnetic Effects as a Novel Low-Grade Thermal Energy Harvesting Technology Catia Rodrigues[1], Ana Pires[1], Isabel Gonçalves[1], Andre Pereira[1], Joana Oliveira[2] and Joao Ventura[1]; [1]University of Porto - Faculty of Sciences, Portugal; [2]University of Porto - Faculty of Engineering, Portugal

Energy has been one of the major driving forces behind our societal development and economic growth. However, the resulting surge in energy demand has also led to the major environmental crisis we now face. Thus, new energy generation technologies able to convert low-grade thermal energy into electricity are urgent to tackle the continuous surge in energy demand. Here, a hybrid device that couples triboelectric and thermomagnetic effects to generate electrical power in the presence of small temperature gradients near room temperature was demonstrated [1]. Triboelectric nanogenerators (TENGs), appearing just in 2012 [2], are already one of the most promising mechanical energy harvesting technologies [3-5]. In this work, the thermomagnetic effect allowed us to induce the periodic and sustained motion of a second-order ferromagnetic material in temperature gradients below 30 °C. This mechanical motion was converted into electrical energy using a TENG. The applicability of this concept was demonstrated in a broad range of operating temperatures in both the cold (15 to 37 °C) and hot (60 to 90 °C) sides. Varying the temperature gradients with TENG assembled in the cold-side, a maximum power density of 18 mWm^{-2} was reached using a cold- and hot-sides temperature of 30 and 65 °C. When assembled in the hot-side, the TENG generated a maximum power density of 54.7 mWm^{-2} for cold- and hot-side temperature of ~20 and 65 °C. It was further shown that the electrical power generated by the hybrid TENG is more than 35× higher than that obtained by a conventional thermomagnetic generator. This work showed that TENGs is a high-efficient harvesting technology to use the temperature difference and vibration mechanical energy as electrical energy sources.

Discovering Giant Magnetoelastic Effect in Soft Systems for Nanogenerators Xun Zhao; University of California, Los Angeles, United States

Magnetoelastic effect is usually observed in rigid bulky metal alloys. Very recently, we discovered giant magnetoelastic effect in a soft system composed of platinum-catalyzed silicone polymer matrix and neodymium-iron-boron nanomagnets. The soft composite system shows up to four times enhancement of the magnetomechanical coupling factor (T/Pa) than the traditional rigid counterpart owing to a distinct physical mechanism. The giant magnetoelastic effect was further coupled with magnetic induction to invent a soft magnetoelastic nanogenerator as an emerging approach to revive the community of biomechanical energy conversion that is challenged by low current, high internal impedance, and low water/humidity resistance for decent operation stability. This discovery established an alternative way for biomechanical to electrical conversion which could work stably on wet skin or in body fluids without reliance on any encapsulation. We studied its working mechanism by a wavy chain model based on the magnetic dipole-dipole interaction and demagnetizing factor. To facilitate practical applications, we explore their applications as bioelectronics for human-body-centered energy, sensing, and healthcare. For example, we invented a textile magnetoelastic nanogenerator, weaving the 1D soft nanomagnet fibers with conductive yarns, which could used for energy harvesting from human body and convert the arterial pulse into electrical signals.

4:30 PM EL08.07.05
How can the Surface Charge Effects be Advantageous for Enhancing the Piezo-Conversion Efficiency in GaN NWs? Noelle Gogneau[1], Pascal Chretien[2], Amaury Chevillard[1], Tanbir Sodhi[1,2], laurent Couraud[1], Laurent Travers[1], Jean-christophe Harmand[1], Francois Julien[1], Maria Tchernycheva[1] and Frederic Houze[2]; [1]Center for Nanosciences and Nanotechnologies, France; [2]Laboratoire de Génie électrique et électronique de Paris, France

The piezoelectric nanowires (NWs) are considered as promising nanomaterials to develop ultra-compact and high-efficient piezoelectric nanogenerators working under environmental mechanical deformations and vibrations (equivalent forces of few Newton in the 1-200 Hz frequency range) for supplying micro-sensors and medical implants. Especially sub-100 nm-wide NWs present the particularity to exhibit specific properties, non-existing or non-significant at micrometric scales, that can lead to a strong modulation/modification of their characteristics. Among these “new properties”, we can cite the exaltation of the piezoelectric coefficients, the formation of nano-contact at the NW/electrode interface allowing an enhanced energy harvesting, or the modulation of the free carrier concentration due to the surface charge (SC) effects. Regarding this last property, simulations have recently established that these SC effects can be advantageous for improving the piezoelectric response of the NWs, since they can limit, in given conditions, the screening by the free carriers of the piezoelectric charges. In-depth understanding of the relationship between these new properties and the piezoelectric conversion capacities of the NWs is now a prerequisite for further improving the device performances and thus approaching a future technological transfer.
To quantify experimentally the influence of the SC on the piezoelectric response of the GaN NWs, we have developed a new advanced nano-characterization tool based on AFM probing the piezo-conversion properties of NWs axially compressed with a well-controlled applied force. This unique technique, in addition to mimic the main deformations undergone by the nanostructures when they are integrated into a device, allow to measure simultaneously and thus correlate the output voltage generated by each NW of the array and its NW deformation rate. In other words, we can quantify the electromechanical coupling coefficient of each tested GaN NWs, one of the figures of merit of the piezoelectricity.
With this new system, we have measured the electromechanical coupling coefficient of GaN NWs characterized by an equivalent height and a diameter evolving between 20 and 110 nm. We established, for NW presenting the same compression degree, that the coupling coefficient is strongly affected by the surface charge effects. For large diameter (60 nm in the intrinsic doping conditions of our NWs), the SC have no effect on the piezo-conversion and thus this one is only controlled by the NW mechanical characteristics. By contrast, for lower diameters, the SC effects become favorable for piezo-conversion due to the strong reduction of screening effect of the piezo-charges into the fully depleted NWs. Thus, we observe an enhancement of the piezoelectric response of the NWs. Especially, we demonstrate that by finely architecting the NWs dimension, the SC effects can be advantageous for strongly improving the electromechanical conversion efficiency of GaN NWs up to 43,2%.

P-N Junction-Based Piezoelectric Smart Devices for Energy Harvesting and Self-Power Sensing Qinrong He, Xuan Li, Han Zhang and Joe Briscoe; Queen Mary University of London, United Kingdom

With increasing development of “Internet of Things” (IoT), it is particularly desirable to research flexible energy harvesters for the field of wireless, portable and monitoring fields, which can capture multiple forms of mechanical energy with enhanced energy conversion efficiency. Herein, textile and carbon fibres were used as flexible substrates to fabricate energy harvesters. P-N junction-based ZnO energy harvesters were designed to combine the advantage of ZnO piezoelectricity and the flexibility of textile and carbon fibres. PEDOT:PSS and CuSCN are used to reduce the external and internal screening effect by forming a P-N junction and surface passivation to enhance the performance, respectively.[1-2] PEDOT:PSS/CuSCN/ZnO structure was successfully fabricated on conductive Cu/Ni coated textile and carbon fibres. The textile-based device generated increasing output voltage from 0.2 V to 1.81 V as the shaking frequency increases from 19 Hz to 26 Hz, which was harvested to activate an LCD screen.[3] Carbon fibre-based devices generated increasing output voltage from 1.4 V to 7.6 V as the acceleration from an impacting force increased from at 0.1 m/s^2 to 0.4 m/s^2. Both of the above flexible devices exhibited high stability and durability under 26000 cycles test, and were also able to harvest energy from biomechanical forces such as impacting, flicking and gentle finger tapping . In addition, a carbon-fibre-based composite, carbon fibre-reinforced plastic (CFRP)-based self-power sensor was also fabricated, which exhibited output voltage from 0.27 V to 3.53 V under different impacting acceleration from 0.1 to 0.4 m/s^2 with good stability during a 26000 cycles test. The results provide an efficient method for future energy harvester and self-powered devices to harvest various mechanical source from the environment for portable electronics application.

5:00 PM EL08.08.04
Hybrid Energy Harvester Based on Perovskite Solar Cell and ZnO Piezoelectric Nanogenerator Yuan Zhang, Xuan Li and Joe Briscoe; Queen Mary University of London, United Kingdom

With the consumption of fossil fuels and the increasing awareness of environmental protection, more and more efforts are being put into the development of renewable and clean energy. Mechanical energy is the one of the most abundant and accessible energy sources, and has been widely harvested by large-scale technologies such as wind power or tidal stream generators. Piezoelectric nanogenerators (PENGs) provide a potential way to convert small

mechanical energy such as body motion or vibration into electricity, which can be used to power small portable electronics, medical bio implants, remote wireless sensors etc. Also, solar energy offers the potential to provide much higher power levels than motion since the sun delivers more energy to the earth in 1 h than the entire planet consumes in one year. However, light is not always available, nor is movement, therefore a hybrid energy harvester that can make use of both sources provide a more reliable and high-level of power for small, portable or self-powered devices.
Here, a combined solar and piezoelectric hybrid energy harvester (HEH) was designed, fabricated and tested, which combined a PENG and perovskite solar cell with the structure of PET/ITO/ZnO seed layer/ZnO nanorods/perovskite/hole transport layer/Au. Oscillation (NG) and illumination (PV effect) testing indicated that HEHs operated as kinetic and solar energy harvesters both separately and simultaneously. The length and diameter of ZnO nanorods, and the composition of perovskite were optimised to achieve the enhancement of both PV and NG output performance. The coupling effect between perovskite and piezoelectric ZnO nanorods, as known as the piezo-phototronic effect, was also investigated.

5:00 PM EL08.08.05
Manufacturing of Advanced Piezoelectric Nanogenerator by Functionalizing PVDF with $LiTaO_3$ and Multiwalled Carbon Nanotubes (MWCNTs) for Energy Harvesting and Sensing Applications Islam Uddin Shipu, Zaida Carballo, Rigobert Ybarra and Mohammed Uddin; The University of Texas Rio Grande Valley, United States

One of the freely available green energy sources that might be used to satisfy the small-scale energy need is mechanical energy. In order to capture mechanical energy, power the next generation of electronic gadgets, and health monitoring flexible piezoelectric nanogenerators made of light weight polymers and carbon nanotubes have drawn a lot of attention. Lithium tantalate ($LiTaO_3$) nanoparticles were prepared and utilized to create a flexible piezoelectric nanogenerator (FPNG). A compact piezoelectric nanogenerator that successfully transfers mechanical energy into electricity was then created using lightweight polyvinylidene fluoride (PVDF), multiwalled carbon nanotubes (MWCNTs), and $LiTaO_3$ nanoparticles. To create a piezoelectric composite film, $LiTaO_3$ nanoparticles were first prepared and loaded into poly vinylidene difluoride (PVDF) and multi-walled carbon nanotubes (MWCNTs). This piezoelectric composite film was then placed between two copper electrodes to create an flexible piezoelectric nanogenerator (FPNG). It was thoroughly examined and adjusted how the concentration of $LiTaO_3$ injected into PVDF and MWCNT affected the electrical performance of FPNG. 1.5%, 2.5%, 3%, and 5% $LiTaO_3$ were used to manufacture the flexible piezoelectric films and then the films' XRD, XPS, SEM characteristics were analyzed as well as the voltage and current were measured. Open-circuit voltage and short-circuit current measurements for the 3 wt% FPNG were ~70V and ~8µA respectively. The nanogenerator was further put to the test by combining it with common electronic parts including capacitors, bridge rectifiers, and 10 LEDs. By transforming human walking force into energy, multiple piezoelectric films can light a room even without electricity. The FPNG was used to harness diverse biomechanical energy. This FPNG was also employed as a sensor for in vitro and in vivo biological applications such as blood flow, respiration, and muscle contraction.

5:00 PM EL08.08.06
On the Effect of Dielectric Relaxation Mechanisms on the Performance of a Multi-layered Triboelectric Nanogenerator Xiaoyue Zhao and Zoubeida Ounaies; The Pennsylvania State University, United States

With the rapid development of the Internet of Things (IoT), a growing number of mobile electronics are being connected to the internet and working in an environment without human interventions. Therefore, there is a crucial need for an alternative energy technology that can harvest energy from ambient environment to self-power devices, due to the inadequacy of conventional energy sources. Among the many energy harvesting technologies, the triboelectric nanogenerator (TENG) is attracting attention recently since it is flexible, portable, cost effective and light in weight. TENGs utilize the triboelectric effect to generate electrical energy when two materials come in contact. The ubiquity of triboelectric effect makes TENG a potential energy source for many applications, such as wearable electronics, smart buildings, and implantable medical devices. Currently, TENGs are capable of milliwatt power; for this reason, their output needs to be enhanced to realize widespread adoption. Previous studies have found that the performance of TENGs can be improved by employing a muti-layer material configuration where each layer contributes to a unique part in the charge generation and transport mechanisms. This improvement cannot be explained using theory since the theoretical calculations of the power output assume that the charges are confined at the contact surface. Therefore, a comprehensive study of the mechanism behind the enhancement of triboelectric output for multi-layer materials is needed. In this work, layered materials of Polydimethylsiloxane (PDMS) and P(VDF-TrFE) are investigated and assessed against single layered PDMS as the control material. The number of layers, as well as the polarization and dielectric properties of P(VDF-TrFE) are tuned to maximize the triboelectric output. For example, a two-layer material consisting of PDMS and electrically poled P(VDF-TrFE) shows a 25% increase in the triboelectric output compared to a single-layer PDMS sample. The enhancement of the triboelectric output is then interpreted using dielectric spectroscopy. Specifically, the triboelectric output of the designed muti-layer material configuration along with the control TENG is quantified by measuring the open-circuit voltage and short-circuit current of the samples. In addition, the TENGs are characterized using dielectric spectroscopy to probe the charge transport, interfacial polarization, and other polarization effects in the multilayered materials. This study aims to relate the charge propagation and trapping to the change in the triboelectric output in multilayered dielectric materials. The findings will shed light on the mechanisms and contribute to the widespread adoption of TENG as an environmental-friendly energy technology for our society.

High Performance Mechanical Energy Harvesting from Ionomer Coated Carbon Nanotube Yarn Twist Gyu Hyeon Song, Jong Woo Park and Seon Jeong Kim; Hanyang University, Korea (the Republic of)

Mechanical energy harvesters such as piezoelectric, triboelectric are widely investigated to scavenge electrical energy from body movements to ocean waves. A high-power yarn-type mechanical energy harvester called "twistron" was reported in 2017. When stretching it, the increased twist reduces the effective surface area forming an electrical double layer capacitance (EDLC), and electricity is produced in proportion to the amount of EDLC change. By stretching with a sinusoidal applied strain, 140 mV of maximum open circuit voltage (OCV) and 250 W/kg of maximum peak power was obtained. Here, we increased the generated voltage from twistron by coating potential of zero charge (PZC) shifting materials. The shifted PZC increases the amount of intrinsic bias voltage (|OCV-PZC|) used for harvesting electricity. By coating the PZC shifting materials, the produced maximum OCV and peak power increased 1.63 and 4.06 times. Also, by comprising the yarn pair asymmetrically with pristine CNT and the PZC shifting materials coated CNT, the generated voltage can be the sum of the voltages from each electrode. Since the intrinsic bias voltage becomes negative, the direction of generated voltage becomes reversed for PZC-shifted materials coated CNT twistrons compared to pristine CNTs. These asymmetrically composing twistron yarn pairs were attached to joints such as the elbow, knee, and fingers in a form of textile, and energy harvesting from bending motions in seawater was demonstrated. Improved performance of twistron harvester was achieved by the simple coating of PZC shifting materials. Increased voltage without cell separation for serial connection is beneficial to be utilized in confined spaces.

5:00 PM EL08.08.09
Mover Electrode/Stater with Double Electrodes Triboelectric Nanogenerator with High Instantaneous Current Triggered by a Surficial Contact Electrode Haitao Wang[1], Yasuyoshi Kurokawa[1], Kazuhiro Gotoh[1], Shinya Kato[2], Jia-Han Zhang[3] and Noritaka Usami[1]; [1]Nagoya University, Japan; [2]Nagoya Institute of Technology, Japan; [3]Nanjing University, China

The conventional vertical contact-separation triboelectric nanogenerator (CS-TENG) and single-electrode triboelectric nanogenerator (SE-TENG) has attracted much attention due to practicality. In applications, although CS-TENG is always preferred than SE-TENG owing to the unique double-sided power generation layers, the top mover part and the bottom stator part should be connected by conductive wires, which lead to inconvenient control and unstable performance. On the contrary, in case of SE-TENG, the mover part is free to contact and separate with the stator part without connecting any conductive wires. However, the output is much lower than CS-TENG. Remarkably, a droplet-based electricity generator (DEG), which converts water-droplet energy into electrical energy, was invented in 2020. The DEG demonstrated several orders of magnitude higher instantaneous output than its counterparts. The DEG typically consists of tiny piece of top electrode and full coverage of bottom electrode, and a dielectric material between them. The core novelty lies in introducing a new bulk effect characterized by the formation of a closed loop between droplet, electrodes, and dielectric material. Charges flow directionally from a bottom electrode into the water contacted to the top electrode. In this study, inspired from the DEG, we introduce the mover electrode to DEG and call the device mover electrode/stater with double electrodes TENG (MESD-TENG). The MESD-TENG can achieve the same bulk effect in the case of solid-solid contact. The MESD-TENG was designed to meet the merits of CS-TENG, SE-TENG and DEG at the same time.
The MESD-TENG and CS-TENG were fabricated. In the case of the MESD-TENG, a fluorine-doped tin oxide (FTO)-coated glass (500 mm× 500 mm) was used as the top mover part. For a bottom stator part, the f(FEP) film (500 mm× 500 mm) was pasted on the another FTO-coated glass covered by FEP film. In this system, the top FTO acts as the tribo-positive layer and electrode simultaneously, the FEP film acts the tribo-negative layer, and the bottom FTO acts an electrode. The tiny piece of Al electrode was pasted on the FEP film. The size of the Al electrode is 10 mm × 5 mm. The Al electrode was connected to the bottom FTO electrode through external circuit. The bottom stater part was fixed and the top mover part was made moved iteratively by a step motor at 0.5 Hz. In the case of CS-TENG, FTO-coated glass (500 mm× 500 mm) was used as the top mover part. For a bottom stator part, the f(FEP) film (500 mm× 500 mm) was pasted on the another FTO-coated glass covered by FEP film. FTO in the top mover part was connected to the bottom FTO electrode through external circuit. The bottom stater part was fixed and the top mover part was made moved iteratively by a step motor at 0.5 Hz. The electrical output of them was measured by the electrometer (Keithley 6517b).
As a result, the MESD-TENG achieved a 15-fold enhancement of current and voltage of almost the same order of magnitude compared to the CS-TENG. For a more intuitive verification, we compared brightness when the same numbers of LED arrays (50 LEDs) are driven by the two devices of MESD-TENG and conventional CS-TENG under the same 0.5 Hz, and the results shows the LED arrays driven by MESD-TENG are lighted up much brighter than the other one. Therefore, this work provides an effective method to develop high-performance nanogenerators for further practical application.

5:00 PM EL08.08.10
Multi-Layered Triboelectric Nanogenerator for Human-Machine Interface Using an Artificial Synaptic Device Yong-Jin Park, Yun Goo Ro, Young-Eun Shin, Cheolhong Park, Sangyun Na, Yoojin Chang and Hyunhyub Ko; Ulsan National Institute of Science & Technology (UNIST), Korea (the Republic of)

Artificial synaptic device provides functions of sensing, short-term and long-term memory, which can find applications in various human-machine interfaces. Memory and sensing functions with low energy consumption are considered as a key of the neuromorphic system that is superior to high energy consuming von Neumann computing architecture. Triboelectric nanogenerator (TENG) provides spike-like impulses similar to the action potential propagation in the biological system, which can be utilized for the operation of artificial synaptic devices. Herein, we propose multi-layered TENG (M-TENG) capable of generating multiple spike impulses by a single mechanical stimulus based on tribo-positive microdome-patterned polydimethylsiloxane (PDMS) and tribo-negative 1H,1H,2H,2H-perfluorooctyltrichlorosilan (FOTS)-coated $BaTiO_3$/PDMS (FBP) composite films. While conventional triboelectric devices generate two spike peaks when the top and bottom triboelectric layers contact and separate with each other *via* contact electrification and electrostatic induction, our M-TENG can generate distinct multiple spikes corresponding to the number of layers under a single mechanical stimulus of the same applied force and frequency. Moreover, our M-TENG shows 1.33 times higher output charge compared to conventional single-layered TENG and the power density of 7.56 $\mu W/cm^2$ at 100 MΩ under the applied force of 19.6 kPa. For the application in artificial synaptic devices, M-TENG is coupled with organic electrochemical transistor (OECT), where multiple spikes generated from M-TENG are served as the gate voltage for the self-powered system. Our synaptic device exhibits continuous increase and gradual decay of post-synaptic current under several stimulations, leading to long-term plasticity (LTP). LTP is formed by paired-pulse facilitation (PPF) of excitatory post-synaptic current (EPSC). The efficiency of the triggered EPSC can be expressed by PPF index with different time intervals of stimulations. To further investigate human-machine interface using the artificial synaptic devices, a robotic hand is operated by training process mimicking memory consolidation.

5:00 PM EL08.08.11
Compressibility Effect of Charge Generating Layer on Output Performance of Triboelectric Nanogenerator Junho Jang[1], Chungryong Choi[2] and Jinkon Kim[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Kumoh National Institute of Technology, Korea (the Republic of)

Triboelectric nanogenerator (TENG) that can be used in next-generation wearable devices, have received great attention due to their simple device structure and low cost. Among many factors to affect the output of TENG, the compressibility of a charge generating layer becomes very important, because it influences the contact area as well as the number of induced charges. Nevertheless, it has been challenging to achieve high compressibility with conventional polymers due to the intrinsic entanglement of polymer chains. To significantly reduce the entanglement of polymeric materials for achieving low compressive modulus (E) or high compressibility, we chose bottlebrush polymers. Our study leverages bottlebrush elastomers, which suppress chain entanglements—an effect that significantly lowers various mechanical moduli compared to conventional linear polymer networks. We found that TENG output performance such as voltage, current and surface potential, are increased with decreasing E of the charge generating layer. When we used crosslinked bottlebrush poly(dimethyl siloxane) (PDMS) as a charge generating layer of TENG device, the output voltage (120 V) was more than twice larger than that (55 V) of conventional crosslinked PDMS without having bottle brush. These results demonstrate the power of controlling polymer architecture in the context of advanced electronic applications.

5:00 PM EL08.08.12
Development of Double Schottky Piezotronic Nano-newton Force Sensor based on Porous ZnO Nanorod Arrays Yi Miao Lin, Yu-Liang Hsiao and Chuan-Pu Liu; National Cheng Kung University, Taiwan

Force sensors based on piezotronic effect have received significant attention for the application in the internet of things, wearable electronics, biomedical engineering, and high-electron-mobility transistor due to their high sensitivity, fast response, and low energy consumption. The piezotronic force sensors rely on the current changes manipulated by the piezo-potential built at the Schottky interface, where most of them are working based on single-Schottky device, implying that the signals can only be read at either positive or negative bias. Contrarily, Double Schottky based piezotronic force sensors provide a possibility, allowing two modes both at positive and negative bias can be operated within one sensor unit for the advanced micro/nano electronic devices. Among the piezoelectric material, ZnO has been widely developedin applications such as sensors, photocatalysis, and energy harvesting because it is adaptable in multiple nanostructureswith piezotronics/ piezo-phototronic properties. In this study, intrinsic n-type ZnO and p-type Sb-doped ZnO nanorods were demonstrated to perform single and double Schottky piezo-tronic force sensor devices by applying ultra-low compressive force ranging from 20nN to 100nN with conductive atomic force microscopy (C-AFM). To improve the sensitivity of the force sensors, hydrogen annealing was performed to make porous structure to enhance the piezoelectricity of ZnO. To further clarify the contribution from porous structure, oxygen and argon annealing at different temperatures was performed to explore the influence of crystallinity, defects, and carrier concentrations on the sensitivity.In this study, the mechanisms of electrical transport of single and double schottky piezo-tronic force sensors have been comprehensively investigated.

5:00 PM EL08.08.13
Magneto-Responsive Switching of Liquid-Solid Triboelectrification for Self-Powered Magnetic Proximity Sensor Soyeon Yun[1], Kijung Yong[1] and Seunghyup Lee[2]; [1]POSTECH, Korea (the Republic of); [2]korea institute of Ceramic Engineering and Technology, Korea (the Republic of)

Water droplet-based triboelectric nanogenerators (WD-TENGs) harvest energy from triboelectrification between water drop and solid surface. WD-TENGs are highly advantageous to convert abundant rain drop energy.
This study proposed a new concept for switching of liquid-solid triboelectrification by introduction of a magnetocontrollable lubricant-infused layer as a triboelectric layer. This layer was composed of magneto-responsive micropillars and lubricating oil. The micropillars showed two different aligning structure states that determine the continuity of lubricant layer. As the direction of the applied magnetic field changes, vertically standing micropillars start to lie down and the continuous lubricant layer is generated. The lubricant layer works for preventing liquid-solid triboelectrification. Triboelectric switching resulted from reversible change between these two states. The electrical outputs showed a difference of nearly three times, so it could be clearly defined as ON and OFF states. The triboelectric switching cycles assured excellent reversibility and stability even after almost one hundred cycles.
The triboelectric switching has been analyzed in detail for factors that can affect the behavior of water droplets, such as the thickness of lubricant layer, drop height of water droplet and inclination angle of TENG.
Also, switching characteristics showed reversible wettability change and it was utilized to recover the performance of WD-TENG even under high humidity environment. Unlike most WD-TENGs, our device can avoid surface wetting problems and generate sustainable electrical power in extreme condition. To extend the usability, the proposed device could work as a self-powered magnetic proximity sensor. Our work presents a new idea of magneto-responsive triboelectric switching, extending the TENG applicablity in low-power-consumption applications such as no-extra power supply-need switches and self-powered sensors.

5:00 PM EL08.08.14
Sustainable Charged Composites with Amphiphobic Surfaces for Harsh Environment–Tolerant Non-Contact Mode Triboelectric Nanogenerators GiHyeon Han[1] and Jeong Min Baik[2]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

Here, we report the harsh environment–tolerant and robust non-contact mode triboelectric nanogenerators based on sustainable charged TPU-SiO_2 and PDMS-PTFE composites with amphiphobic surfaces. In the composites, SiO_2 and PTFE particles are well-distributed with ethanol and n-hexane as dispersing agents, respectively. The PDMS-PTFE composites are then etched and fluorinated, resulted in the formation of the amphiphobic surfaces. As a practical non-contact mode application, a speed sensor fabricated using the two composites can stably detect a vehicle speed of 3.75 km/h when exposed to high humidity (~ 99 %) and various chemical oils. It also shows the enhanced charge retention characteristic of the composites by 6 times.

5:00 PM EL08.08.15
Real-time Observation of Ferroelectric Domains and Domain-Wall Motions in Plastic/Ferroelectric Crystal Films Itsuki Miyamoto[1], Satoshi Matsuoka[1], Jun'ya Tsutsumi[2], Jun Harada[3] and Tatsuo Hasegawa[1]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]Hokkaido University, Japan

Plastic/Ferroelectric crystals are a class of newly discovered ferroelectric molecular materials that attract considerable attentions as potential alternatives to widely used ferroelectric ceramics [1]. In the compounds, spontaneous polarization arises through the freeze of rotational motion of polar globular cations. Because of the solution processability and unique multiaxial ferroelectricity, the plastic/ferroelectric crystals are expected for device application by facile thin-film preparation. Among a variety of compounds reported so far, 1-azabicyclo[2.2.1] heptanium perrhenate (AH-R) exhibits 4-axis spontaneous polarization at room temperature and outstanding ferroelectric properties (P_s = 4.1 μC/cm^2, E_c = 2 - 4 kV/cm) even in bulk polycrystalline samples [2].

Herein we report ferroelectric domain structures and the response to applied electric fields in solution-processed AH-R crystalline thin films. We adopted birefringent field-modulation imaging technique, an optical imaging for observing ferroelectric domains via the Pockels effect under in-plane electric fields ($<< E_c$) [3,4]. We successfully observed various patterns of ferroelectric domains that are formed by three different types of domain boundaries in as-grown films. We then visualized step-by-step polarization orientation process by applying pulsed DC electric fields ($> E_c$) through the field-modulation imaging measurements. We found that the domain walls which involve lattice deformation and are nearly parallel to the external field begin to move along the direction perpendicular to the applied electric field. We finally observed that the polarization of entire area between electrodes is oriented to the same direction after several seconds.

We also performed a high-speed imaging experiment for observing periodic dynamics of domain wall motions during the polarization switching process under applying alternating (AC) electric fields. With gate bias control of the image intensifier installed in front of the image sensor, delay of the exposure to polarized light microscopy was swept so as to visualize the motion as a sequence of the images. We achieved visualization of smooth and repetitive behavior of the domain wall motions, where the striped domain walls perpendicular to the field are maintained while those parallel to the field move to expand the reversed domains. Based on the observations, we discuss motions of domain walls that drive the polarization reversal under electric fields. Such direct observation of domain behavior are expected to elucidate microscopic mechanisms of switching characteristics in multiaxial plastic/ferroelectric crystals.

Progress Towards Piezoelectric (Ba,Ca)(Ti,Zr)O_3 Thin Film Using Wet Chemical Solution Deposition Hannes Rijckaert, Ewout Picavet, Isabel Van Driessche, Klaartje De Buysser and Jeroen Beeckman; Ghent University, Belgium

Today, piezoelectric materials play an important role in numerous applications such as sensors, actuators, transducers, and energy harvesters. Piezoelectric energy harvesters cannot reach the efficiency and scale of solar cells or wind turbines, but they are excellent power sources where electrical cables are undesired and miniaturization is a key factor. Lead-based piezoelectric materials such as Pb(Zr,Ti)O_3 (PZT) is currently the most widely used material in such systems. This is due to their strong piezoelectric coefficient and electromechanical coupling coefficient. However, the use of PZT is not an option due to the presence of lead and **the development of alternative "greener" and "superior" materials** with comparable or better piezoelectric properties is required. Barium titanate ($BaTiO_3$) is one of **the suitable lead-free piezoelectric candidates** due to its promising piezoelectric properties. To improve its piezoelectric properties, several $BaTiO_3$-based solid solutions with different substituents have been studied. In 2009, some researchers have reported a significant breakthrough in $BaTiO_3$ perovskite doped with Ca and Zr atoms, leading to the $(Ba,Ca)(Ti,Zr)O_3$ (BCTZ) solid solution with an outstanding piezoelectric coefficient.

Since **BCTZ material offers promising piezoelectric properties**, making thin films of this material is of particular interest for use in various applications. Also, the integration of piezoelectric films on silicon (Si) or silicon nitride (SiN) based platforms is crucial for the miniaturization of electronic and photonic components. In this work, **wet chemical solution deposition (CSD) technique is introduced as a rapid integration** to develop a cost-effective, reproducible and high quality industrial pathway to piezoelectric BCTZ film on desired substrate. Therefore, the formulation of the environmentally friendly BCTZ precursor solution is highly important and must be stable prior to the CSD process with good wetting behavior and good homogeneity on desired substrate. Here we are able to develop **the environmentally benign BCTZ** inks based on the short carboxylic acid route as metal organic decomposition (MOD) method. These modified BCTZ inks can be deposited on several type of substrate such as $LaAlO_3$, $SrTiO_3$, Si, SiO2/Si and buffered Si using spin-coating or ink-jet printing techniques. After deposition, a comprehensive study of the thermal process is carried out to elucidate the nucleation and growth mechanism of the BCTZ film. This extensive study has led to **(*h*00) epitaxial BCTZ film with superior piezoelectric and ferroelectric properties on different substrates**. This approach presents some new specific challenges and opportunities to improve the functional and structural properties of epitaxial BCTZ films on different types of substrates prior to applications.

This newly developed approach will also simplify the cumbersome transfer of piezoelectric BCTZ film from single crystal substrate to flexible substrate, thus meeting the strict requirements for the **successful implementation of piezoelectric BXT material in several applications**.

Theoretical and Experimental Study of Self-Powered Piezoelectric Sensors Response to Applied Force Xabier Garcia-Casas[1], Jorge Budagosky[1,2], Francisco Aparicio[2], Juan Sanchez-Valencia[1], Angel Barranco[1] and Ana Borras[1]; [1]CSIC, Spain; [2]Universidad de Sevilla, Spain

Nanogenerators are devices that can effectively convert mechanical energy into electricity. Thus, nanogenerators can be implemented in self-powered sensors for many applications such as internet of things, environmental monitoring, health and medical monitoring and security. In this emerging context, providing a theoretical model and a mathematical representation that links the electrical output signal with the applied mechanical stimulus is a key point to understand and optimize this type of self-powered sensors.
In this communication, we present a theoretical description about the derivation of the output signal of a piezoelectric self-powered sensor. Our work is based on the constitutive differential equation derived from Maxwell's equations [1], in which a change in the effective surface charge $\sigma(t)$ due to a certain stimulus ($\sigma_p(t)$) produces a displacement current through the dielectric layers in the nanogenerator. Unfortunately, the closed analytic expression of the solution under an arbitrary time dependent function $\sigma_p(t)$ cannot be integrated. Thus, we propose it as an expansion series of the successive time derivatives or antiderivatives of the stimulus, in our case the applied force. This theoretical approximation allows us to distinguish and analyze two different regimes depending on the device and measurement configurations. In the first regime, the output signal is proportional to the force, and is observed for high impedance loads and top-bottom device configurations (lower impedance matching). In the second regime, the output signal is proportional to the time derivative of the force, and occurs for low impedance loads and laterally connected devices (higher impedance matching). For intermediate conditions, more terms of the function series need to be considered.
Our theoretical considerations were corroborated for real devices [2,3], which were manufactured and measured under these regimes and the results were compared with numerical simulations. Thus, the presented models provide an effective theoretical foundation for understanding and predicting the sensitivity regions of nanogenerators and self-powered sensors for practical applications.

Triboelectric Properties of Electrospun Biomaterial Nanofibers Shivangi Agarwal, Robert Ccorahua and Wenzhuo Wu; Purdue University, United States

This research systematically explores the different characteristics and advantages of producing the biomaterial-based nanofibers using the manufacturing technique of electrospinning. This manufacturing method is further employed under various parameters including the ratio of the solvents, the temperature, the voltage, the distance of the collector, and the pumping rate. These parameters affect the structure of the electrospun fibers and hence their triboelectric properties. Next, this research compares the triboelectric properties of our electrospun fibers with those of other common processing methods used for biomaterials. Moreover, we evaluate the mechanical and optical properties of electrospun biomaterial fibers. These properties further improve the strength, durability, and triboelectric properties of the produced nanofibers. Depending on various conditions, we determine their advantages and applications in the textile industry. The results of this research would be helpful in producing/researching a better method for an environmentally friendly biomaterial-based triboelectric sensor that can be used in smart textiles for cardiovascular sensors and other applications.

5:00 PM EL08.08.20
Piezoelectric Nanogenerator Platform Integrating Laterally Grown ZnO Nanowires within Topographic Nanograting Electrodes Minwook Kim, Kwangjun Kim and Jong G. Ok; Seoul National University of Science and Technology, Korea (the Republic of)

Portable electronic devices such as personal healthcare sensors and smart wearable devices are of emerging demand, which require low power consumption and/or self-powering function in order for obviating extra batteries. Piezoelectric materials and piezo-driven nanogenerators for converting mechanical motion into electrical energy can provide a practical solution to this end. Among many piezoelectric materials, zinc oxide (ZnO) has been a workhorse for various piezoelectric devices because it is biocompatible, environmentally friendly, and can be engineered into various structural configurations in a relatively easy way. Among various structural forms of ZnO, 1D structures such as nanowire arrays are suitable for piezoelectric-based nanogenerators because they can generate piezoelectric voltage through higher elastic strain upon mechanical deformation. As a process for synthesizing ZnO nanowires, various methods such as chemical vapor deposition (CVD) and hydrothermal reaction can be used [1]. However, the CVD-based synthesis and the high-temperature synthesis of the Zn-salt-based ZnO seed layer, which require a high-temperature environment, introduce limitations in the substrate material, which poses a great obstacle to the development of flexible piezoelectric nanogenerators to maximize device displacement. Addressing this issue, it is highly requested to grow ZnO nanowires through seedless hydrothermal synthesis on metal thin films. This research develops a piezoelectric nanogenerator framework that integrates ZnO nanowires inside a laterally arrayed, topographic electrodes on flexible substrates. In more detail, a nanograting pattern with an aspect ratio of 1:1 was formed on a PET substrate by UV nanoimprint lithography, and glancing angle deposition (GLAD) was performed at an angle of 45° to selectively deposit a metal thin film on the nanograting pattern, especially on the sidewall region. Depositing Ag on one side and depositing Au on the opposite side, another GLAD was performed by using the catalytically inactive Cr layer at an angle of 80° to selectively deposit a Cr layer only on the top of the nanograting pattern. Following our previously developed recipe [2], ZnO nanowires were then grown selectively between the patterned valleys, forming numerous bridges. Bending of the ZnO nanowires laterally connecting the adjacent nanograting electrodes occurs according to the bending of the base substrate, and piezoelectric polarization occurs in the countless cross-linked structures. Considering the electron affinity of ZnO (4.5 eV) and work functions of Au (5.1-5.47 eV) and Ag (4.52-4.74 eV), the Schottky junction and Ohmic junction are formed in between ZnO-Au and ZnO-Ag interfaces, respectively. [3]. Due to the difference in the junction, a rectification action preferentially occurs at the ZnO-Au junction, which suggests that the device can also be used as a DC nanogenerator.

Materials and Structural Design Approaches of Intelligent Piezoelectric Fibers for Self-Powered Sensing Miso Kim; Sungkyunkwan University, Korea (the Republic of)

Electrospun polymeric piezoelectric fibers have considerable potential for shape-adaptive mechanical energy harvesting and self-powered sensing in biomedical, wearable, and industrial applications. However, their unsatisfactory piezoelectric performance remains an issue to be overcome. While strategies for increasing the crystallinity of electroactive β phases have thus far been the major focus in realizing enhanced piezoelectric performance, tailoring the fiber morphology can also be a promising alternative. Here, we summarize a collection of advances that push the boundaries to achieve a drastic enhancement of self-powered sensing performance by tailoring both material and structural properties of electrospun piezoelectric polymer fibers at multi-scales. As one of the recent advances, we demonstrate a distinctive design strategy for fabricating P(VDF-TrFE) fibers with surface porosity under ambient humidity conditions via nonsolvent-induced phase separation (NIPS). The key aspect of this material design is the porosity engineering of electrospun piezoelectric polymer fibers. Considering the thermodynamic properties of the P(VDF-TrFE) polymer solution in combination with the kinetics of electrospinning, we successfully implemented surface porosity in the P(VDF-TrFE) fibers under ambient humidity conditions. Notably, electrospun P(VDF-TrFE) fibers with higher surface porosity outperform their smooth-surfaced counterparts with a higher β phase content in terms of output voltage and power generation. Further engineering structural morphology of piezoelectric materials from molecular to fiber and yarn structures will be discussed as a route to achieving improvement in the key figures of merit for energy harvesting and sensing, along with our unfolding new understanding of the underlying physics.

9:00 AM EL08.09.02
Control of Artificial Relaxor Behaviors in Ferroelectric/Dielectric Superlattices Zishen Tian[1,2], Michael Xu[3], Jieun Kim[1,4], Hao Pan[1], Djamila Lou[1], Xiaoxi Huang[1], James M. LeBeau[3] and Lane Martin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Massachusetts Institute of Technology, United States; [4]University of Wisconsin–Madison, United States

Piezoelectric materials are an important class of functional materials, with applications ranging from sensors and actuators to energy harvesters and magnetoelectric devices. Understanding the structure-property relations and tuning the response of piezoelectrics is, thus, of great technological importance. Relaxor ferroelectrics such as $(1\text{-}x)\text{PbMg}_{1/3}\text{Nb}_{2/3}\text{O}_3\text{-}(x)\text{PbTiO}_3$ and $\text{BaZr}_x\text{Ti}_{1\text{-}x}\text{O}_3$, in particular, have drawn considerable attention as high-performance piezoelectric materials due to their ultrahigh piezoelectric coefficients, but the complex structure-property relation in relaxor ferroelectrics remains underexplored. In general, it is thought that the chemical disorder of the cations generates random fields which are essential to the formation of relaxor-like polar order. Thus, manipulation of the chemical order should provide a pathway to control the relaxor-like polar order, and hence the dielectric and piezoelectric response of relaxors. In conventional relaxors based on solid solutions, however, the deterministic control of chemical order is challenging due to the inherent randomness, which calls for a new platform for unveiling the structure-property relations of relaxors.

Recently, fabrication of artificial relaxors based on superlattices has been proposed as a novel pathway to achieve the chemical-order control at unit-cell precision [1]. Here, $[\text{BaTiO}_3]_m/[\text{BaZrO}_3]_n$ superlattices, wherein the nanoscale-polar structures are confined in the ferroelectric BaTiO_3 layers, while the dielectric BaZrO_3 layers tune the spacing between neighboring layers of nanoscale-polar structures, are proposed and used as a model system to explore the effect of chemical-order control. $[\text{BaTiO}_3]_m/[\text{BaZrO}_3]_n$ superlattices (m, n = 4-12 unit cells) were fabricated via pulsed-laser deposition and characterized by X-ray diffraction and atomic-resolution microscopy. These studies confirm the production of high-quality heterostructures, wherein the BaTiO_3 and BaZrO_3 layers are coherently strained to each other with relatively sharp interfaces in between. Dielectric permittivity measurements revealed significantly enhanced in-plane dielectric-maximum temperature T_m^IP in the superlattices compared with the solid solution $\text{BaZr}_{0.5}\text{Ti}_{0.5}\text{O}_3$ (from 173 K to ≥433 K), and a trend of higher T_m^IP in superlattices with larger BaTiO_3-layer thickness (from 433 K to ≥573 K as m increases from 4 to 12). Subsequent measurements of hysteresis loops and third-harmonic nonlinearity revealed relaxor-like behavior in the superlattices with the smallest BaTiO_3-layer thickness and ferroelectric-like behavior in the superlattices with larger BaTiO_3-layer thickness, with the crossover appearing between $m = 4$ and $m \geq 8$. Piezoelectric measurements along the out-of-plane direction revealed that the effective piezoelectric coefficient d_{33} is enhanced in superlattices with the smallest periodicity ($m = n = 4$, d_{33} = 7.8 pm/V) compared to both superlattices with larger periodicities ($m = n = 12$, d_{33} = 4.8 pm/V) and the solid solution (5.4

pm/V). Higher $BaTiO_3$ composition in the superlattice further enhances the piezoelectric response ($m = 12$, $n = 4$, $d_{33} = 12.3$ pm/V).

Altogether, these results suggest that an artificial relaxor phase can be achieved in ferroelectric/dielectric superlattices such as $[BaTiO_3]_m/[BaZrO_3]_n$, wherein the chemical order can be deterministically controlled and the relaxor behavior can be manipulated. Considering both the dielectric and piezoelectric response can be tuned by the chemical order, this provides a novel platform for exploring the complex structure-property relation in relaxor ferroelectrics, and opens up future opportunities for the design of high-performance piezoelectric superlattices.

Synthesis of Ferroelectric PVDF-TrFE Nanoparticles for Ultrasound-Driven Electrostimulation Zulmari Silva, Yizhan Wang, Corey Carlos, Jun Li and Xudong Wang; University of Wisconsin--Madison, United States

P(VDF-TrFE) is a well-known ferroelectric co-polymer that can spontaneously present in its piezoelectric crystalline phase. The size and shape control in the nanoscale would open many opportunities in modern biomedical applications. In this work, we synthesized nanostructured P(VDF-TrFE) NPs through a self-assembly synthesis method which resulted in spherical NPs. The as-received NPs had spiked surface features, which offer substantially large high surface to volume ratio. The NP was formed through the agglomeration and assembly of P(VDF-TrFE) flakes formed during nucleation into the 3D spherical structures due to Ostwald ripening process. The NPs size and morphology can be controlled by tunning the rate of the reaction between the solvents used in the synthesis. The formation of the crystalline ferroelectric β phase of the as-grown NPs could be further improved through an annealing process. Piezoelectric force microcopy revealed a qualitative description of the converse piezoelectric structure-property relationship. Because of its strong piezoelectric property, the as-received NPs can effectively respond to external ultrasound stimuli and provide localized electric field. This self-generated piezoelectricity enables a self-powered electrostimulation that may be used to achieve many therapeutic purposes. Our studies further showed that these piezoelectric NPs may be an effective approach toward non-invasive cancer treatments through an irreversible electroporation (IRE) effect.

9:30 AM EL08.09.04
Wet Spun Core-Shell Fibers for Wearable Triboelectric Nanogenerators Doga Doganay, Melih O. Cicek, Onuralp Cakir, Onur Demircioglu and Husnu E. Unalan; Middle East Technical University, Turkey

The advancements in communication technologies and the cooperation of different disciplines such as the internet of things, artificial intelligence and data science have made a significant contribution to the development of wearable electronic devices. Rechargeable batteries and capacitors are currently used to power up these devices. However, the shortcomings of these power supplies limit the use of wearable electronics. First, they are heavy and bulky that reduce comfort. In addition, their capacity is limited. They require frequent charging, and they carry potential risks. Triboelectric nanogenerators (TENGs) have a significant potential to be used as a reliable, inexhaustible, sustainable, and economically feasible power source. In this study, core-shell TENG electrodes were fabricated via co-wet spinning process. The core of the TENG electrodes were consisted of thermoplastic polyurethane (TPU) matrix and carbon black (CB) and silver nanowire (Ag NW) additives. The core fibers were responsible to carry induced electrons resulting from contact electrification. The fabricated shell layer was bare TPU and acted as tribo-charged surface. The effect of TPU concentration within the doping solution for the shell on the output performance of the TENGs were investigated. The open circuit voltage, short circuit current, open circuit charges and maximum power output of the 1 cm long core shell fiber TENGs (PDMS/Al was the counter electrode) were recorded as 1V, 20 nA, 8 nC and 0.07 µW/cm, respectively. Moreover, the output performances of the core shell fibers were also quite stable up to 50 % strain. These results indicated that, wet spun core-shell fibers carry great potential for wearable TENGs.

9:45 AM EL08.09.05
Self-Powered Wireless Sensing Systems Enabled by Triboelectric-Discharge Effect Haoyu Wang[1] and Yunlong Zi[1,2]; [1]Chinese University of Hong Kong, China; [2]The Hong Kong University of Science and Technology (Guangzhou), China

With the rapid growth of the smart city, wireless sensors are highly preferred in plenty of application scenarios. However, traditional wireless sensing and transmission technology still requires multiple modules for sensing, signal modulation, transmission, and power, making the whole system bulky, rigid, and costly. The posed challenges, including but not limited to the distributed power supply and wireless signal transmission, limit the application scenarios of traditional sensing nodes. To address the challenges of real-time sensing, power supply, and wireless signal transmission in current wireless sensors, we proposed a paradigm shift wireless sensing solution based on the breakdown discharge–induced displacement current. With the working principle of triboelectrification, electrostatic induction, and breakdown discharge, the input mechanical trigger can directly convert to electromagnetic (EM) wave to achieve wireless signal transmission in this solution. Through that, we can combine the abovementioned functional modules in a single unit of self-powered wireless sensing e-sticker (SWISE), which is small (down to 9 mm × 9 mm), thin (down to 95 µm), light (down to 16 mg), intrinsically flexible, and fully self-powered without using batteries or cables, whose signal can be detected over 30 m away omnidirectionally. Furthermore, SWISEs have functions of multipoint motion sensing and gas detection in fully self-powered manner. On the basis of SWISE, through studies about EM wave characteristics and the equivalent circuit model, we put forward the signal modulation strategy of the SWISE wireless signal achieved through the parameters in the equivalent circuit model, such as resistance, capacitance, and inductance, where the experimental result matched the theory. Based on this signal modulation strategy, we couple commercial sensors of different mechanics with the EM wave generated by the triboelectric-discharge effect to realize a general self-powered wireless sensing solution for various physical signals, where the information of the sensors is coupled into the EM wave by SWISE and can be decoded by the receiver. Then, a self-powered wireless temperature and pressure sensing system is demonstrated, with an error rate down to 0.18%, and a multi-point sensing array is also realized for broad potential applications. To conclude, the triboelectric-discharge effect-enabled self-powered wireless sensing system proposes a self-powered wireless information transmission platform that is compatible with various commercial sensors with different physical signals detection abilities, which promises great potential for self-powered wireless sensing in the smart city and Internet of Things, such as robotic dynamic sensing, infrastructure monitoring, human-machine interface, etc.

Engineered Carbon Nanohybrids for Wearable Moist-Electric Generators Sang-Joon Park, Byeong-Cheol Kang and Tae-Jun Ha; Kwangwoon University, Korea (the Republic of)

Energy-harvesting electronics have been of great scientific and technological interests in the fields of self-powered systems utilized for powering various electronic applications [1]. Among energy harvesting technologies, nanogenerators such as triboelectric, piezoelectric, and pyroelectric nanogenerators have been widely investigated owing to their simple device configuration and power generation [2]. However, instantaneous alternating output current and low energy conversion efficiency generated by these types of nanogenerators limit their potential in self-powered electronics requiring sustainable direct current power [3]. In this presentation, we will demonstrate engineered carbon nanohybrids for high-performance moist-electric generators (MEGs) which enable to produce continuous and stable electricity for self-powered systems. The mechanism regarding effective collecting charges directly generated from atmospheric humidity is discussed by investigating the incorporation of engineered carbon nanohybrids. We will also demonstrate wearable MEGs exhibiting the improved electric characteristics of open-circuit voltage and short-circuit current under different relative humidity conditions and long-term operational stability against mechanical bending stress. We believe that this work can open-up a new route for emerging energy materials for self-powered nanogenerators.

Trifunctional Smart Finger Based on Triboelectric and Hygroelectric Hybridized Mechanism Xiaoting Ma, Jiaming Zhou, Jingyi Gao and Dong-Myeong Shin; The University of Hong Kong, China

Electronic skin (E-skin) mimicking the sensory functions of human skin holds huge application potential in fields such as robotics, prosthetics, healthcare, and human machine interface. However, most E-skin sensors are able to only detect one or two types of stimuli, which greatly limits their capabilities and further applications. Here, we present a trifunctional smart finger having the advantages of self-powering, simple structure, compacted size and multiple functionalities. The sensory unit of the smart finger was innovatively designed with an aluminum electrode, a gold electrode and a layer of single-ion conducting Nafion film which functions both as the triboelectric and hygroelectric layer. The instantaneous triboelectric signal can simulate the signal of fast adapting mechanoreceptors whereas the sustained hygroelectric signal can imitate the signal of slow adapting mechanoreceptors. Meanwhile, as the Nafion film is hygroscopic material, the triboelectric and hygroelectric signals can also reflect the humid level of the environment. By this triboelectric and hygroelectric hybridized mechanism, the smart finger is capable of simultaneously sensing the static pressure, dynamic forces and environmental relative humidity (RH). Assisted by machine learning data processing, the pressure, vibration frequency and RH of environment can be identified at an accuracy rate as high as 84.0%-100.0% by the smart finger. Furthermore, the sensing capability of the sensory units were well maintained even after being scaled into a 5×5 sensory array, proving the scalability and effectiveness of this hybridizing strategy. Such a versatile smart finger not only provides the fundamental insights into the hybridization of triboelectricity and hygroelectricity, but also a new paradigm of multiple functional sensors with extremely simple structure and excellent accuracy rate of perception for mimicking the human finger which has the highest density of sensory receptors in human skin.

Power Management of Triboelectric Nanogenerators for Self-Powered Electronics Applications Xiaoting Ma, Jiaming Zhou and Dong-Myeong Shin; University of Hong Kong, Hong Kong

In the era of the internet of things, wearable electronic technology can help citizens to avail advanced features and characteristics in different facets of their daily life. These wearable electronics are powered by current energy storage devices that need regular recharging, but the increasing demand for continuous operation is driving research into new power supplies that can deliver stable electricity. One major development has been a conceptual shift away from grid supply charging toward self-powering, in which the devices continuously operate without external power feeding. Triboelectric nanogenerators (TENGs) are emerging as a power supply for self-powered electronics due to their light weight, simple fabrication, diversity in material selection, and high energy conversion efficiency, but the power output of TENGs needs to be trimmed to power the electronics stably. There is a need for flexible power management for self-powered electronic applications, particularly for wearable devices. In this talk, I will address several strategies for power management of TENGs to achieve high-performing self-powered electronics, including voltage trimming, humidity insensitivity, and durability control.

Machine Learning Enabled Triboelectric Textile Sensing System for Object Recognition Shujia Xu[1,1] and Wenzhuo Wu[1,1,2]; [1]Purdue University, United States; [2]Regenstrief Center for Healthcare Engineering, United States

The human tactile sensation can perceive the properties of diverse objects when grasping objects. The development of smart artificial tactile sensory systems with the dexterity of human grasp remains a challenge. The self-powered triboelectric tactile sensor is attractive to be applied for grasp tactile sensing due to its simple construction, and ubiquitous triboelectric effect in daily life. The integration of machine learning techniques can reveal hidden information from tactile signals and enable intelligent sensing applications. Here, we develop a machine-learning enabled smart glove system based on triboelectric tactile sensors for object recognition, which could "feel" the properties (e.g., surface) of objects. TENG sensors are integrated into the glove to perceive information about various objects. The smart glove system equipped with self-powered triboelectric sensors while endowing dexterous hand manipulation of objects is promising for various emerging applications in human-machine interface, mixed-reality, robotics, etc.

2:00 PM EL08.11.04
***In Situ* Quantitative Study of Nanoscale Contact Electrification Between Identical Materials** Ruizhe Yang and Jun Liu; University at Buffalo, The State University of New York, United States

Contact electrification (CE or triboelectrification) is a well-known phenomenon in which charge transfer occurs between two distinct materials. In previous studies, the CE between insulators, semiconductors and metals has been widely discussed, while CE involving two identical materials has drawn increasing attention due to their implication for industries such as pharmaceutical powder processing, optics manufacturing and etc. It is generally accepted that the triboelectric effect depends on the transfer of electron ions and/or charged molecular fragments. A common idea is that the differences in work function of two contacting materials drive charge transfer, the Volt-Helmholtz hypothesis. However, this fails to explain many experimental observations, such as charging that occurs when two pieces of the same material are rubbed against each other. Although work function difference is important, it is not the only cause of triboelectricity. Here, we design and demonstrate the in-situ triboelectric characterization between two identical material based on a combination of contact-mode atomic force microscopy (AFM), Kelvin Probe Force microscopy (KPFM) and conductive AFM (CAFM). By analyzing force-dependent surface charging (charge density), *I-V* characterization (effective energy barrier height) and etc., the results indicate that flexoelectric effect may be involved in triboelectrification, where a coupling of strain gradients during asperity contacts, polarization and local band bending.

Output Performance of the Triboelectric Nanogenerator with Carboxymethylated Cellulose Nanofiber and Perfluoroalkoxy Alkane Films Deepika Thakur[1], Soonmin Seo[2] and Jinho Hyun[1]; [1]Seoul National University, Korea (the Republic of); [2]Gachon University, Korea (the Republic of)

The carboxymethylated cellulose nanofiber (CM-CNF) and perfluoroalkoxy alkane (PFA) films were used for the fabrication of triboelectric nanogenerator (TENG). The fabrication of CM-CNF/PFA TENG was simply done by origami based folding technique. After drying the CM-CNF suspension at room temperature, the thin film with desirable dimension was obtained for the fabrication of TENG. The fabricated TENG device consisted of 5-layer folded structure, and could be stretched, compressed and released based on the contact-separation mode while operation. The carboxymethylation reaction time and the degree of substitution had the effect on triboelectric charge generation of CM-CNF film. Also, mechanical strength of CM-CNF film was dependent on the carboxymethylation degree. The output performance of TENG with CM-CNF film having different carboxymethylation content was analyzed systematically. The direct influence of functionalized CNF through carboxymethylation was first time explored for the triboelectric charge generations in this work.

3:30 PM EL08.11.06
Output Performance Enhancement of Perovskite Composite Triboelectric Nanogenerator by Light Modulated Surface Charge Density Minje Kim, Sol Lee, Viet Anh Cao, Pangun Park and Junghyo Nah; Chungnam National University, Korea (the Republic of)

Triboelectric nanogenerators (TENGs) have gained attention due to their ability to generate relatively high output power by excavating various vibrating resources that exist in our environment. To date, various efforts, such as surface patterning, chemical functionalization, and dielectric permittivity modulation have been made to improve output performance of the TENGs. However, the output performance of TENG has still been limited due to relatively low current density as the current induction relies only on the triboelectric frictional surfaces. Recently, methylammonium lead triiodide organometal halide ($MAPbI_3$) perovskite has been extensively investigated as light-emitting diodes and photodetectors due to its excellent light absorption capability. The irradiated light separates electrons and holes in $MAPbI_3$, accumulating the separated electrons and holes on the top and bottom surfaces. Therefore, by exploiting the light absorption property of perovskite layer as a friction layer, the surface charge density of the friction surface can be modulated by light irradiation. However, it is difficult to adopt as a triboelectric friction layer because it can easily deteriorate due to a physical impact applied to the perovskite layer in the friction contact separation mode.
In this work, we demonstrate the fabrication and performance of the TENG fabricated using ferroelectric $MAPbI_3$ and ferroelectric PVDF-TrFE polymer composite. By composite formation, the frictional surface charge density can be effectively modulated by light irradiation, to increase the output performance of TENG. In addition, degradation of the perovskite was effectively prevented since it is packaged inside PVDF matrix, guaranteeing a long-term stability. Besides, electrical polarization can also be applied to further increase surface charge density because the composite layer is composed of ferroelectric materials. The approach introduced here effectively enhances the surface charge density and thus output performance of TENGs.

Nanocomposite Materials for Eco-Friendly Tribo- and Piezoelectric Nanogenerators Bernd Wicklein[1,2] and Il-Kwon Oh[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Materials Science Institute of Madrid, Spain

Circularity and sustainability of energy devices are gaining importance in the face of growing global energy demand, which enlarges the electronics waste as well as increases the scarcity of critical energy materials. Triboelectric nanogenerators (TENG), which have a great potential in providing renewable energy, often lack sustainability themselves as the constituting materials are mostly petrol-based, fluorinated polymers and metals.[1,2] Therefore, revalorized biomass like lignocellulosics and agri-food residues are increasingly considered as triboactive components.[3] Similar concerns surround piezoelectric nanogenerators (PENG), where lead-free inorganic materials and natural polymers are sought as new sustainable components of PENGs.[4]
Here, we present preliminary results of eco-friendly nanogenerators based on different bionanocomposites. Biopolymers like cellulose, keratin, lignin, chitosan and alginate are investigated both as coating and matrix with different fillers such as nanocarbons and barium titanate (BTO) particles in order to tune the triboelectric and piezoelectric properties. In addition, the role of porosity is a further parameter under investigation both for the electrical output and complementary properties. Herein, carbon fiber assemblies and brushes are also explored as substrates for the construction of 3-dimensional triboactive elements. Finally, contact-separation and single-electrode nanogenerators are constructed and tested for different insulation and harvesting applications.

Lignin-Based Bio-Triboelectric Films for Self-Powered Wearable Devices Robert Ccorahua[1,1], Yi Zheng[2] and Wenzhuo Wu[1,1,1]; [1]Purdue University, United States; [2]Kansas State University, United States

Lignin is a complex biopolymer that keeps the structural integrity of plants and represents ~ 40% (wt.%) of the plant biomass. It is also the second largest biopolymer on earth after cellulose. This naturally abundant material is a potentially renewable resource that is now part of transforming forest and agricultural feedstock towards a more sustainable resource management. However, a dominant aromatic structure hinders lignin's processability using non-organic solvents. Herein, we manufactured lignin films through blade-coating by implementing a new water-based environmentally friendly processing method without using organic or corrosive solvents. Lignin-based films were prepared by various blade-coating manufacturing parameters and the triboelectric performance was evaluated. The films manufactured by the optimal parameters were compared to pure biopolymer films, showing outstanding properties as a triboelectric material. Moreover, we assessed the performance of the films as self-powered wearable devices in human-machine interface applications. Our environmental-friendly processing method is expected to promote the broader application of lignin for wearable devices and other emerging technologies.

Humidity-Tolerant Moisture-Driven Energy Generator with Bi-Layer Aerogel/Hydrogel Asymmetrical Structure Kaiying Zhao, HoYeon Kim and Cheolmin Park; Yonsei Univeristy, Korea (the Republic of)

Free-standing and film-type moisture-driven energy generators (MEGs) that harness the preferential interaction of ionized moisture with hydrophilic materials are interesting owing to their wearability and portability without needing for a water container. However, most such MEGs work in limited humidity conditions where moisture is rapidly evaporated from the devices with a moisture gradient. Herein, we present a high-performance MEG with excellent humidity tolerance and sustainable power-production capability. The bilayer-based device comprises a negatively surface-charged, hydrophilic MXene ($Ti_3C_2T_x$) aerogel and polyacrylamide (PAM) ionic hydrogel. The preferential selection on the surface of the porous MXene aerogel of positive charges supplied from the salts, and water in the hydrogel is predicted by the first principle simulation, resulting in a high electric output in a wide relative humidity range: from 20% to 95%. Our MXene aerogel MEG produces a maximum open-circuit voltage, short-circuit current density, and power density of approximately 570 mV, 1160 μA cm^{-2}, and 24.8 μW cm^{-2}, respectively. Furthermore, by replacing the hydrogel with an organohydrogel of PAM that has excellent water retention and structural stability, a device with long-term electricity generation is realized, which has an output voltage lasting for more than 15 days in a broad temperature range (from –20 to 80 °C). Our MXene aerogel MEGs connected in series supply sufficient power for commercial electronic components in various outdoor environments. Moreover, a MXene aerogel MEG is mounted on the skin for recognizing finger bending and facial expression in the variation of its output current.

5:00 PM EL08.12.02
Effect of Various Ionic Liquids on the Performance of Triboelectric Nanogenerators Sujeong Gwak, Hyeonseo Joo and Ju-Hyuck Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

In recent years, renewable and clean energy are attracting attention due to the increase in environmental problems caused by using limited traditional resources. Such renewable energy has excellent energy potential, but it also has a large amount of wasted energy, requiring developed technology to harvest energy sources effectively. Nanogenerators can be suitable, and different types of nanogenerators have been developed recently. A triboelectric nanogenerator (TENG) is one type of nanogenerator that makes electricity by converting mechanical energy into electrical energy. It is based on contact electrification and electrostatic induction effect by selecting two different suitable triboelectric materials and contacting each other.
All materials around us can have triboelectric properties; generally, they can represent them in the triboelectric series. When two materials with a significant difference in charge affinity on the triboelectric series are separated after contact with an external force, it shows a high output performance. From the material perspective, one of the most widely studied dielectric materials, the copolymer of (polyvinylidene fluoride) (PVDF) such as poly (vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP), has high dielectric constant and highly electronegative fluorine C-F bond which cause enormous charge accepting properties and. However, there is a limit to associating with only traditional triboelectric materials to improve the TENG output.
To advance the polymer charge accepting properties for increasing the lack of energy conversion efficiency, several materials were blended with polymer, but still, it has environmental and non-flexibility issues to use as an electrolyte. Therefore, ionic liquid (IL) has been reported for available materials with polymer electrolytes to cover up the disadvantages recently. It can enhance the TENG output of their high capacitance and mobility of ions in the polymer electrolyte layer. The specific capacitance of material can be defined as a dielectric constant which can significantly increase the charge density accumulation of materials surface while each material is physically contacted. Also, an electric double layer (EDL) is formed by the charge accumulation of mobile cations and anions when external forces are applied. It is also used as a plasticizer, making the polymer electrolyte flexible and boosting ionic conductivity by weakening the polymer chains to increase the mobility of ions. For this, varying each cation and anion type may affect the polymer electrolyte properties for enhancing the TENG output performance. Still, the effect of various types of IL in polymer electrolyte studies on improving TENG output performances is lacking; investigation of multiple varieties of IL on triboelectric properties is needed.

5:00 PM EL08.12.06
Distributive Role of Frictional-Heat on Sliding Contact Electrification—*In Operando* Measurement of Surface Charge and Temperature Variation Dong woo Lee, Daesol Kong, Young Joon Ko and Jong Hoon Jung; Inha University, Korea (the Republic of)

In-Operando technology can contribute to understanding the fundamental mechanisms and the mechanism of triboelectric charging through measurement of the relevant physical quantities during physical contact of two materials, which has not yet been clearly elucidated. For this goal, the correlation between frictional heat and triboelectric charge in metal-polymer triboelectric nanogenerators is reported by *in-operando* temperature measurements. Fluorine-doped tin oxide (FTO) metal slides under different contact pressures between polydimethylsiloxane (PDMS) polymers according to different degrees of cross-linking made by mixing ratios. Both triboelectric charge and temperature change increase and saturate with different time constants. Specifically, saturated triboelectric charge and temperature increase as contact pressure increases. In contrast, the saturated triboelectric charge increases, and the saturation temperature decreases with the mixing ratio increasing. X-ray photoelectron spectroscopy and thermogravimetry measurement showed that the chemical bonds rupture event during the triboelectrification and charged materials transferred from PDMS to FTO according to the mixing ratio and sliding time dependent triboelectric charge. This shows that frictional heat is distributed to bond failure and temperature change through the activation energy and friction coefficient of PDMS. Measurements of *in-operando* temperature changes provide important information on the specific coupling of triboelectric charging and detailed charge transfer processes during physical contact.

5:00 PM EL08.12.07
Stretchable and Transparent Plasticized PVC-Gel-Based Triboelectric Nanogenerators for Energy Harvesting Seung-Ju Oh[1], Insun Woo[1], Dong-Heon Han[1], Jae Uk Yoon[1], Hyun-su Park[1], Jin Woo Bae[1], Eun-Ho Sohn[2,3] and Jaewon Choi[4]; [1]Korea University of Technology and Education, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of); [3]University of Science and Technology, Korea (the Republic of); [4]Jeongseok Chemical R&D Center, Korea (the Republic of)

Stretchable and Transparent triboelectric nanogenerators (STTENGs) for wearable electronics are in significant demand in the area of self-powered energy harvesting and storage devices. Here, a single-layer STTENG based on the plasticized polyvinyl chloride (PVC)-gel is proposed for mechanical energy harvesting. In particular, the plasticized PVC-gel plays a crucial role in both a dielectric and a conducting layer in the STTENG. The STTENG demonstrates high stretchability (~250%), high transparency (~91%), and great dielectric property (190 times than intrinsic PVC). Moreover, the plasticized PVC-gel-based STTENG shows more negative triboelectric property rather than the unplasticized PVC-based triboelectric nanogenerator. The output performance of the STTENG reaches 24.7 V and 0.83 µA, which is 20 times much higher output performance compared to the unplasticized PVC-based triboelectric nanogenerator. In addition, the STTENG at 80% stretched states even shows stable output voltage and current without the performance degradation. Consequently, the STTENG can be potentially expected to be used in stretchable wearable electronics, electronics skins, soft robots, smart displays, etc.

5:00 PM EL08.12.08
Switchable Power Generation in Triboelectric Nanogenerator Enabled by Controlled Electrostatic Discharge Jiaming Zhou, Xiaoting Ma, Jingyi Gao and Dong-Myeong Shin; University of Hong Kong, Hong Kong

As the main energy supply for people's daily life, the energy created by nuclear and coal plays an important role in the history of human development. However, at the same time, they also hinder environmental protection and sustainable development. With the growing awareness of the energy crisis, renewable green energy has been proposed as a promising solution. Among all types of energy, water energy has attracted great interest due to its abundance and recyclability. Humans have developed very well-established methods to harvest large-scale hydropower from waterwheel irrigation in ancient times to the current hydroelectric power generation. For small-scale water such as droplets, triboelectric nanogenerators (TENGs) have emerged as one of the main approaches to convert these ambient mechanical energies into electrical energy. The application of TENGs in droplet energy harvesting has been extensively studied by researchers. However, conventional droplet-based TENGs utilize the periodic sliding of droplets from the friction surface to generate pulsed alternating current (AC), which cannot be directly used as a power source. A rectifier bridge or a power management circuit used to transfer AC into direct current (DC) will greatly reduce the portability of TENGs.
In nature, DC discharge usually occurs during lightning; when the electric charge in the cloud accumulates to a certain strength, it will form a circuit (ie, lightning) by breaking down the air. The lightning tends to require extremely large voltages (several thousand volts), but the required voltage drops dramatically during the breakdown at extremely small distances (only 327V at 7.5 microns). Herein, inspired by the phenomenon of lightning, a droplet-based direct current triboelectric nanogenerator (DDC-TENG) without any rectifier is designed. It utilizes the electrostatic potential generated between the water droplet and the triboelectric layer, and based on the dielectric breakdown mechanism, a small gap is formed between the triboelectric layer and the electrode through photolithography. When the water droplet hits the triboelectric layer, the large voltage generated from the triboelectric layer can break down the air in the gap. Using this mechanism, this sandwich structure single electrode mode DDC-TENG can generate a unidirectional voltage (over 3 V) and unidirectionally transferred charge (maximum 0.63nC) in the periodic motion of droplets. This new design provides a new way to harvest the micromechanical energy of water droplets and directly use them in devices. Moreover, the flexible DDC-TENG produced by using flexible ITO film can be attached to rough and uneven places, which greatly broadens the application area. And due to the increase in the size of the device, the maximum voltage can reach more than 10V, and the maximum current exceeds 160nA.

5:00 PM EL08.12.09
Umbrella-Shaped Wind TENG for Omnidirectional Energy Harvesting WooYoung Jang[1,2], Dokyung Kim[1] and Jaesam Sim[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Chonnam National University, Korea (the Republic of)

Novelty / Progress Claim(s)
In this study, we have developed a 3D(three dimensional) stereoscopic structure-based triboelectric nanogenerator for low speed and omnidirectional wind harvesting. This harvester consists of three stereoscopic structures each independently suspended on a pole by a thread that one stereoscopic structure of polytetrafluoroethylene (PTFE) material is located between two stereoscopic structures using aluminum (Al) material. The thread allows the stereoscopic structures to move freely, resulting to induce high kinetic energy even at low wind speeds. The stereoscopic structure design makes it to harvest electrical energy in all wind directions when wind is applied. The developed harvester exhibited output voltage and current of 2.584 mV and 0.169 µA at low wind speed of 0.5 m/s, and it was confirmed that the output power was increased as the wind speed was strong from 0.5 m/s to 4.0 m/s.
Background / State of the Art
Wind-driven triboelectric nanogenerator (WTENG) is a renewable energy source. WTENG is largely divided into two categories classified as low and high wind speed. It is easy to harvest energy in a high-speed environment, but there are limitations to the application because the universal wind speed on the surface is range from 2.5 to 4.0 m/s [1]. In addition, since the wind is not flow in one direction, harvesting the energy at low wind speed in all directions is necessary for actual environments to [2].
Description of the New Method or System
The three stereoscopic structures are arranged vertically in overlapping. This design induces to amplify kinetic energy through a chain reaction when the stereoscopic structures move by the wind. Unlike flapping-based WTENG harvesting energy in most unidirectional and bi-directional directions, our WTENG using thread stereoscopic structure allows energy harvesting in all directions of 360 degrees. When the Al stereoscopic structure at the top moves to the middle stereoscopic structure of PTFE contacts by applied wind, the electron flows from the Al stereoscopic structure at the top to the Al stereoscopic structure at the bottom. After that, the top stereoscopic structure and middle stereoscopic structure are separated, and then the middle stereoscopic structure of PTFE contacts on the Al stereoscopic structure at the bottom sequentially. This motion allows that the electron moves in reverse direction to harvest energy.
Experimental Results
The generated kinetic energy according to the number of moving stereoscopic structures. First case is that only middle stereoscopic structure of PTFE

moves whereas two stereoscopic structures of Al material are fixed. Second case is the reverse condition of the first case, and in third case, all stereoscopic structures move freely. In three cases, output voltages are 4.368 V, 8.8 V and 12.626 V, respectively. The output voltage in case of all stereoscopic structures moving is 2.89 times higher than that of first case. This is because the larger the number of stereoscopic structures, the larger the area of received the wind, and the kinetic energy is amplified as those stereoscopic structures sequentially collide. It can be seen that electrical energy was successfully harvested at the wind speed from 0.5 m/s to 4.0 m/s. As a result of impedance matching, the output power and voltage have maximum at an external load of 60 MΩ. It is confirmed that the open circuit voltage and short circuit current are 25.66 V and 0.726 µA. As a result, the developed device was confirmed to be capable of harvesting wind energy range from 0.5 to 4.0 m/s in omnidirectional wind.

2D MXene Embedded Sulfur-Rich-Polymer for High-Performance Triboelectric Negative Material Woongbi Cho[1], Hyeonhoo Lee[1], Sungsu Kim[2], Minbaek Lee[2], Tae Hee Han[1] and Jeong Jae Wie[1]; [1]Hanyang University, Korea (the Republic of); [2]Inha University, Korea (the Republic of)

Recently, we reported an inverse-vulcanized sulfur-rich polymer (SRP) as a new framework in a series of tribo-negative materials via direct F_2 gas treatment on surface and phase-separation of poly(pentafluoro styrene) (PPFS), in order to achieve high-performance and waste-based triboelectric nano-generator (TENG). However, utilization of fluorine materials can cause environmental pollution. In addition, further enhancement of power density is required from previous systems to stably operate devices or sensors with high durability. Herein, an emerging 2D-material, MXene ($Ti_3C_2T_x$) was introduced to SPR due to its plentiful negatively charged terminal groups (-F, -OH, -O, -Cl). We construct vertical contact separation mode TENG by assembling the SPR/MXene composites with a minute amount of MXene and aluminum as a counterpart. In case of a 4-inch wafer sized TENG, the power density of SRP/MXene composites-based TENG reached 3.89 W m^{-2} after corona discharging to the TENG. We believe that our inverse-vulcanized SRP/MXene composites can contribute to constructing waste-based and self-rechargeable devices driven by power generations of the TENG.

Triboelectric Generation in Harsh Environments—Temperature and Pressure Dependence Under Methane and Crude Oil Catia Rodrigues, Andre Pereira and Joao Ventura; University of Porto - Faculty of Sciences, Portugal

There is an increasingly need to monitor crucial safety and environmental parameters in extraction wells in order to prevent disasters. However, present solutions to feed sensors are inefficient, costly and risky. Furthermore, present energy harvesting technologies do not cope well with the extreme conditions encountered in oil and gas wells that operate at high temperatures, high pressures and involve a highly corrosive environment. The demonstration of new energy harvesting technologies able to operate in these extreme conditions would make a leap forward in their applicability. Triboelectric nanogenerators appearing just in 2012 are the most promising energy harvesting technology able to convert ambient mechanical energy into usefull electrical power [1-3]. Here, we demonstrated a triboelectric nanogenerator (TENG) able to generate electrical energy in harsh conditions similar to those found in extraction wells (pressures up to 830 bar and temperatures up to 120 C) in direct contact with methane and crude oil [4]. The electrical performance of the assembled device shows a slight increase with increasing pressure from 28 to 119 bar, in methane. However, the electrical outputs decreased strongly with increasing temperature from 25 up to 80 C. This clearly demonstrates that temperature is the most critical parameter for TENGs operating in harsh environments. Furthermore, energy harvesting experiments performed in crude oil reveal a decrease of the electric outputs with increasing crude temperature and pressure, but the assembled device continued to generate electrical energy up to pressures of 830 bar and temperatures of 120 C. This study clearly demonstrates the suitability of triboelectric devices to harvest energy in harsh environments opening a wide new range of possible applications.

5:00 PM EL08.12.12

Self-Poled Flexible Piezoelectric Devices Kim Hwanmin[1], Do Hyeon Woo[1,2], Hyoung-Su Han[1], Chang Won Ahn[1], Jong Hoon Jung[3], Tae Heon Kim[1] and Ill Won Kim[1]; [1]University of Ulsan, Korea (the Republic of); [2]Quintess Co., Ltd., Korea (the Republic of); [3]Inha University, Korea (the Republic of)

Flexible piezoelectric thin films have been widely studied recently as biomedical devices, MEMS, nano devices, body wearables, and energy harvesters. The flexible piezoelectric element is manufactured through an etching and transport process. There is a risk of damage and deterioration of properties in the process. Therefore, to avoid damage and deterioration of the piezoelectric film during the etching, transport, and poling processes, a simple fabrication process for an excellent flexible piezoelectric device is highly desirable [1]. In this study, $Pb(Zr_{0.52,}Ti_{0.48})O_3$ (PZT) thin films were directly grown on flexible metal foil substrates to fabricate flexible piezoelectric thin film devices without etching and transfer processes, and the ferroelectric and piezoelectric properties were investigated. The fabricated flexible PZT (1mm)/$LaNiO_3$/Metal foil heterostructure piezoelectric device shows a piezoelectric coefficient (d_{33}) of 89 ± 11 pC/N without the poling process, which means as-grown PZT film has a specific polarization alignment without the poling process. The self-polarization phenomenon in the film occurs from the metal foil substrate because the thermal expansion coefficient (α) if metal foil is relatively larger than the PZT film ($\alpha_{\text{metal foil}} \sim 18 \times 10^{-6}\ K^{-1}$, $\alpha_{PZT} \sim 8.5 \times 10^{-6}\ K^{-1}$) [2,3]. Due to different thermal expansion coefficients, the PZT film receives compressive stress (-724 MPa) from the metal foil substrate during the film growth at a high temperature (650°C) and then reduces to room temperature. In the PZT film, a strain gradient occurs because the compressive stress of the lower portion of the PZT film (interface between the substrate and the PZT film) is stronger than that of the upper portion of the PZT film (the surface of the PZT film). The strain gradient in the PZT/LNO/metal foil film causes the PZT film to have a specific polarization value due to the flexoelectric effect without polarization treatment. In addition, using an energy harvesting tester, the utilization of PZT/LNO/metal foil film as a flexible piezoelectric device was investigated. Therefore, it is expected that the flexible piezoelectric thin film of PZT (1mm)/$LaNiO_3$/Metal foil can be easily used as a piezoelectric sensor and energy harvesting device without transport, etching, and poling processes.

5:00 PM EL08.12.13
The Application of Polyvinylidene Fluoride-Based Piezoelectric Nanogenerator for Harsh Environment Dawoon Jin and Jong Hoon Jung; Inha Univercity, Korea (the Republic of)

Energy harvesting system has become one of the most critical issues for sustainable development. Among various energy resources, mechanical energy is abundant and ubiquitous. Many studies have demonstrated that the piezoelectric nanogenerator (PENG) effectively converts tiny mechanical vibrations to electricity. However, their performances are rarely investigated under harsh environmental conditions. So, their performances should be investigated under harsh environmental conditions to harvest energy at various conditions
In this study, a multilayered polyvinylidene fluoride (PVDF) film-based piezoelectric nanogenerator (ML-PENG) is demonstrated to generate stable power outputs at cryogenic temperatures and low pressures, even under UV irradiation. ML-PENG generates an open-circuit voltage of 1 V and a short-circuit current of 8 nA at -266 °C and 10^{-5} Torr. The output power is enough to operate several light-emitting diodes by harvesting biomechanical energy under simulated Martian conditions, such as -50 °C, CO_2-rich, and UV-irradiated environments.

5:00 PM EL08.12.14
Energy Harvesting of Two-Phase Gas/Liquid Flows Using Piezoelectric Materials Joao Ventura[1], Catia Rodrigues[1], Andre Pereira[1], Joao Magalhaes[2] and Jonas Schmidt[2]; [1]University of Porto - Faculty of Sciences, Portugal; [2]inanoEnergy, Portugal

In today's world, it is becoming increasingly important to use every kind of energy that is available around us due to the major environmental crisis we face. Thus, there is an emerging need to develop new technologies that harvest energy from all renewable sources that surround us. Different nanogenerators using different physics effects have emerged in the last years as solutions to harvest energy from the environment through a clean process [1-3]. In this work, we simulated and developed a piezoelectric membrane assembled inside a Venturi tube to harvest kinetic energy from different fluid flows. The energy generation of our piezoelectric membrane was enhanced through the dimensions optimization of the Venturi tube using finite element method simulations. Thus, the velocity variation inside the Venturi tube was improved by changing the minimum chocking point diameter (in the middle), the length of the tube and angles of the slopes leading to the center. In addition, it was also simulated the influence of obstacles integrated inside the Venturi tube with different shapes (rectangle-, ellipsoidal-, right-angled triangle-, teeth-shaped obstacles) in order to increases the fluid speed and consequently the turbulence. An increase of the fluid speed was achieved, with the highest value obtained when obstacles based on right-angled triangle shape were located in the chocking point of the Venturi tube, i.e. in the smallest diameter. Based on the simulated results, experimental tests using a piezoelectric PVDF (polyvinylidene fluoride) membrane inside a simple tube and enhanced 3D printed Venturi tubes were performed under air, nitrogen (N_2) and carbon dioxide (CO_2). The maximum generated voltage by the piezo-membrane increased from ~ 1.5 V to 3V when implemented inside the Venturi tube under an airflow of ~ 45 L/min. Finally, we demonstrated the possibility of storing the generated electrical power under various flows in air (at room temperature) and gas-liquid $N_{2,}$ and gas-liquid CO_2 (at low temperatures, down to -50 C). This work shows the potential of mechanical energy harvesting technologies to be implement inside refrigeration systems to feed sensors and monitor in real time.

5:00 PM EL08.12.16
On the Curie Temperature Dependence of a Hybrid Thermomagnetic-Triboelectric Nanogenerator Rita Bugalhao, Catia Rodrigues and Joao Ventura; University of Porto - Faculty of Sciences, Portugal

Energy is increasingly one of the major and most important forces on our society, making its generation and harvesting a broadened studied topic. Due to this high demand for the distribution of electrical power, the interest in Energy Harvesting (EH), the concept of converting unused ambient energy from our surrounding environment into electrical energy, is increasing. Amongst the various available external sources, thermal energy is one of the most researched for the purpose of EH, not only because it is the most ubiquitous one, but also for being the form of energy that all the others are eventually turned into. Thermal EH relies on "free heat", so a beneficial alternative of a green energy source would be to capture this lost heat, convert it into electrical energy and use it to re-power devices.

Thus, our study focuses on researching a device that performs such conversion in the low-grade temperature range. Our setup is composed of an NdFeB permanent magnet on top of a hot source and a triboelectric nanogenerator (TENG) directly above a cold source. Between them is a thermomagnetic material (TMM) with a Curie temperature (Tc) near room temperature, where an oscillatory motion is forced through heating and cooling. When heated above T_c, the thermomagnetic material transitions from ferromagnetic to paramagnetic and falls on the TENG, generating an energy peak. Then, the thermomagnetic material is cooled below Tc, leading to a paramagnetic-ferromagnetic phase transition. When that occurs, the thermomagnetic material is once again attracted by the permanent magnet and lifts off the TENG, generating another energy peak. This cycle repeats as long as the TMM's temperature oscillates around Tc.

Here, we present a study on how the Curie temperature (ranging from 32.0 to 43.7 C) of the TMM influences the energy generation, optimum resistance and oscillation frequency of the proposed device, aiming for its optimization and potential assessment. We demonstrate that the operating frequency range of the hybrid thermomagnetic-triboelectric nanogenerator strongly depends on the Tc of the TMM, with optimum hot side temperatures (for which the frequency is maximum) being found between 40 C and 70 C with increasing Tc. The combination of a TMM with Tc = 39.9 C and a zigzag PTFE-Nylon TENG led to the best results, giving an open circuit voltage of 8 V, a short circuit current of 0.36 µA and a motion frequency of 66 mHz.

The Physics of Contact-Electrification and the Theory of TENG Zhong Lin Wang[1,2]; [1]Georgia Institute of Technology, United States; [2]Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, China

Contact electrification (CE) (or usually called "triboelectrification") effect, the most fundamental effect for electricity, has been known for over 2600 years since ancient Greek time, but its scientific mechanism remains unclear. The study of triboelectrification is recently revived due to the invention of the triboelectric nanogenerators (TENGs) by using the coupling of triboelectrification and electrostatic induction effects. In this talk, we first present the physics mechanism of triboelectrification for general materials. Our model is extended to liquid-solid contact electrification, reviving the classical understanding about the formation of electric double layers. Secondly, the fundamental theory of the TENGs is explored based on a group of reformulated Maxwell equations. In the Maxwell's displacement current proposed in 1861, the term $e\P\boldsymbol{E}/\P t$ gives the birth of electromagnetic wave, which is the foundation of wireless communication, radar and later the information technology. Our study indicates that, owing to the presence of surface polarization charges present on the surfaces of the dielectric media in TENG, an additional term $\P\boldsymbol{P}_s/\P t$ that is due to non-electric field induced polarization should be added in the Maxwell's displacement current, which is the output electric current of the TENG. Therefore, our TENGs are the applications of Maxwell's displacement current in energy and sensors.

Strategies to Improve Efficiency and Durability of Triboelectric Nanogenerator Chenguo Hu; Chongqing University, China

Triboelectric nanogenerator is one of the most important technologies to solve distributed energy supply of wireless sensor networks where the wired electricity is not available. However, its low output efficiency and interface abrasion hinder its practical application. The main factors affecting the output charge density of TENG are poor interface contact, air breakdown effect and insufficient charge generation capacity. Mechanical wear and thermal loss of the interface are another challenge for the TENG, which limits its durability and practical application. In this paper, I will introduce the strategies adopted by our research group to improve the output performance of the TENG and reduce interface abrasion, including charge excitation, material modification and enhancement of contact efficiency, and intermittent contact mode, non-contact mode, static friction mode and liquid lubrication mode. The mechanism of charge transportation and the device design method of obtaining maximized output charge density are presented.

Inkjet-Printing Self-Powered Triboelectric Sensor on Fiber Substrate for Wearable Healthcare and Human-Interactive Applications Chi Zhang, Lei Zhang and Dachao Li; Tianjin University, China

With the development of IoTs, big data, and artificial intelligence, various wearable electronics have been rapidly expanded, such as wearable smart watch/bracelet, biomedical applications, smart sportswear, and virtual reality. However, current wearable electronic devices inevitably require power sources and have to be charged or replaced frequently, which will limit the applications of wearable electronics. Recently, the textile TENG which integrates self-powered triboelectric sensors with daily clothes, brings a novel insight into wearable electronics and improves personal intelligence in the era of the IoTs. For example, Meng *et. al* developed a triboelectric textile sensing system for human pulse wave monitoring (***Matter***, 2020, 2, 794-804). Zhou *et. al* developed a machine-learning-assisted stretchable triboelectric strain sensor array for sign-to-speech translation (***Nature Electronics***, 2020, 3, 571–578). In this respect, 1D-shaped fiber TENGs have become a research hotspot due to the advantages of light weight, small size, good air permeability, compatibility with daily clothes, and adaptation to frequent mechanical deformations in daily life. Nevertheless, most current fiber-based TENGs are based on either a mixing or coating method to integrate an elastic fiber matrix with conductive electrodes, which always struggles to achieve the high-precision and customized fabrication of the triboelectric sensors on the small-diameter and large-curvature fiber surface.

In this work, we report an inkjet-printed fiber-based triboelectric strain sensor (IPFTS) for wearable applications. The helical-structure Ag ink was successfully inkjet-printed on the stretchable PU fiber surface with controllable thickness and turn number, and then encapsulated by Eco-Flex elastomer. The printable fiber diameter is as low as 500 μm with a large curvature of 4000 m^{-1}. Benefiting from the structural advantages, the SPFTS presents a large strain range (0-250%), excellent linear sensitivity (0.47), fast response (70 ms), and great mechanical stability (no decay was observed during the 40-minutes reciprocating 100% stretching-releasing process). Several system-level wearable health monitoring and human-interactive applications are demonstrated through our IPFTS, including heartbeat signal detection for arrhythmia screening, respiration signal detection for assessing sleep status, motion monitoring, and sign language gesture recognition. Benefiting from these features, the IPFTS shows huge application potential in wearable electronics, human-machine interfaces, and artificial intelligence.

10:15 PM EL08.13.04
Hybrid Smart Fiber with Spontaneous Self-Charging for Wearable Electronic Applications Yuljae Cho; Shanghai Jiao Tong University, China

Wearable electronics have been commercialized in recent years as exemplified by smart watches and smart glasses which provide great convenience for our daily lives with advanced functions. Attributed to recent development in long-life batteries, these devices can be frequently re-charged through an external power supply with long life expectancy. The dependence on the external energy source, however, has limited implementation of the wearable electronics for advanced applications where standalone wearables are highly required, such as wearable bio-medical devices.

In spite of its importance, a self-charging capability in wearable devices has been its early stage of development at present. It has been a challenging issue to directly add advanced functions to wearable devices built on bulk textile platform due to lack of controllability in the bulk form. In contrast, for wearables, a bottom-up approach starting from the building block fiber/yarn allows to engineer and functionalize each layer and component with high controllability. Therefore, building wearables from fibers/yarns provides a viable solution to introduce advanced functionality, particularly, the self-charging capability for advanced wearable electronics. However, another challenge arises due to an one-dimensional (1D) nature of the fiber which makes it incompatible with conventional layer preparation methods on two-dimensional (2D) forms, such as the bulk textile. Therefore, the key to further advance wearable electronics is on (1) direct control of the building block fiber/yarn, and (2) development of the scalable method applicable to the 1D platform.

In light of this, we have demonstrated a template-free scalable method which enables to control key device parameters at the building block fiber scale. Our bottom-up approach using high plasma energy demonstrated an effective direct control of building block fibers, leading to an enhanced spontaneous self-charging capability. Successful implementation of the spontaneous self-charging at the building block fiber scale proves that our new method developed is a promising route to tackle the current bottlenecks that the wearable electronics confront and through this advance the future self-powered wearable electronics.

Enhancing the Output Performance of Triboelectric Nanogenerators Through Rationally Utilizing the Temperature Change and Electric Field Change Juan Wen, Bolang Chen, Changxin Qi, Ruichao Zhang, Li Ang Zhang, Longfei Wang and Yong Qin; Lanzhou University, China

Triboelectric nanogenerator (TENG) has wide applications in implantable biomonitoring, man-machine interaction, internet of things and smart city, et al. Continuously enhancing its output performance is the main challenge in the development of TENG. In this present, firstly, we will talk how to utilize the high temperature originally harmful to the performance of TENG to increase the output performance by rational design [1]. Then, the inhomogeneous triboelectric charge distribution and its cancellation effect on driving the free electrons flowing in the external circuit is pointed out to result in the low output of the flutter-driven triboelectric nanogenerators, and the method of electrode segmentation and integration is developed to enhance the output performance [2]. After that, the electric field distribution inside and outside TENG is detailly analyzed, and the outside electric field change is utilized to enhance the output current density [3], and simultaneously enhance the output current and output voltage [4].

Self-Powered Human-Machine Interacting Sensors Yanchao Mao; Zhengzhou University, China

Human-machine interface (HMI) sensor is a technology to transfer and exchange information between human and machine, which has aroused lots of attention recently. We developed a series of self-powered HMI sensors on the basis of triboelectric nanogenerator (TENG). An intelligent wireless respiratory monitoring and alert system was developed by using a TENG based self-powered HMI sensor to real-time alert apnea remotely by using a cell phone to send a warning massage. By utilizing the charges naturally carried on the human body and a TENG, a self-powered touch-free HMI screen sensor is developed for recognizing diverse gestures in a noncontact operating mode. A thermoregulating and self-powered E-skin based on liquid metal as a phase change material is developed. And this TENG based self-powered E-skin can dynamically thermoregulate according to the surrounding temperature through a phase change. A liquid metal electrode that we call a kirigami-structured LM paper (KLP) is developed. Upon integration with a TENG principle, the KLP can also operate as a self-powered E-skin to call a cellphone on the human skin. An intelligent noncontact gesture-recognition HMI system is presented through the integration of a triboelectric self-powered touchless sensor and deep learning technology. This self-powered HMI system is further applied to control a robot for collecting throat swabs in a noncontact mode.

Optimization of a Two-Stage Power Management Circuit for Triboelectric Nanogenerators Philippe Basset[1] and Dimitri Galayko[2]; [1]Univ Gustave Eiffel, France; [2]Sorbonne Université, France

Optimization of a two-stage power management circuit for triboelectric nanogenerators

Triboelectric nanogenerators generate high AC voltages that are often rectified using stable charge-pumps such as half-wave and full-wave diode bridges. For better understanding and to provide guidelines for designing a practical system using a TENG to power a sensor, we have developed a comprehensive general theory that determines the optimal electrical bias conditions for this class of rectifiers. Generic formulas have been derived for any stable charge-pump to determine key figures, such as the optimal bias voltage of the TENG, the maximum energy that can be converted, or the number of mechanical cycles to reach this maximum [1].

Through theoretical analysis of the QV-cycles of a given TENG combined with its rectifier, the missing constants of the generic formulas can be obtained. We have applied this approach to full-wave and half-wave diode bridges and their key figures have been calculated and validated experimentally. It is confirmed that half-wave rectifiers always have a higher saturated voltage, as well as a higher maximum energy per cycle, but at the cost of a longer start-up time. On the contrary, full-wave rectifiers perform better only when the output voltage is much lower than the internal triboelectric voltage of the TENG [2].

In order to provide an output voltage of a few volts suitable for most applications, these rectifiers can be followed by a DC-DC buck converter, in a so-called two-stage configuration [3]. Based on the developed theory, we have shown that the optimal activation of the buck switch is between 0.5 and 0.7 of the saturation voltage of the charge-pump, depending on the hysteresis of the switch, and that the charging time of the output capacitor is at least twice as fast with a half-wave rectifier than with a full-wave rectifier. The theoretical results were confirmed by simulations and experiments using a plasma switch.

9:00 AM EL08.14.03
Enhancing the Current Density of a Piezoelectric Nanogenerator Using a Three-Dimensional Intercalation Electrode Long Gu; Xidian University, China

The low output current density of piezoelectric nanogenerators (PENGs) severely restricts their application for ambient mechanical energy harvest. This has been a key challenge in the development of PENG. Here, to conquer this, based on a piezoelectric material with a high piezoelectric coefficient (Sm-PMN-PT), a new design of PENG with a three-dimensional intercalation electrode (IENG) is proposed. By creating many boundary interfaces inside the piezoelectric material, the total amount of surface polarization charges increased, which contributes to an increased current density. The IENG can output a maximum peak short circuit current of 320 μA, and the corresponding current density of 290 μA/cm^2 is 1.93 and 1.61 times the record values of PENG and triboelectric nanogenerator (TENG), respectively. It can also charge a 1 μF capacitor from 0 V to 8 V in 21 cycles, and the equivalent surface charge density of 1690 μC/m2 is 1.35 times the record value of TENG.

9:15 AM EL08.14.04
Towards Smart Tactile Sensing by Cascade Connecting Piezoelectric Film and Field Effect Transistors Jinbo Pang[1], Chongyang Hou[1] and Hong Liu[1,2]; [1]University of Jinan, China; [2]Shandong University, China

The electronic skin based tactile sensors [1] has become an important platform to host multiple sensors for wearable electronics in the Internet of Thing era [2, 3]. The piezoelectric pressure sensor [4, 5] has featured advantages of high sensitivity, i.e., large output voltage from subtle deformation and small strain. However, the large output voltage may suppress its applications due to the requirement of high-voltage meters. Therefore, the transduction of voltage to current provides an efficient solution. The field-effect transistors have shown great charge carrier mobility and current on/off ratio based on graphene [6-8] and other 2D materials [9-11]. Here, we employ the field-effect transistor based on metal dichalcogenides to convert the piezoelectric voltage of pressure sensor to the drain current by connecting the sensor electrode to gate electrode. We have achieved the linear response versus the weight load ranging from

2 g to 60 g. The pressure gauge has shown great potentials for applications in wearable healthcare electronics.

Keywords: Tactile sensors, piezoelectric voltage, PVDF, TMDCs, field-effect transistors, gate voltage regulation, transconductance

Probing the Local Piezoelectric Response of Semiconducting ZnO Nanowires by Piezoresponse Force Microscopy and Finite Element Modeling
Gustavo Ardila and Thomas Jalabert; Grenoble Alpes University, France

Zinc oxide (ZnO) nanowires (NWs) are excellent candidates for the fabrication of piezoelectric transducers such as energy harvesters, mechanical sensors and piezotronic devices thanks to its low-cost and environment friendly fabrication process. However, most of theoretical works considering semiconducting properties in ZnO could not account for its high piezoelectric response [1] since the electric potential decreases because of free electron screening [2]. A Surface Fermi Level Pinning (SFLP) mechanism has recently been proposed as an intrinsic property of ZnO NWs to solve this contradiction [3]. Nevertheless important electric parameters for the energy conversion efficiency such as the piezoelectric coefficient (e.g. d33) and the open circuit potential (Voc) have not yet been investigated using models coupling semiconducting and piezoelectric properties.

We used a new strategy improving piezoresponse force microscopy (PFM) measurements to map the piezoresponse amplitude on the top surface of vertically aligned ZnO NWs. Consistently with previous models [3], the piezoresponse amplitude is larger than on ZnO thin films. We observed that the piezoresponse is larger on NWs with small diameters and when the tip is on the edge of the NWs. We interpret our results by a modification of the depletion region inside the NW due to the influence of geometry on the free carriers' distribution. We performed a Finite Element Method simulation to quantitatively support our experimental results. This is the first model including the mechanical, piezoelectric and semiconducting properties of the material in the PFM configuration. We also used this model to investigate the piezoelectric response of Vertically Integrated NanoGenerators (VINGs). We found a saturation of the piezoresponse with the increase of the NW length in VINGs made of thin NW depleted up to their core. This saturation was due to the incapacity of surface traps to maintain depletion along the whole NW beyond a critical height as a result of the electric potential shift induced by piezoelectric polarization. The critical height is strongly dependent on the surface trap density and on the crystal orientation and therefore on the type of mechanical load (compression/elongation). Finally, we showed that the influence of surface traps on the piezoelectric response of semiconductor based transducers was strongly dependent on the traps dynamics [4]. This emphasizes the strong influence of the working frequency on the piezoelectric performances of semiconductor based transducers.

Ferroelectric Integrated Self-Powered Photodetector and Optoelectronic Synapse Jianhua Hao[1,2]; [1]The Hong Kong Polytechnic University, Hong Kong; [2]The Hong Kong Polytechnic University Shenzhen Research Institute, China

It is known that a steady-state photovoltaic response can be generated along the ferroelectric polarization direction due to the strong inversion symmetry breaking. Such a unique mechanism endows ferroelectric photovoltaics with exceptional properties. It is noticeable that hybrid perovskite ferroelectrics produce a revival of interest in ferroelectric photovoltaics because of the robust ferroelectricity coexisting with superior semiconducting properties. In our recent work, the in-plane multiaxial ferroelectricity of hybrid perovskite ferroelectric was investigated. Systematic investigations, including electrical-poling-dependent photocurrent and ferroelectric polarization switching, are further carried out to reveal the photovoltaic behavior via a dynamic poling process. Electric-field-induced effects are responsible for the self-powered ability in the ferroelectric integrated photodetectors. On the other hand, the development of optoelectronic synapses can provide an important breakthrough toward creating a sophisticated and adaptable artificial visual system. We demonstrate multifunctional optoelectronic synaptic device based on ferroelectric α-In_2Se_3/GaSe heterojunctions to mimic the entire human visual system at the single device level. The results show that the ferroelectric integrated heterojunction device is capable of performing logic operations and recognizing images. The works are supported by the grants from the National Natural Science Foundation of China (No. 52233014) and Research Grants Council of Hong Kong (PolyU SRFS2122-5S02).

High-Performance Triboelectric Nanogenerator and Tribophotonics Yunlong Zi[1,2,3]; [1]Hong Kong University of Science and Technology (Guangzhou), China; [2]The Hong Kong University of Science and Technology, Hong Kong; [3]Chinese University of Hong Kong, Hong Kong

As the development of the Internet of Things (IoT), trillions of widely-distributed devices are integrated for health monitoring, biomedical sensing, environmental protection, infrastructure monitoring, and security, which require power supplies. To provide a sustainable power solution, triboelectric nanogenerator (TENG) has been developed since 2012 for high-efficiency mechanical energy harvesting from the ambient environment. The PI's team has made significant contributions to fundamental studies about the triboelectric effect, discharge, and TENG output characteristics. and Multiple strategies to greatly enhance the output performance of TENG has been demonstrated, such as the high-pressure environment and the liquid-solid interface. On the other hand, the PI's team also proposed and developed the concept of tribophotonics: tribo-charge induced tuning or generation of photons toward self-powered wireless sensing, which can be achieved through tunable liquid lens, liquid crystal, optical switch, tribo-induced electroluminescence (TIEL), and discharge. These studies will drive the further development of TENG technology for broad applications in blue energy harvesting, the IoT, human-machine interface, health & infrastructure monitoring, wearable & implantable electronics, towards high-efficiency self-powered systems.

9:30 PM EL08.15.04
Bilateral Piezoelectric Charge Modulation——A Perspective of Piezo-Phototronic Effect in Multi-Layer Structured Optoelectronic Devices Wenbo Peng; Xi'an Jiaotong University, China

Piezo-phototronic effect utilizes the strain induced piezoelectric charges inside the piezoelectric semiconductors to modulate the local energy band diagram at the interface of junctions, thus controlling the photo-generated carriers' behaviors and the performance of optoelectronic devices. Since its invention in 2010, piezo-phototronic effect is vastly demonstrated in photodetectors, light-emitting diodes, and solar cells, where only one interface is modulated by piezoelectric charges. In 2018, we first propose to construct multi-layered structure for efficient utilization of piezoelectric charges with both polarities and obtain better performance optimization by piezo-phototronic effect, which we recently name as *Bilateral Piezoelectric Charge Modulation*. Here, we summarize the recent progresses of our researches on bilateral piezoelectric charge modulation, including both experimental results and analytical theories. An n-ZnO/p-Si/n-ZnO double heterojunction bipolar phototransistor is designed, and the regulation of bilateral piezoelectric charges on bipolar phototransistor's performances is studied from the perspectives of theoretical derivation and experimental research simultaneously. A theoretical model of n-ZnO/p-Si/n-ZnO double heterojunction bipolar phototransistor is established, and the influence of four polar combinations of piezoelectric charges induced by different strains formed at the interface of two heterojunctions on the characteristics of phototransistor is carefully studied. The theoretical calculation results show that, when positive piezoelectric charges are generated at both two interfaces, the regulation of strain on the phototransistor is a superposition of two positive effects, which can significantly improve the performances of phototransistor. Then an n-ZnO/p-Si/n-ZnO double heterojunction bipolar phototransistor is experimentally prepared. By rationally designing the device structure, positive piezoelectric charges could be simultaneously generated at the two heterojunction interfaces when an external compressive strain is applied. The saturation current of phototransistor is significantly improved, and the photoresponsivity is also improved to a certain extent by the applied compressive strain. To further optimize the performances, the effects of interdigitated electrode's size, substrate and ZnO layer on the strain regulation of device performance are carefully studied. The experimental results show that when the p-Si substrate is used, the size of interdigitated electrodes is chosen as channel width $W_0 = 80$ μm, the channel length $L = 5$ μm, and the number of electrodes $N = 14$, and the ZnO nanowires layer prepared by low temperature hydrothermal growth method is used as both emitter and collector, the strain induced bilateral piezoelectric charges regulation of the obtained bipolar phototransistor is the best. At a compressive strain of -1.37%, the photoresponsivity is enhanced from 0.96 A/W to 20 A/W with an increase of about 2000%, indicating the significant modulation of applied strain on the performances of heterojunction bipolar phototransistor.

Liquid–Solid Interface-Based Triboelectric Tactile Sensor with Ultrahigh Sensitivity Zhen Wen; Soochow University, China

Traditional triboelectric tactile sensors based on solid–solid interface have illustrated promising application prospects through optimization approach. However, the poor sensitivity and reliability caused by hard contact-electrification still poses challenges for the practical applications. In this work, a liquid–solid interface ferrofluid-based triboelectric tactile sensor (FTTS) with ultrahigh sensitivity is proposed. Relying on the fluidity and magnetism of ferrofluid, the topography of microstructure can be flexibly adjusted by directly employing ferrofluid as triboelectric material and controlling the position of outward magnet. To date, an ultrahigh sensitivity of 21.48 kPa^{-1} for the triboelectric sensors can be achieved due to the high spike microstructure, low Young's modulus of ferrofluid and efficient solid–liquid interface contact-electrification. The detection limit of FTTS of 1.25 Pa with a wide detection range to 390 kPa was also obtained. In addition, the oleophobic property between ferrofluid and poly-tetra-fluoro-ethylene triboelectric layer can greatly reduce the wear and tear, resulting in the great improvement of stability. Finally, a strategy for personalized password lock with high security level has been demonstrated, illustrating a great perspective for practical application in smart home, artificial intelligence, Internet of things, etc.

8:30 AM EL08.16.04
Vortex-Assisted Assembly of Electrode Arrays onto Micro-Nano-Scale Piezoelectric Fibers Tong Li[1,2] and Zhang-Qi Feng[1]; [1]Nanjing University of Science and Technology, China; [2]City University of Hong Kong, Hong Kong

Electrostimulation, simulating endogenous bioelectricity, comes to the fore as a promising bioelectronic medicine in clinical practice and has been approved by the US Food and Drug Administration. Research in this field is largely driven by the use of micropipette electrodes, active transistor arrays and high-density multielectrode arrays. However, the inability to construct these electrode arrays on micro-nano-scale bioscaffold carriers remains a

roadblock toward practical applications. As a result, the existing precise electrostimulation theory and its studies are still primarily at the conceptual level and cannot be applied to biomaterial-based clinical trials.
In this work, we report the fabrication of electrode arrays on piezoelectric fibers by vortex-assisted assembly technique in large scale such that they can function well in vitro, and ex vitro, as well as in vivo. It shows extremely high spatial resolution of ~1.6 ± 0.2 μm, which is at least 5 times higher than reported conventionally. Electrodes assemble around piezoelectric fibers into D periodic banding-like arrays on native collagen fibers, which is conducive to the mechanical interlock with cells, so as to improve cell adhesion that is a key parameter for mechanical forces generated by cell activity. With this foundation, piezoelectric fibers are able to yield, in response to the cell-intrinsic force, a local electric potential favored by electroactive cells that varies in a stepwise gradient along the electrode arrays on piezoelectric fiber. This work offers a scalable solution for the construction of electrode arrays on micro-nano-scale bioscaffold carriers, paving the way for future bioelectronic therapies in clinical trials.

Abstract Presented (ON-DEMAND ONLY) Piezoelectric Materials and Energy Harvesting Devices for Biological Applications Hamideh Khanbareh and Vlad Jarkov; University of Bath, United Kingdom

Aging, disease and injury can cause permanent tissue damage, particularly in the case of organs which have limited healing capabilities, such as the central nervous system (CNS) and cartilage. Electrical stimulation can enhance cell regeneration by altering the cellular response to stimulate repair. This has been shown on conductive materials, powered by batteries. However, once the batteries have exceeded their lifetime, they require surgical replacement, exposing patients to health risks. The challenge for the long-term use of such devices is a reliable source that generates electricity from human-activity-induced thermal and vibrational energy.
Ferroelectric materials possess an inherent polarisation, thus surface charge that varies upon a change in pressure and temperature, through piezoelectricity and pyroelectricity, respectively. Therefore, they can interact with cells through electrical signals to stimulate repair. However, common ferroelectric materials such as lead zirconate titanate (PZT) and polyvinylidene-difluoride (PVDF) contain toxic or non-biodegradable components and are thus not favourable for implantation. In this work we show successful fabrication and characterisation of biocompatible ferroelectric polymer composites in the form of thin membranes and 3D porous scaffolds.
Thin ferroelectric membranes of Polydimethylsiloxane (PDMS)-potassium sodium lithium niobate (KNLN) have been prepared via in-situ poling-dielectrophoresis to obtain high piezoelectric sensitivity while maintaining flexibility [1]. A significant improvement in piezoelectric properties of quasi 1–3 composites is achieved by a combination of dielectrophoretic alignment of the ceramic particles and poling process. The degree of structuring as well as the functional properties of the in-situ structured and poled composites are enhanced significantly compared to those of the conventionally manufactured structured composites [1, 2].
3D porous scaffolds of cellulose, poly (lactic acid) (PLA) and chitosan KNLN have also been produced by freeze-casting technique; using the anisotropic solidification of a suspension to achieve aligned porosity for guiding cell outgrowth. Piezoelectric particles of KNLN of varying weight fractions (10, 20, 30 and 40%) have been integrated and poled using corona technique. The resultant composites show enhanced average pore size and interconnectivity as well as piezoelectricity ideal for soft tissue regeneration applications. This research is the first to report the fabrication and material characterisation of highly porous Cellulose-KNLN and PLA-chitosan-KNLN composites prepared by freeze casting. Morphological characterisation of the obtained microstructures has been performed and linked to the processing parameters and final properties. A poling study has also been performed to achieve piezoelectric properties. The highly interconnected aligned structures with ideal mean pore size have been obtained with PLA and chitosan freeze-cast scaffolds and enhanced with the incorporation of KNLN, up to 20wt% desirable for soft tissue applications.

Magnetic Properties of Quasi-2D Layered van der Waals Crystals Under External Stimuli Srinivasa Rao Singamaneni; The University of Texas at El Paso, United States

The research on (quasi) 2D magnetism propelled rapidly since the first experimental discovery of atomically thin magnets in 2017. Since the magnetic properties of bulk (quasi-2D) crystals serve as a basis for the understanding of magnetic phenomenon in reduced dimensions (true 2D limit), a profound knowledge and understanding of these compounds is evidently needed at quasi-2D level, especially considering that magnetic mono and bilayers of a wide range of 2D magnets have now become accessible. In this talk, I will present and discuss our recent findings1-7 in tuning the magnetic properties of quasi-2D layered van der Waals magnets by photoexcitation, proton irradiation, intercalation, and by the application of pressure. NRC, ACS PRF, NSF, and DOE supported this work.

Direct Growth of Graphene on UVC-LEDs by a Plasma-Enhanced Low Temperature CVD Process Hehe Zhang, Umut Kaya, Johanna Meier, Wolfgang Mertin and Gerd Bacher; Werkstoffe der Elektrotechnik & CENIDE, Germany

Among others, drinking water supply, medical care and air pollution control are major and global challenges of our time. For this, an efficient disinfection, e.g., by using ultraviolet (UV) light is required. It is expected that UV light-emitting diodes (UV-LEDs) based on aluminum-gallium nitride ($Al_xGa_{1-x}N$) heterostructures will replace Hg-containing light sources in the near future as they are considered to be an ecologically and economically attractive alternative. However, the efficiencies of UV-LEDs in the technologically relevant UVC-regime are still limited. One reason is the poor conductivity of the p-$Al_xGa_{1-x}N$ layer that requires the integration of a transparent current spreading layer (TCSL) for LEDs in standard geometry. Due to the poor transparency in the UVC range, ITO as commonly used for visible LEDs is not suitable. The high electrical conductivity and the high transparency over the whole UV-VIS-spectrum make graphene a highly promising candidate for the TCSL [1]. However, up to now, graphene used as TCSL in UVC LEDs is not yet reported.
In this work, we present the successful direct growth of a graphene layer on top of the p-$Al_xGa_{1-x}N$ cladding layer in a UVC-LED. For the growth, we employ a direct current plasma-enhanced (PE)CVD process with a methane / nitrogen mixture at temperatures as low as 670°C, expanding our previous work on GaN [2]. Optimizing gas mixture ratio, growth temperature and growth time, we obtained graphene with Raman intensity ratios $I_D/I_G \approx 2.1$ and $I_{2D}/I_G \approx 1.3$, respectively. The optical transparency of the as-grown graphene layer exceeds 90% over the whole spectral range spanning from 270 nm to 800 nm and we achieved a sheet resistance of around 5 kΩ/sq. Our UVC-LED with graphene as a TCSL shows a diode-like I-V behavior with a current density of approximately 0.1 mA/cm^2 at 4 V and 0.23 mA/cm^2 at 5 V, respectively. The emission maximum of the LED is at a wavelength of 275 nm (5 V). A distinct current spreading effect is observed.

11:15 AM EL09.01.03
Epitaxial Molybdenum Disulfide/Gallium Nitride Junctions—Low-Knee-Voltage Schottky-Diode Behavior at Optimized Interfaces Hae in Yang, Danial Coyle, Michelle Wurch, Prachi Yadav, Michael I. Valentin, Mahesh Neupane, Kortney Almeida and Ludwig Bartels; University of California, Riverside, United States

The existence of bandgaps in transition metal dichalcogenides (TMDs) such as molybdenum disulfide (MoS_2) offers an attractive possibility of using these two-dimensional layered materials in various device applications. Gallium nitride (GaN), initially introduced into semiconductor technology as a wide-band-gap material able to provide blue light-emitting diodes, has found a number of additional applications for power conversion. MoS_2 and GaN are almost lattice matched at a mismatch of only ~0.8%, leading to an interest in the epitaxial relationship. Integration of MoS_2 with wide band gap GaN could provide an avenue toward high-performance devices. The interface for MoS2 on GaN plays an important role in determining the properties of heterojunctions.

Here, we demonstrate the optimization of the MoS_2/GaN interface and MoS_2 growth epitaxially on GaN. We use a high vacuum CVD growth technique. First, we clean the GaN substrate with a broad range of sputter fluence and anneal it with ammonia gas to generate well-defined surface termination. Next, we grow a controlled layer number of MoS_2 by exposing hot metallic molybdenum to H_2S gas at 650 °C. All process was performed without breaking the vacuum. We grow single-layer as well as 4-layer, which are monitored by colorimetric measurements of the reflection of the filaments from the sample, allowing us to end the deposition process at the desired number of integer layers.

We use low-energy electron diffraction (LEED) and DFT simulation to demonstrate epitaxial MoS_2 grown on GaN and interface quality. We observed 22 patterns resulting from a doubling of the periodicity, which attests to a clean and well-ordered termination of the GaN substrate. X-ray photoelectron spectroscopy (XPS) is used to evaluate the cleanliness of GaN and interpret transport measurements. Atomic force microscopy (AFM) was analyzed to characterize surfaces after MoS_2 growth. We fabricate MoS_2-GaN diode to test the impact of different interface preparation on electrical properties. We find a high-performance behavior achieved by optimizing in situ interface preparation: low turn-on voltage (~0.3 V) Schottky-diode behavior, on/off current ratio of ~10^5. This highlights the technological potential of devices and gives us a guideline for interface preparation for further research.

11:30 AM EL09.01.04
Aerosol-Jet Printed, High Performance MoS_2 Nanosheet Photodetectors Enabled by Megasonic Exfoliation Lidia Kuo[1], Vinod K. Sangwan[1], Sonal Rangnekar[1], Ting-Ching Chu[1], David Lam[1], Zhehao Zhu[1], Lee Richter[2], Ruipeng Li[3], Beata Szydlowska[1], Julia R. Downing[1], Benjamin Luijten[1], Lincoln J. Lauhon[1] and Mark C. Hersam[1]; [1]Northwestern University, United States; [2]National Institute of Standards and Technology, United States; [3]Brookhaven National Laboratory, United States

Printing solution-processed inks of 2D materials offers a scalable and cost-effective path towards mechanically flexible optoelectronics. In particular, aerosol jet printing (AJP) is a promising means to achieve all-printed circuits and systems, offering micrometer-scale resolution and broad ink processing capabilities. In this work, I will present aerosol-jet-printed, ultrahigh-responsivity photodetectors that consist of well-aligned, percolating networks of semiconducting MoS_2 nanosheets paired with printed graphene electrodes on flexible polyimide substrates. An MoS_2 ink containing high-aspect-ratio nanosheets with a large fraction of monolayers is obtained by electrochemical exfoliation, followed by megasonic atomization during AJP, which not only aerosolizes the inks but also further exfoliates the nanosheets during printing. The ink is also formulated with terpineol, a high-boiling-point solvent that is critical for achieving aligned nanosheets in uniform morphology. After printing, the devices undergo photonic annealing, which removes insulating residues from the film and yields quasi-ohmic contacts between MoS2 and graphene. The resultant photodetectors have responsivities exceeding 10^3 A W^{-1} in the visible range (515.6 nm), outperforming previously reported all-printed photodetectors by over three orders of magnitude. These photodetectors are also mechanically robust, withstanding over 1,000 bending cycles with negligible changes in device metrics. Overall, this work demonstrates that megasonic exfoliation coupled with modular design of AJP ink formulation not only preserves superlative optoelectronic properties of individual MoS_2 nanosheets, but also offers a scalable additive manufacturing scheme for mechanically flexible optoelectronics.

SESSION EL09.02: Synthesis of 2D Optoelectronic Materials and Their Heterostructures II

Selenides and Hybrid Halide Perovskites for Superconducting, Quantum and Optical Absorber Applications Anupama B. Kaul; University of North Texas, United States

The excitonic and multibody interactions in some semiconducting two-dimensional (2D) crystallites, their strain-dependent properties and pristine atomically flat interfaces, coupled with the ability to solution-process these materials, offer a rich playground to unveil fundamental physical mechanisms for exciting and innovative devices. Amongst these, the transition metal dichalcogenides (TMDCs), such as tungsten diselenide (WSe_2) and niobium diselenide ($NbSe_2$) are finding promise in nanoelectronics, optoelectronics, sensors and quantum photonics. On the other hand, halide perovskites in their 2D form exhibit equally intriguing optoelectronic properties for photo absorbers and solar cells. In this work, we have analysed the light-matter interactions in superconducting $NbSe_2$, semiconducting WSe_2 and 2D perovskites toward sensing devices enabled by quantum phenomena. Solution-processing of some of these 2D materials has provided a pathway to realize a rich plethora of flexible and bendable sensing devices which will also be discussed.

2:15 PM EL09.02.02
Wafer Scale High Responsive Active Matrix Image Sensor Enabled by Nanoparous MoS2 Intregated with IGZO Switching Transistor Anamika Sen, Arindam Bala and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

The image sensors development with in-sensor switching capability is important to realize high performance optoelectronics. In view of this, an active pixel image sensor array based on nanoporous bilayer molybdenum disulfide (MoS_2), two-dimensional (2D) transition metal dichalcogenides (TMDCs) have demonstrated. The presented active pixel image sensor includes one switching transistor with indium–gallium–zinc-oxide (IGZO) as an active channel material and a photo-sensing transistor with nanoporous bilayer MoS_2-channel. The nanoporous structure is fabricated directly on MoS_2, grown on a 4-inch Si/SiO_2 wafer, utilizing block copolymer lithography. The nanoporous structure of the MoS_2 sensing transistor gives rise to generation of subgap states within bandgap, which promotes trap-assisted photogating effect. The nanoporous MoS_2 phototransistors exploit mechanism involving the photogating effect to achieve high responsivity of 5.2 10^4 A/W. Further, nanoporous MoS_2 phototransistors integrated with IGZO switching transistors are assessed with image mapping for blue (405 nm), green (532 nm) and red (638 nm) incident lights using nine sets of 4×4 active-matrix image sensor throughout the 4-inch wafer. Generally, confronted challenge on TMDCs-based active-matrix image sensors is the fabrication of an integrated circuit with elevated performance is resolved by boosting trap assisted photogating mechanism in MoS_2. Marginal deviation in electrical performance parameters of 144 devices presents reliability in non-transfer, nanostructured MoS_2 fabrication technique. Our high-performance active-pixel image sensor matrix delivers the state-of-art in a 2D material based on integrated circuitry and pixel image sensor applications.

2:30 PM EL09.02.04
Growth of 2D Tungsten Disulfide on Sapphire and SiO_2/Si Using Ammonium Paratungstate as a Precursor Yi Ting Chen; National Taiwan University of Science and Technology, Taiwan

2D transition metal dichalcogenides have attracted extensive attention in recent years due to their intriguing features including semiconducting properties, tunable mobility, and flexibility. The potential of these materials for future applications largely relies on the strategies to effectively control the growth parameters for achieving large size and layer tunable material growth. In this work, we have attempted to directly grow WS_2 triangular flakes on sapphire and SiO_2/Si substrates via chemical vapor deposition (CVD) by using ammonium paratungstate as a precursor. Monolayer to few-layer of WS_2 can be effectively grown by controlling growth conditions such as sulfur concentration, argon flow rate, and growth temperature. Then, the as-grown WS_2 is further confirmed by the Raman, photoluminescence (PL), and atomic force microscopy (AFM). In addition, the as-grown WS_2 has been transferred on top of the electrodes on SiO_2/Si to fabricate a field-effect transistor device. The device shows the p-type behavior of WS_2 with a field-effect mobility of 0.00949 cm^2/Vs at room temperature. The result demonstrated herein shows the potential of ammonium paratungstate as an effective alternative precursor in the growth of tungsten based 2D semiconducting materials.

2:45 PM EL09.02.05
Unraveling the Charge Transport Mechanisms in Covalently Interconnected Solution-Processed MoS_2 Electronic Devices Francesca Urban[1,2,3], Stefano Ippolito[4], Wenhao Zheng[5], Onofrio Mazzarisi[6], Cataldo Valentini[1], Adam Kelly[7,2,3], Sai Manoj Gali[8], Mischa Bonn[5], David Beljonne[8], Federico Corberi[9], Jonathan N. Coleman[7,2,3], Hai Wang[5] and Paolo Samorì[1]; [1]Institut de Science et d'Ingénierie Supramoléculaires, France; [2]AMBER, Ireland; [3]Trinity College Dublin, The University of Dublin, Ireland; [4]A.J. Drexel Nanomaterials Institute, United States; [5]Max Planck Institute for Polymer Research, Germany; [6]Max Planck Institute for Mathematics in the Sciences, Germany; [7]Centre for Research on Adaptive Nanostructures and Nanodevices, Ireland; [8]Université de Mons, Belgium; [9]Università degli Studi di Salerno, Italy

Solution-processed semiconducting transition metal dichalcogenides (TMDs) are a hot-topic research trend in printed (opto)-electronics.
Indeed, liquid phase exfoliation is an efficient strategy to convert bulk layered materials into thin nanosheets dispersed in a suitable solvent[1]. The obtained inks can be printed into thin films using several approaches, including ink-jet printing, screen printing, and spray coating[2], thereby promoting the advances of printed electronics where low-cost and large-area fabrication is as relevant as device performance.
However, the device performance is limited by structural defects resulting from the exfoliation process and poor inter-flake electronic connectivity within

the films. The formation of covalent interconnected networks of TMDs potentially represent an efficient strategy to simultaneously heal sulfur vacancies and bridge adjacent flakes, thereby generating percolation pathways for the charge transport, ultimately boosting the electrical performance[3].
Here, we unveil the charge transport mechanisms of printed devices based on covalent MoS_2 networks via multiscale analysis, by comparing the effects of aromatic vs. aliphatic dithiolated linkers. Temperature-dependent electrical measurements reveal hopping as the dominant transport mechanism and a novel analysis based on percolation theory attributes the superior performance of devices functionalized with π-conjugated molecules to the improved inter-flake electronic connectivity and formation of additional percolation paths. Our findings provide valuable guidelines for improving the charge transport properties in MoS_2 devices based on covalent networks.

Two-dimensional van der Waals (2D-vdW) layered hexagonal boron nitride (h-BN) has gained tremendous research interest over recent years due to its unique growth morphology and consequent fascinating properties, and application potentials in nano-optoelectronics. However, the high-quality domain growth of h-BN thin films directly on insulating substrates remains significantly challenging because of high-bonding anisotropicity and complex growth kinetics, thus hindering its usefulness in integrated nano-devices. We report the growth h-BN thin films directly on low-miscut atomically smooth insulating c-Al2O3 substrates by using the pulsed laser deposition (PLD) method, showing remarkable unidirectional triangular-shape domain growth as well as nanosheets-like surface morphology, depending on the growth temperature. Comprehensive chemical, spectroscopic, microscopic, optical, magnetic and tribological characterizations further demonstrates the excellent crystalline quality, numerous functional properties, and application potentials of films [1]. Our observations might pave the way for large-area direct growth of electronic-quality 2D h-BN thin films on insulating substrates for high-performance nano-optoelectronics, and would be beneficial for hetero engineering of 2D-vdW materials with emergent phenomena.

Stacking 2D Chalcogenides with Atomic Layer Deposition Jun Yang, Fabian Krahl, Samik Mukherjee, Sebastian Lehmann and Kornelius Nielsch; Leibniz Institute for solid State and Materials Research, Germany

Chalcogenides, especially transition metal dichalcogenides (TDMC, but also some other chalcogenides like SnS_2 and Sb_2Se_3) can have a layered structure similar to graphene, but instead of being a semimetal they offer a wide variety from semiconducting to conducting materials that are interesting for efficient, fast and flexible (opto-)electronics. Their electronic behavior can be strongly influenced by the thickness of the material (e.g. how many sheets are stacked on top of each other).[1]
With atomic layer deposition (ALD) the layer stacking and individual layer thickness can be precisely controlled in the nm scale and several 2D materials have already been successfully deposited with ALD [2,3]. ALD is scalable and can coat uneven surfaces, which sets ALD apart from many other methods for the synthesis of 2D materials e.g.exfoliation. This makes the prospect of depositing functional thin films of 2D materials with ALD very tantalizing.
We utilize ALD to deposit superlattice stacks of 2D materials with "spacing" materials in between to examine their electrical properties. An example is our fabrication of a superlattice consisting of SnS_2 and Sb_2S_3 with ALD. I'll present our results on the properties of ALD deposited SnS_2/Sb_2S_3 superlattices and future prospects of inorganic-organic hybrid materials with 2D materials using Atomic and Molecular layer deposition (ALD/MLD).

Two-dimensional transition metal dichalcogenides (TMDs) remain a topic of immense interest due to their wide range of promising properties including but not limited to the electrical, optical, and mechanical kinds. Specifically, given their low operational switching costs, they find many niche applications such as in neuromorphic computing and low subthreshold swing Field Effect Transistors (FETs). Challenges, however, lie in the process of crystal growth— and more specifically—channel/contact engineering for various device applications. To date, two major methods to engineer metal-TMD contacts have been proposed. 'Top contacts' involve fabricating metal electrodes directly on the surface of TMD flakes, and 'edge contacts' involve transferring TMD flakes onto pre-patterned metal electrodes, possibly followed by a functionalization step to ensure better contacts. In this work, through a holistic approach, we demonstrate kinetics-governed in-situ growth regimes (surface or edge growth from metal) of WSe_2, provide mechanistic understanding of these regimes, and fabricate an in-situ device with flawless source-to-drain channel contacts, demonstrating a 2D semiconductor transistor via a "transfer-free" method within the 450-600 ^{0}C, 2 h-time window for Back End Of Line (BEOL) integration. We leverage directional edge growth to fabricate contacts that exhibit robust thickness-dependent junction tunability. FET measurements reveal a low subthreshold swing of ~140 mV/decade, a mobility of 107 ± 38 $cm^2V^{-1}s^{-1}$, and robust ON/OFF ratios of $\sim 10^6$.

SESSION EL09.03: Synthesis of 2D Optoelectronic Materials and Their Heterostructures III

Photon Upconversion in a 2D Inorganic–Organic Semiconductor Heterostructure Reynolds Dziobek-Garrett[1], Christian J. Imperiale[2], Mark W. Wilson[2] and Thomas Kempa[1]; [1]Johns Hopkins University, United States; [2]University of Toronto, Canada

Van der Waals heterostructures (vdWHs) comprised of stacked 2D crystal monolayers can be used to elicit emergent electronic and photonic phenomena. Moreover, energy transfer processes may be engineered via vdWHs by taking advantage of the atomically-abrupt, Å-scale, and topologically tailorable interfaces within them. Here, we prepare heterostructures comprised of 2D WSe_2 monolayers interfaced with DBP-doped rubrene, an organic semiconductor capable of triplet fusion. We fabricate these films over large areas entirely through vapor deposition methods, thereby demonstrating a pathway toward device-scale heterostructures. Time-resolved and steady-state photoluminescence measurements reveal both quenching of WSe_2 emission by rubrene and emission from the DBP species at 612 nm, for excitation at 730 nm, which is clear evidence of photon upconversion. Through an analysis of the decay dynamics in the heterostructure we conclude that excitation transfer from WSe_2 to the triplet state of rubrene proceeds on sub-nanosecond timescales. The dependence of the upconversion emission on excitation intensity is consistent with a triplet fusion mechanism, and we achieve maximum efficiency (linear regime) of the upconversion emission at threshold intensities as low as 110 mW/cm^2, which is comparable to the solar irradiance. This study highlights the potential for advanced optoelectronic applications employing vdWHs which leverage strongly-bound excitons in monolayer TMDs and organic semiconductors.

8:45 AM EL09.03.02
Hierarchical Structuring of Solution-Processed 2D Semiconductors for Wafer-Scale, Stretchable Electronics Dongjoon Rhee[1,2], Myeongjin Jung[2], Jihyun Kim[2], Okin Song[2], Jason Lynch[1], Boyun Han[2], Deep M. Jariwala[1] and Joohoon Kang[2]; [1]University of Pennsylvania, United States; [2]Sungkyunkwan University, Korea (the Republic of)

Two-dimensional (2D) semiconductors have gained significant attention for next-generation electronics that are light-weight, flexible, and stretchable. Achieving stretchability in 2D semiconductors while suppressing crack formation, however, is still difficult without introducing lithographically etched micropatterns, which significantly reduces active device areas. Furthermore, scalable synthesis of high-quality 2D materials in a cost-effective, high-throughput manner remains challenging. In this talk, I will present a solution-based hierarchical structuring strategy to create stretchable 2D semiconducting films that are continuous over wafer-scale areas. Electrochemically exfoliated MoS_2 nanosheets with large lateral sizes (~1 μm) are first assembled into a uniform film on a pre-strained thermoplastic substrate, followed by strain relief of the substrate to create nanoscale wrinkles. Subsequent strain relief cycles with the presence of soluble polymer films produce hierarchical wrinkles with multi-generational structures. Stretchable MoS_2 films are then realized by curing an elastomer directly on the wrinkled surface and dissolving the thermoplastic. Because the film was continuous over large areas, an array of two-terminal devices could be deterministically fabricated by simply depositing electrodes without alignment procedures. Three-generation hierarchical MoS_2 wrinkles are resistant to cracking up to 100% substrate stretching and achieve drastically enhanced photoresponsivity compared to the flat counterpart over the visible and NIR regimes, while the flat MoS_2 film is beneficial in creating strain sensors because of its strain-dependent electrical response.

9:00 AM EL09.03.03
Quasi-One-Dimensional Molybdenum Disulfide Nanoribbons Ganesh Ghimire[1], Rajesh Ulaganathan[1], Denys Miakota[1], Agnès Tempez[2], Marc Chaigneau[2] and Stela Canulescu[1]; [1]Technical University of Denmark, Denmark; [2]Horiba France SA, France

One-dimensional (1D) materials, such as nanowires, nanotubes, and nanorods, have been studied intensively recently due to their unusual structural characteristics and novel physical properties[1–3]. Similarly, 1D structures of transition metal dichalcogenides (TMDs), such as WS_2 nanorods, have been shown to exhibit striking functionalities compared to their two-dimensional (2D) counterparts, such as enhanced photovoltaic effect in bulk, in the absence of a p-n junction [1]. These findings can lead to many exciting opportunities for their utilization in optoelectronic devices, such as solar cells, photodetectors, laser diodes, and light-emitting diodes.

This paper will discuss a novel approach for synthesizing MoS_2 nanostructures with tunable dimensionality ranging from 2D to 1D. In our process, epitaxial precursors of transition metal oxides, i.e., ultra-thin films of MoO_x ($x<3$) grown by Pulsed Laser Deposition (PLD), serve as precursors [2,3]. We will show that the addition of halides during sulfurization leads to unidirectional growth into quasi-1D MoS_2 nanoribbons. The morphological and atomic resolution imaging studies reveal an anisotropic growth of epitaxial quasi-1D nanoribbons in either 2H or 3H stacking orientation. Tip-enhanced photoluminescence (TEPL) spectroscopy reveals a photoluminescence (PL) emission from the edge of the nanoribbons and no emission from the core of the quasi-1D structures. Moreover, we observe an edge-enhanced secondary harmonic generation (SHG) of the quasi-1D MoS_2 nanoribbons, which will be discussed in detail during the talk. Finally, we will report the first ultrasensitive photodetector based on a single 1D MoS_2 nanoribbon. The highly crystalline quasi-1D ribbon device exhibits a high photocurrent response under illumination and outstanding stability. Photocurrent measurements of single-ribbon photodetector made on SiO_2/Si substrate exhibit a photoresponsivity above 500 AW^{-1} at a wavelength of 532 nm, which exceeds that of graphene, MoS_2, or other nanoribbon-based devices. The experimental results show that single-crystalline quasi-1D MoS2 nanoribbons have immense potential for high-performance photodetector applications.

SESSION EL09.04: Structural Characterization of Layered Optoelectronic Materials
Session Chairs: Thomas Kempa and Sudha Mokkapati
Wednesday Morning, April 12, 2023
Moscone West, Level 3, Room 3009

10:00 AM *EL09.04.01
2D Quantum Materials and Devices at the Atomic Scale Adina Luican-Mayer; University of Ottawa, Canada

In this talk, I will focus on two topics: 1. Scanning tunnelling microscopy and spectroscopy experiments aimed at creating novel moiré structures by twisting 2D layers, including the demonstration of reversible local response of domain wall networks in ferroelectric interfaces of marginally twisted WS_2 bilayers and spectroscopic evidence of flat bands in antiparallel twisted WS_2 bilayers; 2. I will discuss our progress in realizing quantum-confined devices in WS_2 monolayers including demonstration of gate-defined quantum dots, charge detectors and 1D transport.

10:30 AM EL09.04.02
Interferometric 4D-STEM Imaging of Lattice Reconstruction in Transition Metal Dichalcogenide Moiré Bilayers Madeline Van Winkle, Isaac Craig and Kwabena Bediako; University of California, Berkeley, United States

Moiré superlattices, formed by vertically stacking van der Waals layers with a small rotational offset and/or lattice mismatch, are a powerful platform for modulating the physicochemical behavior of two-dimensional solids. Moiré architectures comprised of semiconducting transition metal dichalcogenides (TMDs) are of significant fundamental and technological interest because they exhibit distinctively tunable optoelectronic features, such as inter- and intralayer moiré excitons and trions, as well as relatively robust correlated electronic phases, including Wigner crystal and correlated insulating states. While the electronic band structures of moiré superlattices can be intentionally modified by changing the extent of crystallographic misalignment between constituent layers, intrinsic lattice reconstruction also plays an underlying yet significant role in controlling the emergent behavior in these systems. Reconstruction of the superlattice and the development of intralayer shear strain subsequently lead to reconstruction of the electronic band structure, affecting features such as the depth of the moiré potential, the 'flatness' of low-energy bands, and the real-space localization of charge carriers. Visualizing the structure and strain fields of TMD moiré materials is therefore paramount to understanding and controlling their (opto)electronic behavior. Although scanning probe and electron microscopy techniques have provided a qualitative picture of reconstruction in TMD moiré bilayers, understood in terms of the variation in interlayer stacking energy throughout the superlattice, the physical mechanisms by which reconstruction occurs and the distribution of reconstruction strain have thus far only been simulated. In this talk, I will demonstrate how interferometric four-dimensional scanning transmission electron microscopy can be used to quantitatively map the mechanical deformations through which reconstruction occurs and the corresponding strain distributions in small-angle twisted bilayer MoS_2 and WSe_2/MoS_2 heterobilayers with sub-nanometer resolution. This work sheds light on the distinct effects of twist angle, lattice constant mismatch, extrinsic heterostrain, and symmetry of the superlattice on the reconstruction process in TMD moirés and provides a framework for measuring mechanical deformations and strain in a wide array of moiré materials for direct correlative measurements between structure and emergent (opto)electronic phenomena.

10:45 AM EL09.04.03
Thickness-Dependent Interactions Between Helical Chains of 2D Tellurene Kunyan Zhang[1], Gang Wan[2], Shelly Kelly[3], Wenzhuo Wu[4] and Shengxi Huang[1]; [1]Rice University, United States; [2]Stanford University, United States; [3]Argonne National Laboratory, United States; [4]Purdue University, United States

Tellurene is the two-dimensional (2D) form of tellurium consisting of helical Te chains. The unique crystal structure of tellurene brings about remarkable properties, such as high hole mobility, excellent thermoelectricity, and anisotropic optical nonlinearity. 2D tellurene is predicted to have different phases because of the interaction between helical Te chains. However, it is not clear yet how the bonding of the helical chain changes due to interactions between chains, especially for Te with different thicknesses. In this work, we directly measured the bonding of Te within one helical chain and between different chains using x-ray absorption spectroscopy (XAS). We further demonstrated that the interaction between chains was strengthened when the thickness of tellurene decreased. This dependence on thickness is also consistent with the increased phonon frequency for smaller thicknesses. This work reveals the atomic bonding of 2D tellurene and paves the way for investigating the phase change of nanoscale elemental semiconductors.

SESSION EL09.05: Emerging 2D Optoelectronic Materials—Perovskites, Metal-Oxides, Hybrid HeterostructuresandModelling of 2D Materials and Heterostructures—New Discoveries and Predictions
Session Chair: Sonia Conesa-Boj

1:30 PM EL09.05.01
Light-Induced Halide Segregation in Mixed-Halide Ruddlesden-Popper Quasi-2D Perovskites Kunal Datta[1], Alessandro Caiazzo[1], Michael A. Hope[2], Junyu Li[1], Aditya Mishra[2], Manuel Cordova[2], Zehua Chen[1], Lyndon Emsley[2], Martijn M. Wienk[1] and Rene A. Janssen[1]; [1]Technische Universiteit Eindhoven, Netherlands; [2]Ecole Polytechnique Fédérale de Lausanne, Switzerland

Layered Ruddlesden-Popper perovskite phases have emerged as a promising class of optoelectronic materials due to their high defect tolerance, structural tunability between a variety of lower-dimensional phases, and compositional versatility on account of a growing library of spacer cations. However, the photostability of mixed-halide compositions, relevant for light harvesting as well as emission applications, has not yet been comprehensively explored in such materials compared to in three-dimensional (3D) analogs.

This work characterizes light-induced halide segregation in lower-dimensional Ruddlesden-Popper perovskites.[1] Using *in-situ* time- and temperature-dependent photoluminescence (PL) spectroscopy, the optoelectronic behaviour of such mixed-halide layers is tracked.[2] The observations are compared to compositional and structural data, generated using solid state nuclear magnetic resonance (ssNMR) spectroscopy, density functional theory (DFT), and grazing incidence wide angle X-ray scattering (GIWAXS) tools, and a correspondence between optoelectronic instability upon illumination and structural nature of the layer is established.

Phenethylammonium (PEA)-based Ruddlesden-Popper two-dimensional (2D) mixed-halide perovskite thin films ($n = 1$) are first characterized for their photostability and are found to be largely resilient to halide segregation over prolonged exposure to visible light. ssNMR measurements show that this resilience is likely due to the presence of nanoscale iodide-rich sites that limit ion migration pathways which typically drives halide segregation in 3D perovskites.

Quasi-2D perovskite layers are then developed using a co-solvent engineering approach.[3] By tuning the crystallization rate of different *n*-phases, structurally stratified films with lower-dimensional ($n = 1,2$) phases at the substrate interface and higher-dimensional (3D-like) phases at the air interface can be formed. Here, a quasi-2D phase ($n = 2$) is found to be vulnerable to halide segregation, as also observed in 3D-like phases, showing the commonly observed PL red-shift. However, while entropic remixing of halide ions in dark conditions occurs in 3D-like phases, with a blue-shift of the PL peak, the process is absent in the $n = 2$ phase at room temperature and only occurs at elevated temperatures to restore the mixed-phase. This is due to a higher activation barrier for ion migration in such quasi-2D phases.[4]

These observations show that iodide-bromide phase stability in mixed-halide quasi-2D perovskites is strongly related to the structural phase of the layer (n = 1, 2, 3, …). The prevailing view that lower-dimensional phases are inherently stable to ion migration is challenged by observations that clearly show the vulnerability of the $n = 2$ phase to halide segregation. The structural nature of the perovskite is also found to not only determine the tendency of halides to segregate, but also control the halide remixing behaviour in dark conditions.

1:45 PM EL09.05.05
Crystallization Mechanism of Regular- and Reverse-Graded Quasi-2D Perovskites Alessandro Caiazzo, Kunal Datta, Martijn M. Wienk and Rene A. Janssen; TU Eindhoven, Netherlands

Quasi-2D perovskites have recently attracted great interest because of their structural tunability and enhanced stability compared to 3D perovskites. Quasi-2D films display a higher degree of complexity because multiple structural phases are formed during film crystallization. As a result, it is common to observe multidimensional films with both 2D and 3D phases forming a phase distribution gradient, where lower-dimensional phases locate at the bottom, and 3D at the top of the film. Recently, a few studies have found that it is possible to create a reverse-graded quasi-2D perovskite films, where 2D phases locate at the top and 3D ones at the bottom. Even though the crystallization mechanism of quasi-2D perovskites has been investigated before, no study has analyzed the crystallization differences between regular- and reverse-graded quasi-2D perovskites.

In our work, we have fabricated quasi-2D perovskite films using spacers with increasing alky chain length, going from butylammonium to dodecylammonium. First, we found that alkyl spacer length plays a major role in the phase distribution gradient. Short spacers form a conventional 2D-3D gradient, with 2D phases at the bottom, whereas long spacers reverse the gradient. Interested by this behavior, we analyzed the crystallization mechanism via in-situ absorption measurements and described how film formation changes with increasing alkyl spacer length. With the help of these findings, we designed a new fluorinated spacer and used a multispacer approach to tune quasi-2D perovskite film properties, displaying yet another facet of their degree of tunability.

Spatial Control of Substitutional Dopants in Hexagonal Monolayer WS_2: The Effect of Edge Termination Ana Laura Elias[1], Tianyi Zhang[2], Mingzu Liu[3], Kazunori Fujisawa[4], Michael Lucking[5], Kory Beach[6], Fu Zhang[3], Maruda Shanmugasundaram[7], Andrey Krayev[7], William Murray[3], Yu Lei[8], Zhouhang Yu[3], David Sanchez[3], Zhiwen Liu[3], Humberto Terrones[5] and Mauricio Terrones[3]; [1]Binghamton University, United States; [2]Massachusetts Institute of Technology, United States; [3]The Pennsylvania State University, United States; [4]Shinshu University, Japan; [5]Rensselaer Polytechnic Institute, United States; [6]Lawrence Livermore National Laboratory, United States; [7]HORIBA Instruments Inc., United States; [8]Tsinghua Shenzhen International Graduate School, China

The ability of controlling density and spatial distribution of substitutional dopants in semiconductors is crucial for achieving desired physicochemical properties. Substitutional doping with adjustable doping levels has been previously demonstrated in two-dimensional (2D) transition metal dichalcogenides (TMDs); however, the micron spatial control of dopant distribution remains an open field. In this work, we demonstrate that edge termination is an important characteristic of 2D TMD monocrystals that affects the distribution of substitutional dopants. Particularly, in chemical vapor deposition (CVD)-grown monolayer WS_2, we find that a higher density of transition metal dopants is always incorporated in S-terminated domains when compared to W-terminated domains. Two representative examples demonstrate this sub-micron spatial distribution control, including hexagonal Fe- and V-doped WS_2 monolayers. Density functional theory (DFT) calculations are further performed, indicating that the edge-dependent dopant distribution is due to a strong binding of W atoms at W-zigzag edges, resulting in the formation of open sites at S-zigzag edges that enable preferential dopant incorporation. Based on our results, we envision that edge termination in crystalline TMD monolayers can be utilized as a novel and effective knob for engineering the spatial distribution of substitutional dopants, leading to in-plane hetero-/multi-junctions that could display fascinating electronic, optoelectronic, and magnetic properties.

2:45 PM EL09.05.07
Defect-Induced Band Structure Variations in Monolayer Vanadium Molybdenum Disulfide Alloy Yu-Ling Liu[1], Septia Kholimatussadiah[1,2,3],

Mohammad Qorbani[1,2], Kuei-Hsien Chen[1,3] and Li-Chyong Chen[1,2,2]; [1]Center for Condensed Matter Sciences (CCMS), National Taiwan University, Taiwan; [2]National Taiwan University, Taiwan; [3]Academia Sinica, Taiwan

The atomic defects have introduced a wide range of physical properties and potentially invoked many functionalities in two-dimensional transitional metal dichalcogenides. By an advanced polymer-assisted chemical vapor deposition, monolayer $Mo_{1-x}V_xS_2$ alloy was prepared with a high alloying level of up to x ~15%. We observed an apparent photoluminescence quenching and a lower energy absorption edge in the UV-visible spectrum. With a detailed observation of the atomic arrangement in the STEM-HAADF images, we found vanadium substitutional doping and other intrinsic defects, such as sulfur vacancies, antisites, adatoms, and dopant clusters. Using first-principle calculations, we calculated the formation energy of the observed defect types and the corresponding density of states and band structure. The simulation results show obvious bandgap shrinkage after vanadium incorporation and the gap states emerging from the dopant clusters and antisites. We demonstrate that the change in optical property can be attributed to the band structure variation induced by the multiple defect types in the alloy.

First-Principles Calculations of Excitons Including Radiative Recombination and Polaritonic Effects— The Retarded Bethe-Salpeter Equation
Zachary N. Mauri, Christopher Ciccarino and Felipe H. da Jornada; Stanford University, United States

Recent research in 2D materials has revealed a host of phenomena only present in low-dimensional systems, such as the presence of strongly bound excitons due to the electronic confinement and weak dielectric screening. The electronic and optical properties in such systems have been largely captured with success through first-principles techniques based on interacting Green’s function formalisms, such as the ab initio GW and Bethe-Salpeter equation (BSE) approaches, respectively. However, these methods are typically derived assuming instantaneous many-electron interactions. Here, we describe a formalism to include retardation effects into the Bethe-Salpeter equation that is computationally efficient and gauge invariant. While previous efforts have focused on the effect of retardation effects in the direct (screened) electron-hole interactions, we find here that retardation effects in the (bare) exchange interactions are important in low dimensions. Our work predicts a renormalization of the exciton dispersion and a broadening of the exciton dispersion when retardation effects are included. More broadly, our approach can be applied to the study of polaritonic effects directly from standard interacting Green’s-function formalisms.

5:00 PM EL09.06.03
The Role Of Lead Precursors In Driving The Crystallization Of Two-Dimensional Lead Halide Perovskites Leo Sahaya Daphne Antony[1], Sjoerd v. Dongen[1], Gianluca Grimaldi[1], Simon Mathew[2], Arno v. Weijden[1], Lukas Helmbrecht[1], Bruno Ehrler[1], Willem L. Noorduin[1,2] and Esther Alarcon-Llado[1]; [1]AMOLF, Netherlands; [2]Van 't Hoff Institute for Molecular Sciences, Netherlands

Hybrid organic-inorganic perovskite semiconductors have triggered a paradigm shift in the field of photovoltaics. Low dimensional 2D hybrid organic-inorganic lead halide semiconductors have recently attracted major attention, owing to the emergence of new photo-physical properties compared to the 3D perovskites, including exciton-phonon coupling, edge state-based charge dissociation at grain boundaries and photon confinement. The ionic nature of these layered materials also makes them ideal candidates for solution processing into both thin films and nanostructured crystals. Studying the wide range of process parameters in different solution processing techniques like spin coating, and drop casting are important as they greatly influence the crystallization of 2D perovskites. However, this wide range of parameters promoting the crystallization of 2D perovskites is not as well understood as their 3D counterparts, where the inorganic precursor is typically overlooked.
In this work, we report on the role of different lead precursors in the crystallization process of 2D perovskite in drop-cast-based synthesis. In particular, we carefully examine the effect of the lead chemical state of the precursor on the crystallization pathway of BA_2PbI_4 (BAPI) perovskite by exposing lead iodide (PbI_2), lead carbonate ($PbCO_3$) and lead dioxide (PbO_2) agglomerate films to BAI: IPA solution in a dry atmosphere.
We combine in-situ optical microscopy, solution UV-VIS spectroscopy, and time-resolved high-performance liquid chromatography (HPLC) to reveal the different crystallization mechanistic and kinetics in the different lead precursor cases. We find that BAPI growth is fastest for the PbO_2 precursor followed by PbI_2, and the slowest being $PbCO_3$ (unless exposed to air). The fact that PbO_2 is the fastest is very surprising as it is the only precursor with a lead oxidation state (Pb^{4+}) that differs from that in the final product (Pb^{2+}). Optically the reaction appears similar in PbO_2 and PbI_2, but we find that in both cases solvated iodoplumbate complexes are released into the solution. As a result, not only the aggregate film partially converts to BAPI, but also high-quality BAPI crystals form in solution as either square (from PbO_2) or hexagonal (from PbI_2) shaped floating micro-plates. Photoluminescence and single crystal XRD analysis show that these micro-plates are of high crystalline quality, being mostly monocrystalline for the PbO_2 precursor. Careful time-resolved chemical examination of the solution with HPLC reveals the presence of different reaction intermediates in the three cases and therefore pinpoint competing crystallization pathways taking place during exposure, as well as indicates that the in-situ water evolution during the reduction of Pb^{4+} acts as a crystallization catalyst. This work thus provides key insights into inorganic precursors in the BAPI synthesis dynamics, that will contribute towards high-quality 2D perovskite films and microcrystals.

5:00 PM EL09.06.05
Photoinduced Interlayer Heat Transfer in Two-Dimensional TMDC Heterobilayers Visualized by Femtosecond Electron Diffraction Amalya C. Johnson[1], Johnathan Georgaras[1], Xiaozhe Shen[2], Aditya Sood[1], Helen Zeng[1], Ashley P. Saunders[1], Hyungjin Kim[1], Helen Yao[1], Tony F. Heinz[1], Felipe H. da Jornada[1], Aaron Lindenberg[1], Duan Luo[1,2] and Fang Liu[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

When photoexcitation creates charge carriers in TMDC van der Waals heterostructures, phonons will be emitted through electron-phonon coupling during charge carrier scattering and relaxation. After that, further heat exchange and thermalization will occur between the layers. Using ultrafast electron diffraction, photoinduced phonon dynamics are directly revealed in MoS_2/WS_2 and $WSe_2/MoSe_2$ twisted heterobilayers. Upon photoexcitation, the initial charge carrier transfer and relaxation leads to ≤ 1 ps ultrafast lattice heating in each layer of the heterobilayer. Subsequently, we identified a distinct heat transfer channel between the two layers that appears on the order of 20 ps after photoexcitation. We further identified the dependence of this heat transfer rate on heterobilayer twist angles. This experimentally determined heat transfer rate was found to occur up to an order of magnitude faster than predicted in a fully thermalized model. This heat transfer is likely facilitated by the initial nonthermal phonon distribution from carrier scattering and relaxation. Quantitative determination of the ultrafast lattice dynamics across TMDC interfaces is an essential key in understanding the structure-property relationships of 2D heterobilayers. These findings will have direct applications in the design and fabrication of 2D material quantum devices in the future.

A Novel Benzotriazole-Based 2D Interlayer for Passivation of $FAPbI_3$ Solar Cells Alessandro Caiazzo[1], Arthur Maufort[2], Bas T. van Gorkom[1], Willemijn H. Remmerswaal[1], Jordi Ferrer Orri[3], Junyu Li[1], Junke Wang[1], Wouter Van Gompel[2], Caterina Ducati[3], Martijn M. Wienk[1], Samuel D. Stranks[3], Dirk Vanderzande[2] and Rene A. Janssen[1]; [1]TU Eindhoven, Netherlands; [2]Hasselt University, Belgium; [3]University of Cambridge, United Kingdom

Perovskite solar cells based on $FAPbI_3$ active layer have become the standard to make high efficiency solar cells, which recently reached values above 25%. In regular device configuration, the interface between perovskite and hole-transport layer (HTL) has been shown to be highly detrimental for voltage losses, thus requiring the use of a passivation layer to mitigate this phenomenon. A variety of passivation layers have been used in the literature, the majority of them being 2D interlayers formed from conventional spacers such as butylammonium and phenethylammonium iodide.

In our work, we synthesised a series of benzotriazole (BTa)-based ammonium salts, and we showed that this class of materials can form 2D perovskite films and single crystals. When using BTa-2D perovskites as passivation layer onto $FAPbI_3$, we obtained solar cells with efficiency of about 22%, an increase of ~2% compared to the reference. The enhancement of performance is mostly related to an increase of open-circuit voltage (V_{OC}), which brings the V_{OC} to 91% of the radiative limit. The passivation effect was studied via quasi-Fermi level splitting and SEM-cathodoluminescence analysis, finding that BTa passivates both the neat perovskite film and the interface with Spiro-OMeTAD, used as HTL. On a nanometer-level, we show that both grains and grain boundaries are more luminescent after passivation with BTa.

To better understand the formation of 3D/2D heterostructures, we employed a variety of characterization techniques, going from photoluminescence and x-ray diffraction to ultra-sensitive depth-profiling x-ray photoemission spectroscopy. Here, among the insights we obtained, we found that the 2D interlayer is in the order of ~10 nm, but that BTa molecules penetrate in the bulk up to ~50 nm. Furthermore, non-uniform and open 2D passivation layers are enough to improve V_{OC}, whereas closed and thicker films are very detrimental for device performance.

Overall, benzotriazole-2D perovskites are a new class of lower-dimensional perovskites that are efficient in passivating 3D perovskites and that could be used, in future works, as photo-absorber in quasi-2D perovskite solar cells.

First-Principles Study of the Doping-Dependent Exciton and Trion Linewidth in Monolayer $MoTe_2$ Supavit Pokawanvit[1], Aurelie Champagne[2], Jonah B. Haber[2,3], Diana Qiu[4], Jeffrey B. Neaton[2,3,5] and Felipe H. da Jornada[1]; [1]Stanford University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States; [4]Yale University, United States; [5]Kavli Energy NanoScience Institute, United States

The linewidth of excitonic complexes provides direct insights into the nature of optical excitations in materials and their decay pathways. In doped semiconducting monolayers of transition metal dichalcogenides (TMDs), the linewidth associated with an exciton resonance is sensitive to extra charge carriers due to the nontrivial dielectric screening from the Fermi sea and the variety of states an exciton can scatter to, even in the weak-doping limit. Therefore, computational approaches and first-principles calculations can provide unique insights into the microscopic origin of such interactions and the nature of the associated scattering events. In this talk, we present results from first-principles calculations of Dyson-like equations associated with 3- and 4-body interacting particle problems (involving electrons and holes) to address this problem. We compare our results with perturbative calculations based on the scattering of excitons to Fermi-sea electron-hole pairs and assess the importance of many-body screening, band-filling effects, and the *ab initio* description of electron-hole coupling terms.

5:00 PM EL09.06.08
Mimicking IR Visionary System via 0D-2D Heterojunction of InAs QD/WSe_2 Artificial Synapse Hyeongtae Kim[1], Dong Park Lee[1], Nuri Oh[2] and Jun Hong Park[1]; [1]Gyeongsang National University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Emulating visionary and learning/memory function of biological neural system to use 3-terminal transistor is an important technology for effectively controlled in a low power state. In this report, we developed an artificial visionary WSe_2 based 3 Terminal FET with QD to emulate of IR sensitive biological synaptic behavior.

Quantum dots (QDs) combined with 2D WSe_2 to mimicking visionary biological synapse and demonstrate neuromorphic functionalities of the human brain via van-der-Waals (vdW) heterostructure. Compared with existing WSe_2, QD/WSe_2 heterojunction FET induced better electrical characteristic and sensitivity under the illumination of visible light and infrared light.

For mimicking potentiation and depression characteristic of biological synaptic behavior,
Surface morphology and Contact potential of Wse2 and QD/WSe_2 were analysis by Atomic Force Microscope (AFM) and Kelvin probe force microscope (KPFM), respectively. The bonding structure of 0D-2D heterojunction is confirmed by Fourier-transform infrared spectroscopy (FT-IR) and Raman spectroscopy.

This 0D-2D heterojunction structure provide a new pathway to emulating IR sensitive visionary neural system to develop IR sensitive visionary neural system, and emerging materials junctions.

5:00 PM EL09.06.09
NeuroWeb—Atomically Thin, Non-Invasive Surface Electrode Array for Probing Neural Activity Young-Woo Pyo[1], Jung Min Lee[1], Yeon Jun Kim[1], Jin Hee Hong[1,2], Yonghyeon Jo[1,2], Wonsik Choi[1,2], Dingchang Lin[3] and Hong-Gyu Park[1,2,1]; [1]Korea University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of); [3]Johns Hopkins University, Korea (the Republic of)

Electrophysiological recording technologies can provide valuable insights into the functioning of the central and peripheral nervous systems. Surface electrode arrays (SEAs) made of soft materials or implantable multi-electrode arrays (iMEAs) with high electrode density have been widely utilized as neural probes. However, neither of these probe types can simultaneously achieve non-invasiveness and robust neural signal detection(Salatino, J.W., et al. *Nat. Biomed. Eng.* **1** (2017), 862). Here, we present an atomically thin, non-invasive neural probe (the "NeuroWeb") consisting of hexagonal boron nitride and graphene, which leveraged the strengths of both SEAs and iMEAs. The NeuroWeb open lattice structure with a total thickness of 100 nm demonstrated high flexibility and strong adhesion, establishing a conformal and tight interface with the uneven mouse brain surface. Vertical stacking of additional layers showed the feasibility of multiplexing with high electrode densities. Furthermore, *in vivo* electrophysiological recordings and whiskers stimulation experiment revealed that NeuroWeb detected stable single-unit activity of neurons with high signal-to-noise ratios for one week, exhibiting high performance comparable to implantable probes. Specifically, in comparison with 1 mm-thick polymer-metal SEA, NeuroWeb showed significant increases in spike amplitude and number of detected neurons as well as exceptional transparency. Therefore, NeuroWeb can be expected to pave the way for understanding complex brain networks with optical and electrophysiological mapping of the brain.

5:00 PM EL09.06.11
High Thermal Conductivity and Ultra-Low-K Dielectric Constants in Two-Dimensional Polymers Ashutosh Giri; University of Rhode Island, United States

To limit electronic crosstalks in miniaturized microprocessors, low-dielectric-constant (low-k) materials are necessary to limit charge build-up and signal propagation delay. However, lowering the dielectric constant also comes with low thermal conductivities in materials, which complicates heat dissipation in high-power-density chips. Two-dimensional (2D) covalent organic frameworks (COFs) combine high surface-to-volume ratios, which lead to low dielectric permittivities, and periodic layered geometries, which result in high thermal conductivities. Here, we report the measurement of high-quality COF thin films with thermoreflectance spectroscopy to reveal that 2D COFs have high thermal conductivities (1 $W\ m^{-1}\ K^{-1}$) with ultra-low dielectric permittivities ($k = 1.6$). Our results pave way for highly oriented, layered 2D polymers are promising next-generation dielectric layers.
Through systematic atomistic simulations, we also demonstrate that these porous polymers possess tunable mechanical and thermal properties that arise from their singular layered architecture comprising strongly bonded light atoms and periodic laminar pores. For example, the negative Poisson's ratio arises from the weak van der Waals interactions between the two-dimensional layers along with the strong covalent bonds that act as hinges along the layers, which facilitate the twisting and swiveling motion of the phenyl rings relative to the tensile plane. The mechanical and thermal properties of two-dimensional covalent organic frameworks can be tailored through structural modularities such as control over the pore size and/or interlayer separation.

5:00 PM EL09.06.12
Wafer-Scale δ-Waveguides for Two-Dimensional Photonics Hanyu Hong, Myungjae Lee, Jaehyung Yu, Fauzia Mujid, Andrew Ye, Ce Liang and Jiwoong Park; The University of Chicago, United States

Waveguides with strong light-matter interactions have been key ingredients in modern photonic technologies that are designed to confine, direct, and modulate light waves on chip-scale optical circuitry. Recently, van der Waals (vdW) crystals emerged as novel materials that can further miniaturize waveguides to the atomically thin limit, whose operation can be enhanced by plasmonic and excitonic interactions, as demonstrated using graphene and transition metal dichalcogenides. However, efficient large-scale generation and control of photonic modes guided by vdW materials, which is crucial for technological and scientific applications, remains as an unmet challenge. Here, we report three-atom-thick waveguides, named δ-waveguides, based on wafer-scale MoS_2 monolayers that can guide visible and near-infrared light over the millimeter-scale with a low loss of 0.5 dB/mm. They are extremely thin compared to the light wavelengths and the light-trapping mechanism is analogous to a δ-potential well in quantum mechanics. This results in the trapped waves that have a single-mode operation regardless of the wavelength, minimum additional waveguide-related dispersion, and phase propagation of a free beam propagating in the surrounding dielectric. We achieve as high as 30% in-coupling efficiency for the guided mode excitation using an edge-on incidence of a laser beam and produce discrete elements of δ-waveguides placed in a transparent polymer packaging. This enables key functionalities necessary for two-dimensional (2D) photonics, including focusing, interconnection, deflection, and intensity modulation. Our work provides a significant conceptual and technological leap toward developing atomically thin integrated photonic circuitry, where dissimilar photonic components with advanced plasmonic and excitonic properties can be integrated under a single platform.

5:00 PM EL09.06.13
Textured Growth of Oxide Materials via Chemical Solution Deposition – A Case Study for Electro-Optical Thin Films Klaartje De Buysser, Ewout Picavet, Hannes Rijckaert, Laura Van Bossele, Arend Mandelings, Isabel Van Driessche, Dries Van Thourhout and Jeroen Beeckman; Ghent University, Belgium

Shifting for randomly oriented polycrystalline films towards highly oriented thin films has been a subject of many studies. Often this goes hand in hand with vacuum techniques or expensive single crystal substrates. In this presentation, wet chemical solution deposition is used to deposit highly crystalline and orientated thin films. Several strategies are covered such as seed layer deposition, self-templating method and an interlayer deposition. A case study covering electro-optical thin films such as $Pb(Zr, Ti)O_3$, $BaTiO_3$, Nb-based materials and $BiFeO_3$ multiferroic is shown. This study highlights the importance of the chemistry of the precursor solutions, wetting behaviour, deposition method and thermal treatment

5:00 PM EL09.06.15
Optoelectronic Properties of Stacked CVD-grown MoS_2 Monolayers Towards High-Performance 2D Material-Based Photovoltaics Muhammad Aamir Abbas[1], Timothy Ismael[1], Noah Hill[2], Claire Luthy[1] and Matthew D. Escarra[1]; [1]Tulane, United States; [2]The College of Wooster, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) MX_2 such as MoS_2, WSe_2, and $NbSe_2$, etc. show strong light-matter interaction which results in very high absorptance and photogeneration. Due to these excellent optoelectronic properties, TMDCs are being used for various applications e.g., transistors, memory devices, photovoltaics etc. In particular, TMDCs are promising as candidates for flexible and ultra-light photovoltaics. A single MoS_2 monolayer has a thickness of 0.65 nm and can absorb up to 10% of light at wavelengths in the visible and IR spectrum. Apart from high absorption, monolayer MoS_2 has a direct bandgap of 1.85 eV.
Due to the quantum nature of 2D MoS_2, the monolayer-like optoelectronic properties cannot be achieved from films synthesized with multiple layers. To maintain monolayer-like properties for multi-layer films, our strategy is to stack individual MoS_2 monolayers. These monolayers are synthesized on a sapphire substrate using chemical vapor deposition (CVD) with S and MoO_3 precursors carried by Ar gas at 750^oC. After achieving high-quality uniform monolayer MoS_2 films, optoelectronic properties were measured. The absorption spectra of a monolayer MoS_2 shows three peaks A, B, and C at 652 nm, 616 nm, and 431 nm respectively with a C peak absorption of 17.5 %. The absorption spectra were then compared with the computed absorption of the monolayer MoS_2 using measured n and k and the transfer matrix method (TMM). The relative error between model and experiment is <5%. Raman scattering for the monolayer shows E^1_{2G} and A_{1G} peaks at 383.5cm^{-1} and 405 cm^{-1} respectively. The normalized PL intensity of as-grown monolayer MoS_2 shows the peak at 670 nm.
A surface-energy-assisted transfer technique was then used for the stacking of individual monolayers from CVD-grown films. The obtained C-peak of absorption spectra for bi-layer, 3-layers, and 4-layers of stacked MoS_2 is 31%, 41%, and 49% respectively which is in accordance with the computed results using TMM. Raman scattering for bi-layer, 3-layers, and 4-layers of stacked MoS_2 shows peaks at 383.5cm^{-1} and 405 cm^{-1} like the monolayer scattering, as opposed to the well-known Raman peak shift in multi-layer MoS_2. Meanwhile the PL of the stacked films show a peak at 670 nm but with reduced intensity.
Schottky PV contacts were then fabricated using Ti and Pt on a SiO_2/Si substrate as an asymmetric work function interlocking-finger type device onto which the MoS_2 monolayer film is transferred. A band offset of -0.9 eV arises between the Fermi levels of Ti and MoS_2 at their interface while an offset of 0.41 eV arises at the Pt-MoS_2 interface. Efficiency of 0.000018% for a monolayer has been achieved in preliminary devices, with short-circuit current density (J_{sc}) of 0.0006 mA/cm^2 under 1 sun AM1.5D illumination. With much improved electronic transport, we project one monolayer to achieve J_{sc} as

high as 1.49 mA/cm^2 in AM0 conditions, based on measured photon absorption. By taking advantage of our demonstrated ability to stack layers while maintaining monolayer-like optical properties, using TMM we project that with 120 layers, the J_{sc} can be improved to 11 mA/cm^2 for a 2D MoS_2-based PV device.

Currently, we are focused on conserving the PL of the stacked monolayers to maintain high electronic quality in these 2D material stacks. For that purpose, we are optimizing the transfer process by applying different dry transfer techniques e.g., stamping methods, thermal release transfer (TRT), as well as improved wet transfer techniques. In addition to that, we are also working to measure the carrier concentration and mobility for monolayer and stacked monolayer structures using the Van der Pauw method. The results of this stacked monolayer 2D film analysis will be implemented in our COMSOL Multiphysics model of multiple monolayer Schottky 2D PV. The monolayer films will then be stacked on the fabricated Schottky PV devices to enhance their efficiency.

5:00 PM EL09.06.16

Infrared Nanospectroscopy of Photoluminescent Defects Ryan Kowalski[1], David Curie[1], Richard Haglund[1], Zhigang Wu[2] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]NASA Ames Research Center, United States

Quantum information sciences is advancing current technology in several fields by providing secure communications channels, impracticably difficult encryption codes, unprecedented sensing resolution, and uniquely massive computational power. However, realizing such technologies has been inhibited by an underdeveloped infrastructure. Currently, the most successful attempts are from major industrial companies investing largely in superconducting Josephson junction platforms for quantum computing. However, these examples cannot exist outside of cryogenic laboratory conditions, limiting their functionality. Other platforms employ trapped ions under ultra-high vacuum, or semiconductor quantum dots that also must exist at unrealistic temperatures for device usage. An alternative platform that is developing as an excellent candidate for quantum technologies are solid-state point defect single-photon emitters (SPEs). SPEs are optically-active point defects in semiconductor materials that alter the local electronic orbital and emit photons with sub-Poissonian statistics, a purely quantum characteristic.

Point defect SPEs are inherently tied to the crystal lattice of the host material, and therefore interact with the vibrational waves, phonons, that naturally exist throughout the medium. The consequences of these interactions can lead to poor radiative efficiencies, spectral diffusion, and quantum decoherence, a massive detriment to all quantum technology platforms. By studying the interactions between color center electrons and the adjacent lattice, we begin to understand the primary factors that degrade the performance of SPEs. Photoluminescence (PL) spectroscopy is the primary tool for studying SPEs and reveals the energy transitions of the local defect electrons. However, the spatial resolution of PL spectroscopy is restricted by wave interference of the emitted light, which is in the range of hundreds of nanometers compared to the atomic-sized defects. Furthermore, the majority of PL emission is centered around the zero-phonon line (ZPL) energy, while phonon-assisted PL only exists in some SPEs. We employ a novel technique using infrared nano-optic probes to examine SPEs on a much smaller length scale (< 20 nm) and extract more direct information about the local vibrational properties.

As a result of its layered two-dimensional structure, hexagonal boron nitride (hBN) is subject to hemispherical nanobubbles that form in between its layers. These nanobubbles are formed by trapping surface adsorbents between exfoliated layers of hBN crystals, other methods include low-energy ion irradiation. We identify bright, visible-wavelength PL located in nanobubble regions of exfoliated hBN. Examining the bright regions with infrared scattering-type scanning near-field optical microscopy (s-SNOM), we identify a curved morphology with a height of tens of nanometers. Across this feature, nanoscale Fourier transform infrared (nano-FTIR) spectra display a spectral red-shift of the transverse optic (TO) phonon, which has been previously reported and attributed to a strain effect. This evidence suggests strain is a key component to activating SPEs in hBN.

We examine other SPE materials, specifically V_{Si}'s in silicon carbide (4H-SiC). Through focused ion beam irradiation and subsequent annealing of 4H-SiC, we deterministically create V_{Si} defects, a spin-active SPE, at defined spatial intervals (25, 50, 100, 2000 nm). Examining the irradiated regions with nano-FTIR, we identify a blue-shift of the phonon resonance with respect to the non-irradiated regions. This has not been reported previously and the mechanism is still unknown.

Infrared nano-optic probes will reveal direct, nanoscale information about the electron-phonon interactions in SPEs, and therefore accelerate the knowledge and development of quantum technologies.

5:00 PM EL09.06.17

The Self-oriented $La_2O_2CO_3$ Layer: An Integration Tool For Textured Thin Films On Silicon Based Platforms Ewout Picavet, Hannes Rijckaert, Laura Van Bossele, Jeroen Beeckman, Dries Van Thourhout and Klaartje De Buysser; Ghent University, Belgium

A crucial role in the miniaturization of electronic and photonic components is the integration of ferroelectric thin films on silicon (Si) based platforms. As the properties of the thin films depend strongly on the quality and crystallographic orientation of the thin films, direct integration on photonic or electronic Si based chips is not straightforward, resulting in slow, complex and expensive integration processes which limits scalability. To bridge this gap there is a need for a scalable method to integrate highly textured ferroelectric thin films on Si based integrated circuits. We have developed a method that facilitates fast integration via a wet chemical solution deposition (CSD) route. Therefore, the use of an ultrathin (5 – 15 nm) self-oriented $La_2O_2CO_3$ thin film which acts as seed layer to obtain textured ferroelectric thin films was found crucial. In this research, the focus is on the thin film deposition via ink-jet printing, crystallographic phase determination and the self-oriented behavior. Furthermore, this $La_2O_2CO_3$ thin film has a low lattice mismatch with common ferroelectric materials, which makes the CSD deposited thin film an ideal candidate to build-up silicon based active integrated nanophotonic or nanoelectronic devices such as phase modulators, resonators, capacitors, … This research can pave the way towards the integration of ferroelectric thin films in the world of Si based platforms.

5:00 PM EL09.06.18

Molecular Beam Epitaxy of Rare Earth Telluride Thin Films—Crystal Growth and Physical Properties Adrian Llanos and Joseph Falson; Caltech, United States

The Rare Earth Tellurides (R-Te_x where x = 2, 2.5, 3 and R is a member of the lanthanide group) are a family of quasi two dimensional crystals which host a variety of low temperature phases including magnetic, charge-ordered and superconducting (under pressure) ground states. The crystal structure consists of corrugated R-Te insulating layers interspersed with conducting Te square-planar layers. Each additional Te in the chemical formula corresponds to an additional Te layer in the unit cell. Confinement of conduction electrons to these planes implies a strong 2D character reminiscent of the well-known high-Tc cuprate superconductors. A particularly well-studied feature of this family of materials is the formation charge density waves and their concomitant superlattice modulations.

Thus far, only studies on bulk crystals of these materials have been performed. In this talk we will present the first demonstration of epitaxial, single crystal thin films of $DyTe_2$ (Space group: P4/nmm, a = 4.29A, c = 8.91A). We will first describe our novel method for preparing atomically-flat MgO surfaces using laser annealing. We will then proceed to discuss the unique aspects of the layer-by-layer growth as monitored by *in-situ* reflection high energy electron diffraction. Oscillations in the specular intensity demonstrate a layer-by-layer growth mode and by comparing with thickness measured *ex-situ* , we conclude that each oscillation corresponds to the growth of a single unit cell. By observing the phase relationship between the temporal oscillations of spots of different diffraction orders, we are able to distinguish between the growth of corrugated layers and square-net sheets. We will show how changes to the diffraction pattern resulting from differing processing parameters can be used to optimize the growth conditions.

We will then discuss additional characteristics of films grown under differing growth temperatures and elemental flux ratios. Reciprocal space mapping using high resolution x-ray diffraction reveals films with lattice constants relaxed from the value of the substrate. Film quality is further demonstrated with scanning transmission electron microscopy (STEM) where minimal misoriented domains are observed. STEM measurements also confirm that the film grows unit cell-by-unit cell. A sharp interface with the MgO substrate formed by a single Te sheet was observed.

Similar to the bulk case, a wide range of stoichiometries due to Te deficiency were found to form stable, single crystal, single phase films. Using x-ray photoelectron spectroscopy we were able to both estimate relative stoichiometries between films and analyze the impact of off-stoichimetry on the photoelectron spectrum of Te and Dy. Additionally, *in-situ* low energy electron diffraction has revealed a variety of surface reconstructions for differing degrees of Te deficiency, evidence for the existence of charge density waves in the crystal.

Using electrical transport, we observe semiconducting behavior with a power-law temperature dependence, in line with previous reports on bulk crystals. This behavior, which deviates from the ideal Arrhenius-like activated transport behavior is reminiscent of a doped, small-gap semiconductor. While the formation of charge density waves is expected to open a gap in the fermi surface, this temperature dependence of resistance instead suggests an ordered lattice of Te defects may be responsible for the insulating behavior.

We conclude the talk with the prospects for growing other crystals in this family and also highlight some of the challenges for growth of crystals with larger numbers of Te sheets.

5:00 PM EL09.06.19

Wavelength Dependence of Polarization-Resolved Second Harmonic Generation from Ferroelectric SnS Few Layers Redhwan A. Moqbel[1,2,3], Yih-Ren Chang[4], Zi-Yi Li[1,2], Sheng-Hsun Kung[1], Hao-Yu Cheng[1,2,3], Chi-Cheng Lee[5], Kosuke Nagashio[4] and Kung-Hsuan Lin[1]; [1]Institute of Physics Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]Taiwan International Graduate Program, Taiwan; [4]The University of Tokyo, Japan; [5]Tamkang University, Taiwan

Two-dimensional (2D) multiferroic materials, which contain two or more intrinsic ferroic orders hold great promise for different optoelectronic applications[1]. Recently, monolayer orthorhombic structures of group IV metal monochalcogenides (such as GeS, GeSe, SnS, and SnSe) have been predicted to be 2D multiferroic materials, which possess both in-plane ferroelectric and ferroelastic orders with low domain wall energy and low migration barrier[1]. However, it is still challenging to fabricate monolayer or few layer of group IV metal monochalcogenides either from exfoliation or vapor deposition methods [2]. For most bulk crystals, macroscopic ferroelectricity or multiferroic properties disappear because each layers are stacked in an antiferroelectric manner. In this work, we fabricated unique SnS few layer single crystal flakes in which the layers were stacked in an order to keep in-plane polarizations of each layer the same direction. This opens the gate to experimentally manipulate multiferroic phases in these ferroelectric SnS few layer flakes. For measuring the ferroic phases and crystal orientations, it could be conveniently achieved by a non-contact technique of optical second harmonic generation (SHG). We utilized SHG microscopy to measure the polarization-resolved SHG from numerous SnS flakes prepared by physical vapor deposition on mica substrates. The angular-resolved patterns dramatically changed under excitation wavelength between 800 and 1000 nm due to the frequency dependence on SHG susceptibilities. By using first-principles methods within the density functional theory, we calculated the frequency-dependent SHG susceptibilities in the AA-stacking SnS and AC-stacking SnS. The effect of layer dependence on the band structures and SHG susceptibilities was also theoretically investigated. The variation trend of calculated SHG polar patterns as a function of frequency agrees well with that of the experimental results.

High-Resolution Microstructural Analyses of Polymeric Carbon Nitride Incorporated with Graphitic Carbon Shunsuke Mori[1], Niannian Wu[1,2], Nobuhiko Mitoma[1,2], Takuzo Aida[1,2] and Xiuzhen Yu[1]; [1]Riken Center for Emergent Matter Science, Japan; [2]The University of Tokyo, Japan

Graphitic carbon nitride (GCN) is a polymeric semiconductor having a layered structure. Owing to its desirable characteristics for solar water splitting, the GCN attracts much attention as a sustainable metal-free photocatalysis.[1,2] Among the polymorphs in GCN, heptazine-based structure aligned along the in-plane film direction is well-known as a stable one. Recently, research reports demonstrated that the GCN nanosheet incorporated with graphitic carbon can enhance the lifetime of photoexcited electrons due to its high electron-hole separation ability and increase the absorption under visible light.[2] Accordingly, such the C-incorporated GCN is expected to be applied for not only a high-efficiency photocatalysis but also the photovoltaic material promising to various next-generation optoelectronic devices. However, nanosheets are not appropriate for optoelectronics. We have succeeded in fabricating centimeter-scale GCN films that are applicable to optoelectronic devices.[3] The purpose of this study is to clarify the structural feature of the aforementioned polymer, which is still unclear.
Here we show microstructural analyses of C-GCN films using the high-resolution transmission electron microscopy (HREM) technique. Our HREM observations demonstrate the heptazine structure of GCN in the real-space, which is also confirmed by superstructural reflection in the corresponding Fast Fourier Transform (FFT) pattern. Both real-space images and corresponding FFT clearly show the super structure with a long period revealing the polymeric heptazine. Meanwhile, the primitive structure with hexagonal symmetry and a short period is observed and assigned to well-known graphitic carbon, which is clearly distinct from polymeric heptazine. The present study based on the HREM observations provides fundamental microstructural information of C-GCN film, that contributes to a practical design of polymer-based optoelectronic devices.

SESSION EL09.07: Quantum Nanophotonics, Sensing, Flexible Devices and Non-Linear Properties of 2D Materials
Session Chair: Thomas Kempa
Thursday Morning, April 13, 2023
Moscone West, Level 3, Room 3009

8:15 AM *EL09.07.01
Quantum Materials Optoelectronics Zeila Zanolli; Utrecht University, Netherlands

Controlling the properties of quantum materials via external stimuli is a key topic in modern condensed-matter physics. Due to its intrinsic quantum nature, light plays several roles: generating and controlling excited states, and forming hybrid quasiparticles with other excitations in solids. To unlock quantum advantage in electronic, photonic and energy technologies it is required to create new materials and manipulate their properties.

To reach this goal we develop theory and simulation techniques to fully describe the interaction between light (photons), bound electron-holes pairs (excitons) and lattice vibrations (phonons) without adjustable parameters in a quantum many-body framework [1]. Using this approach, we compute optical properties of 2D materials and heterostructures and predict how these properties can be controlled by defect engineering, strain, or twisting.

For instance, we find that vacancies in Transition Metal Dichalcogenides can univocally be identified by their absorption spectra and used as carriers of quantum information [2]. Further, we demonstrate the essential role played by exciton-phonon interaction in photoluminescence of negatively-charged boron vacancy in 2D hexagonal boron nitride [3]. We find intralayer and interlayer excitons in TMD heterostructures and use twisting to tune their absorption energy. Tunable materials are promising platforms for application in quantum information and quantum sensing.

Uniaxial Strain Dependence on Optical Second Harmonic Generation from Indium Selenide Few-Layers Zi-Yi Li[1,2], Hao-Yu Cheng[1,2], Sheng-Hsun Kung[1], Hsuan-Chun Yao[1], Christy Roshini Paul Inbaraj[2], Raman Sankar[1], Min-Nan Ou[1], Yang-Fang Chen[2], Chi-Cheng Lee[3] and Kung-Hsuan Lin[1]; [1]Institute of Physics, Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]Tamkang University, Taiwan

Since the Van der Waals materials can be mechanically exfoliated and transferred to any substrate including bendable polymeric or plastic substrates, studies of 2D materials also benefit the development of flexible devices. Indium selenide (InSe) is an emerging star of the Van der Waals semiconductors due to its superior properties such as ultrahigh mobility and large elastic deformability. It was also applied to bendable photodetectors with high performance and broad spectral response. For application of flexible devices, it is important to understand how strain affects the physical properties. Recently, optical second harmonic generation (SHG) techniques has been demonstrated to be a powerful tool for strain mapping. In addition to the intensity distribution of strain, the direction of the strain distribution can also be mapped by analyzing angle-resolved SHG patterns. For this application, it relies on fundamental understanding of strain effect on the SHG of InSe. In this work, we studied angle-resolved second harmonic generation pattern of InSe few-layers under uniaxial strain both experimentally and theoretically. We used the exfoliation method to fabricate InSe flakes on bendable and transparent substrate, and then measured the SHG images. We found the SHG intensity of InSe decreased while the compressive strain increased. By using first-principles electronic structure theory, we calculated how strain alters the susceptibilities and angle-resolved SHG pattern. The theoretical results agreed with experimental results qualitatively.

Controlling Single-Photon Emission with Ultrathin Transdimensional Plasmonic Films Igor Bondarev; North Carolina Central University, United States

The properties of a two-level quantum dipole emitter near an ultrathin transdimensional (TD) plasmonic film are studied theoretically [1]. TD quantum materials are atomically-thin films of precisely controlled thickness, films made of precisely controlled finite number of monolayers [2-5]. The model system studied mimics a solid-state single-photon source device. The spontaneous and stimulated emission intensity profiles are computed as functions of the excitation frequency and film thickness, followed by the analysis of the second-order photon correlations to explore the photon antibunching effect. It is shown that ultrathin TD films can greatly improve photon antibunching with thickness reduction, which allows one to control the quantum properties of light and make them more pronounced. The theory can be tested in experiments similar to those reported recently for epitaxial TiN films with thicknesses below 10 nm grown on MgO substrates and covered with an AlScN passivation layer [5], with nanodimond NV-centers as DEs deposited on the varied-thickness passivation layer. Knowledge of these features is advantageous for solid-state single-photon source device engineering and in general for the development of the new integrated quantum photonics material platform based on the ultrathin TD plasmonic films.

Highly Sensitive and Selective Sensor Based on Surface Plasmon Resonance Structure with Graphene for the Detection of Sub-ppm 2,4-

dinitrophenol Sung Hwan Cho[1] and Ho Won Jang[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Advanced Institute of Convergence Technology, Korea (the Republic of)

We demonstrate the enhancement of SPR sensor performance by graphene monolayer on the Au layer for detection of ppb-level 2,4-dinitrophenol dissolved in IPA solution. The thickness (50nm) of the Au layer was optimized through the Finite-Difference Time-Domain (FDTD) calculation, and this was confirmed through the reflectivity curve comparison through the actual SPR images to the IPA solution. The performance of the sensor is analyzed via SPR measurements, and the Au-graphene structure is characterized using field emission scanning electron microscopy (FESEM), atomic force microscopy (AFM), Raman spectroscopy, and transmission electron microscopy (TEM). The results from FESEM, AFM, and TEM confirmed the graphene monolayer transferred well on the Au thin film. We showed that the proposed structure has increased the shift in the SPR angle up to 550 resonance units (RU) within the range of 100 – 500 ppb due to the enhanced evanescent field at the sensing layer-analyte interface, and interaction between 2,4-dinitrophenol and monolayer graphene. We demonstrate that π- π interaction between 2,4-dinitrophenol and monolayer graphene plays a dominant role in the enhancement of the SPR response of 2,4-dinitrophenol onto graphene and it is calculated by density functional theory (DFT) calculation and verified through Raman spectrum analysis. As a result of DFT calculation, the 2,4-dinitrophenol was most stable when it existed parallel to graphene, and it was confirmed that the 2D/G ratio decreased and the peak position was shifted in the Raman spectrum in the state adsorbed with the 2,4-dinitrophenol. This sensor exhibits great linearity and repeatability in the ppb level concentration range. Measurement of various organic substances, as well as 2,4-dinitrophenol, was carried out, and selectivity to aromatic substances was confirmed. The results prove that our proposed Au-graphene SPR sensor demonstrated strong performance and reliability for aromatic ring organic compounds selective detection in IPA solution.

Innovative MXenes Carrier Selective Contact for Sb_2Se_3 & CZTSe Hybrid Heterostructure Devices Axel Gon Medaille[1,2], Alex Jimenez Arguijo[1,2], Kunal Tiwari[1,2], Eloi R. Costals[2], Joaquim Puigdollers[2], Sergio Giraldo[2], Marcel Placidi[2], Zacharie Jehl Li-Kao[2] and Edgardo Saucedo Silva[2]; [1]IREC, Spain; [2]Universitat Politècnica de Catalunya, Spain

MXenes are a recently discovered family of inorganic 2D materials combining high conductivity, transparency in ultrathin layers, work function tunability via surface termination and ease of fabrication in large areas, which has found widespread possible applications in energy storage and conversion technologies. As carrier selective contacts become ubiquitous in state-of-the-art photovoltaic research, the use of MXene electrodes is a promising pathway to further improve thin film devices beyond the classic p-n junction architecture. Studies remain scarce and **a fundamental understanding of the absorber/MXene interface**, with a fine tuning of the 2D electrode, is of high interest for the community.
Through this work, we realize photovoltaic devices combining Ti_3C_2Tx as a charge (electron/hole) selective contact layer with Sb_2Se_3 and $Cu_2ZnSnSe_4$, two of the most promising emergent thin film PV absorbers. MXenes sheets are synthetized by selectively etching a Ti_3AlC_2 (MAX) phase using the minimum intensive layer delamination (MILD) method, forming in-situ HF allowing the selective removal of aluminum from the bulk MAX phase. Secondly, following centrifugation and washing processes, the obtained $Ti_3C_2T_x$ solution is deposited on FTO, Mo and ITO substrates with different MXenes concentrations and thicknesses by spray-coating at temperatures ranging from 100 °C up to 200 °C, which permits to obtain **an excellent reproducibility and homogeneity over areas up to 100 cm^2**. It is to our knowledge is the first time that spray-coating deposition of MXene is assessed for energy applications.
Subsequently, surface modifications with selenium Se are performed on the as-deposited $Ti_3C_2T_x$ to **modify the surface termination and consequently the material's work function**, allowing to finely tune the electrode and adapt it to the desired extraction energy level. Se deposition is carried out by thermal evaporation of the element followed by a reactive annealing phase in Se atmosphere. The resulting selenized MXene sheets are used as a substrate for the fabrication of Sb_2Se_3 and CZTSe hybrid heterostructures. An extensive Raman spectroscopy analysis reveals that following the selenization process, the **Se crystallographic structure deposited on the MXenes surface can be modified to be either an equilibrium between Se_8 rings and Se_μ chains or strictly Se_8 rings**. For the sake of comparison, other surface modifications involving organic compounds such as citric acid or perfluorinated ionomer (PFI) and UV-Ozone treatment are performed, with the similar objectives to tune the surface termination of as-deposited MXenes for selective carrier extraction. The devices are completed following the standard CdS/TCO front contact architecture for solar cells and are characterized using room temperature and temperature-dependent optoelectronic analyses methods, shedding light on the mechanisms involved in the photocarrier extraction at the absorber/MXenes interface.
Results of optoelectronic characterizations in the form of J-V, EQE and C-V for the devices will be presented to elaborate on the impact of MXenes concentrations and thickness on PV devices performance, and the **selenization of MXene is found to markedly improve the voltage, current, and conversion efficiency** of the resulting PV devices. Additionally, material characterizations by means of SEM, XRD, XPS and Raman spectroscopy are carried out to assess the physico-chemical properties of the as-deposited layers (both MXenes and absorber) along with the MXenes surface termination modifications. The results will be discussed in the frame of the state of the art and compared with reference devices fabricated on crystalline Silicon. Finally, improvement pathways will be proposed to further tailor the properties of MXenes film to the needs of thin film photovoltaic devices.

10:15 AM EL09.07.06
Multi-Scale Simulations of Supported Pt Nanoclusters on Single-Layer MoS_2 for Chemiresistive Wearable Biosensors Gabriele Boschetto[1], Stefania Carapezzi[1] and Aida Todri-Sanial[1,2]; [1]LIRMM, University of Montpellier, CNRS, France; [2]Technische Universiteit Eindhoven, Netherlands

The development of non-enzymatic sensors is a challenge which requires, on the one hand, careful design of the sensing materials with respect to the chosen analyte, and on the other hand, suitable device architectures. In this context, atomically-thin two-dimensional (2D) materials have attracted a great deal of interest given their desirable mechanical, electrical and optical properties. For instance, single-layer molybdenum disulfide (MoS_2) is an ultra-thin semiconductor which can be used to fabricate devices which go beyond the current state-of-the-art CMOS technology.
Aside from the device level, single-layer MoS2 as a material was also found to be suitable to be used as the sensing platform in FET sensors to detect small molecules (mainly gases) and small biomarkers such as glucose. However, the vast majority of MoS_2 FET sensors rely on an enzymatic sensing mechanism, which involves the functionalization of the 2D material with enzymes specific to the chosen analyte. Enzymatic sensors are generally prone to suffer of low stability with respect to temperature and pH.
In this work, we propose single-layer MoS_2 decorated with Pt nanoparticles as the non-enzymatic sensing platform for the detection of biomarkers (such as cortisol) in human samples. The aim is to assess the suitability of such a sensing platform for the development of wearable and portable cortisol sensors. We perform multi-scale computer simulations at the materials' level up to device scale. First, ab initio simulations within the framework of density functional theory (DFT) allowed us to gain insights into the interaction, at the atomic level, between the analyte (cortisol) and the sensing platform (MoS_2/Pt). Then, by carrying out technology computer-aided design (TCAD) simulations, we were able to consider a device architecture and investigate its performance as cortisol sensor. Following our multi-scale simulation strategy, we were able to propose a FET sensor, whose channel is made of Pt-decorated MoS2. The sensing mechanism relies on the chemiresistive response of the device to the adsorption of cortisol on the channel, which leads to a charge transfer from the analyte to the substrate and, consequently, to the measurable shift in the gate voltage threshold of the FET.
With our findings, we provided important insights and gave our contribution towards the development of highly sensitive non-enzymatic cortisol sensors

based on 2D materials.

Ultra-Stable 2D Layered Perovskite Films for Flexible and Large area X- and Gamma-Ray Detectors Andrea Ciavatti[1,2], Matteo Verdi[1], Laura Basiricò[1], Daniela Cavalcoli[1] and Beatrice Fraboni[1]; [1]DIFA - University of Bologna, Italy; [2]INFN - Bologna, Italy

The recent impressive progress in the field of perovskites assessed their large potential for the development of direct detection of ionizing radiation, as they proven the ability to detect X-ray, coupled to unique properties such as solution-processability, cost-effective fabrication and scalability to large area systems. In particular, the development of light, portable and flexible devices would represent a breakthrough in the field of medical imaging, dosimetry, and public security. Indeed, perovskite film X-ray detectors based on polycrystalline morphologies exhibit excellent performances; however, they are limited by low bulk resistivity, high trap states density and significant ion migration effects leading to large dark current drift. Among the lead-halide perovskite, 2D layered hybrid perovskite have recently attracted increasing attention as active layer in UV-Vis photodetector [1]. These perovskites are represented by the general formula $(R\text{-}NH_3)_2A_{n-1}B_nX_{3n+1}$, where R is an alkyl or aryl group. Low-dimensional perovskites are characterized by a layered crystal structure in which corner-shared BX_6 octahedra sheets are intercalated between bilayers of $R\text{-}NH_3^+$ organic spacers. Their electronic structure is akin to a multiple quantum well where the inorganic layers constitute the wells and the organic spacers the barriers. Due to the high dielectric contrast between the organic and inorganic moieties, the charge carriers are strongly confined with large exciton binding energy, as well as highly anisotropic charge transport. The high resistivity, suppressed ion migration and superior ambient stability makes them an interesting alternative for radiation detection. We present a direct X-ray detector based on PEA_2PbBr_4 polycrystalline films directly deposited by single step spin-coating on a pixelated PET flexible substrate with prepatterned interdigitated metal contacts. The perovskite forms a polycrystalline film with average grain size of 33.5 ± 8.3 µm and thickness of 1.9 ± 0.8 µm. From Current-Voltage measurements the dark current was found to be extremely small (tens of 10^{-12} A at 10 V). The devices demonstrated excellent photocurrent under UV light (375 nm), with fast response of 147 ± 10 ns, an ON/OFF current ratio up to 10^4 and Responsivity up to 12 mA/W. Photocurrent spectrum show an energy gap located at 3.08 eV and a high excitonic peak about 0.06 eV below it. The detector showed a high sensitivity under 150kVp X-ray radiation with a top value of 806 µC Gy^{-1} cm^{-2} and limit of detection down to 42 nGy s^{-1}. The X-ray signal have been acquired under different bending conditions to assess the effect of the mechanical stress [2].
Additionally, the tested devices exhibit exceptionally stable response under constant irradiation and bias. Thus, to evaluate the aging effects and the radiation hardness we performed Photo-Induced Current Transient Spectroscopy (PICTS)[3] characterization and X-ray measurements after 30 days of shelf-storage and after 200 Gy of irradiation. The X-ray signal is constant after 200 Gy of radiation or ten minutes of continuous exposure. At the same time, photocurrent signal, sensitivity and µτ values are stable after 30 days. Interestingly, all the three levels individuated from PICTS spectra are identical after 30 days.
Finally, we implemented and tested devices working at low bias (<5 V), granting the possibility to be powered by a battery-operated, wearable readout electronics, with wireless data communication. We demonstrate how this sensing system can be exploit for the detection of high energy photons emitted by radioisotopes typically used in nuclear medicine (^{18}F, ^{99m}Tc and ^{177}Lu).

Exciton-Resonance Tuning for Atomically-Thin Metasurfaces Ludovica Guarneri[1], Qitong Li[2], Thomas Bauer[1], Jung-Hwan Song[2], Mark L. Brongersma[2] and Jorik Van de Groep[1]; [1]University of Amsterdam, Netherlands; [2]Stanford University, United States

Since the development of diffractive optical elements in the 1970s research has focused on replacing bulky optical elements such as lenses and grating by thin counterparts. Over the last decade, nanophotonic metasurfaces rapidly advanced the development of flat optical elements based on the realization that resonant optical antenna elements enable local phase control. Present applications of metasurface flat optical elements include lenses, polarization control, and beam steering.

Next-generation applications of flat optics such as light detection and ranging (LIDAR), dynamic holography, and computational imaging require dynamic control over optical functionalities, e.g. the focal position or efficiency of optical elements. However, most nanophotonic structures are static after design and fabrication. Current approaches for dynamic control like electrical gating exhibit limited tunability due to the finite electrorefraction and electroabsorption effects in metals and semiconductors.

Here, we demonstrate how exciton resonances in monolayer transition-metal dichalcogenides (TMDs) like WS_2 can function as a new type of tunable resonant light-matter interaction in nanophotonic metasurfaces. By directly patterning the monolayer material, the 2D material is turned into the antenna or metamaterial and incorporation of active materials into larger antenna structures will no longer be needed. Due to their sub-nm thickness, these materials are highly tunable through external control. In this presentation, I will present three applications of exciton-enhanced light scattering.

First, we demonstrate actively-tunable and atomically-thin optical lenses by carving them directly out of large-area monolayer WS_2. Using an electrochemical cell, we electrostatically control the carrier density in the monolayer WS_2 and thereby gain active control over the excitonic light scattering amplitude. Using confocal scanning microscopy, we characterize the focal shape and analyze the focal efficiency. We demonstrate dynamic electrical tuning of the focusing efficiency with a 33% modulation depth through manipulating of the excitonic material resonance properties as opposed to tuning of antenna resonances.

Second, we employ these atomically-thin lenses to directly study the influence of exciton decay and dephasing on the metasurface functionality and spectral line shape. To do this, we employ a helium cryostat to measure the efficiency spectrum as a function of temperature. At ambient conditions, the spectrum shows a strong asymmetric line shape revealing that the scattered light fields are directly governed by the monolayer susceptibility. For decreasing temperatures on the other hand, the exciton energy shows a blue-shift, non-radiative decay and dephasing are suppressed and the exciton becomes fully radiative. By comparing the resulting line shapes to an analytical model, we show that the efficiency of the metasurface lens directly scales with the excitonic oscillator strength and decay dynamics.

Third, we use reflection measurements of monolayer TMD on a quartz substrate to highlight that the interference of the substrate and TMD reflections can strongly influence the exciton line shape. By systematically controlling the substrate reflection with index-matching oils, we engineer the interference and thereby the line shape. We further show how basic, room-temperature reflection measurements allow investigation of the quantum mechanical exciton dynamics. By removing the substrate contribution with a properly chosen oil, we can extract the excitonic decay rates including the quantum mechanical dephasing rate.

The strong light-matter interaction and highly tunable nature of these exciton resonances opens an entirely new approach for the design of dynamic flat optics and metasurfaces with applications in free-space beam tapping, wavefront manipulation, and augmented/virtual reality.

11:15 AM EL09.08.02
Temperature Dependence of Excitonic Auger Recombination in Excitonic-Complex-Free Monolayer WS_2 by Considering the Auger Broadening Effect Donggyu Kim[1], Trang T. Tran[2], Jeongyong Kim[2] and Joon Ik Jang[1]; [1]Sogang University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Monolayer transition metal dichalcogenides (TMDs) have been extensively studied for their optoelectronic properties and application to sizable and flexible light-emitting devices. However, even at moderate exciton densities, their light emitting capability is severely limited by strong exciton-exciton annihilation (EEA) through nonradiative Auger recombination. Consequently, it is essential to understand the fundamental EEA dynamics to achieve a higher quantum yield. Numerous studies on EEA in TMDs, however, do not properly consider so-called Auger broadening, resulting in underestimated values for the Auger coefficient. Also, Auger coefficients measured at low temperatures were seriously affected by the presence of excitonic complex such as trions and biexcitons, yielding less confident results. In order to study EEA in an ideal excitonic system, we transferred monolayer WS_2 on a gold substrate with hBN encapsulation, in which excitons persist as the main species from room temperature to 3 K via suppression of the formation of excitonic complex by metal proximity. To account for the effect of Auger broadening, we numerically solved the rate equation for the precise estimation of the Auger coefficient as a function of temperature by considering the laser pulse width and by spatially averaging the inhomogeneous exciton density. The measured Auger coefficient is about 2.4 cm^2s^{-1} at room temperature, but it significantly drops down to 0.14 cm^2s^{-1} at 3 K. We found that the Auger coefficient A in monolayer WS_2 can be expressed as a function of temperature (T) in the form of $A = \alpha T + \beta$ where $\alpha = 0.00054\ cm^2s^{-1}K^{-1}$ and $\beta = 0.1371\ cm^2s^{-1}$, which is indeed consistent with a theoretical model predicted for direct and exchange processes, respectively. We believe that our results provide more profound understanding of the Auger processes in monolayer TMDs, which potentially provide a guide for enhancing the quantum yield of the TMD materials.

11:30 AM EL09.08.03
Nanothin $Bi_xO_ySe_z$-Enabled Modulation of Photoluminescent Properties of WSe_2 Bethany M. Hudak[1], Zachariah Hennighausen[1,2], Madeleine Phillips[1], Olaf van 't Erve[1] and Rhonda M. Stroud[1,3]; [1]U.S. Naval Research Laboratory, United States; [2]Massachusetts Institute of Technology, United States; [3]Arizona State University, United States

The bright photoluminescent (PL) properties of monolayer transition metal dichalcogenide (TMD) systems like WSe_2 and WS_2 make them appealing for applications such as next-generation optoelectronics and quantum information sciences. The PL originates from tightly bound exitons that are sensitive to changes in the surrounding dielectric environment. Here we show that by growing few-layer Bi_2Se_3 on WSe_2, the PL signal is quenched. Interestingly, the PL signal can be restored in discrete, sub-micrometer spots by exposing the Bi_2Se_3–WSe_2 heterostructure to a high-power laser (393 µW) in an oxygen-rich environment. The PL intensity can further be modulated through control of the laser power and oxygen partial pressure to achieve a continuum of PL values, demonstrating spatially selective tunability of the PL signal.
Raman spectroscopy and optical imaging indicate that the Bi_2Se_3 undergoes a structural phase change during the first laser-oxygen exposure. The laser-oxygen exposed spots were investigated using scanning transmission electron microscopy (STEM) and energy dispersive x-ray spectroscopy (EDS), which shows a 47% oxygen increase and 87% selenium decrease at those locations. Selected area electron diffraction (SAED) of the pristine Bi_2Se_3 and laser-exposed spots show a change in the crystal lattice constant. The SAED pattern of regions exposed to the laser-oxygen environment match well with the rhombohedral R3m Bi_2O_3 phase calculated from first-principles density functional theory (DFT). Bi_2O_3 is a good candidate for solid oxide fuel cells (SOFC) and oxygen separation membranes. Bi_2O_3 exists with a number of different polymorphs, and the properties vary dramatically with the different crystal phases. For instance, the monoclinic α-Bi_2O_3 is stable at room temperature, but it has poor oxygen ion conduction, while the rhombohedral phase offers more competitive oxygen ion transport. However, this phase is difficult to stabilize, resulting in few experimental studies without heavy dopant concentrations. To the best of our knowledge, we have synthesized for the first time a few-layer, nanothin phase of R3m Bi_2O_3 at room temperature and without high dopant concentrations. STEM-EDS measures a small amount of Se remaining, and thus we refer to this phase as $Bi_xO_ySe_z$.
The $Bi_xO_ySe_z$ phase allows for oxygen transport into the interlayer region of the $Bi_xO_ySe_z$–WSe_2 heterostructure, thus decoupling the two layers and restoring the WSe_2 PL signal. The PL intensity modulation is a result of intercalating and deintercalating oxygen between the two materials. The PL intensity cycles with partial pressure of oxygen during laser exposure, suggesting that the PL changes are dependent on an oxygen interaction that doesn't structurally alter the heterostructure, which is consistent with oxygen intercalating and deintercalating between the layers. Using Fick's 2nd Law of Diffusion, we measure oxygen diffusion through the $Bi_xO_ySe_z$ to be 2.61e-18 m^2/s under laser exposure at room temperature, several orders of magnitude above other room-temperature oxygen transporters. Other Bi_2O_3 phases have demonstrated faster oxygen diffusion but require temperatures of 500 °C or greater.
We have demonstrated the fabrication of nanothin $Bi_xO_ySe_z$, closely resembling the rare rhombohedral phase of Bi_2O_3. In addition to the ability to modulate the PL signal of WSe_2, nanothin $Bi_xO_ySe_z$ is a promising, unexplored room-temperature oxygen transporter that could advance low-temperature SOFC technology and syngas production.

11:45 AM EL09.08.04
Ultrafast Pump-Probe Microscopy Studies on Multilayer $MoSe_2$ Cullen P. Walsh, Jason Malizia, Sarah Sutton, John Papanikolas and James Cahoon;

UNC Chapel Hill, United States

As materials in electronics and photonics continue to shrink, nano- and micro-scale structures begin to have an outsized impact on the electronic properties. Studies have found that depending on the material, the structure, and the fabrication process, the energetics and carrier dynamics of a material can change in unexpected ways. Despite all this, structural features are often comingled in experiments, obscuring their individual effects. In order to overcome this, we use ultrafast pump-probe microscopy to isolate and study individual structural features in materials. This presentation will focus on the effects of thickness in the multilayer transition metal dichalcogenide $MoSe_2$ which shows promise in optoelectronic and photocatalytic device applications. Although $MoSe_2$ has been extensity studied in the monolayer, we still do not fully understand how changes in thickness and local structure change its electronic and optical properties. Using the diffraction limited spot size of our setup, we isolate the dynamics at the center of $MoSe_2$ nanoflakes and determine how the dominant carrier relaxation processes change going from 20- to 100-layers in thickness. We also observe and characterize non-linear modulations in the bandgap energy upon photoexcitation and how they change with time and carrier concentration. Finally, we observe a thickness-dependent internal etalon effect in the material which we analyze via a computational dielectric model. Using this comprehensive understanding of the thickness dependence of the carrier dynamics at the center of $MoSe_2$ flakes, we can in the future compare these results to the dynamics at the edges of flakes and around other internal structures (buckles/tears). Overall, by better understanding the impact these structural features have on the carrier dynamics and optical properties of these materials, our work allows for future structural optimization of these materials when used in new or improved optoelectronics and photocatalytic device architectures.

SESSION EL09.09: Optoelectronic Characterization and Optical/Optoelectronic Properties of Layered Optoelectronic Materials and Their Heterostructures II

Confined Excitons at Monolayer Black Phosphorus Edges Souvik Biswas[1], Joeson Wong[1], Supavit Pokawanvit[2], Huairuo Zhang[3], Wei-Chang Yang[3], Hamidreza Akbari[1], Kenji Watanabe[4], Takashi Taniguchi[4], Albert Davydov[3], Felipe H. da Jornada[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]Stanford University, United States; [3]National Institute of Standards and Technology, United States; [4]National Institute for Materials Science, Japan

Atomically sharp or abrupt junctions provide a novel platform to study symmetry-broken physical phenomenon and modification of the local electronic structure at the interface – often resulting in localized or trapped state formation. We report emergence of quantum confined excitons in the emission spectrum in the edges of monolayer black phosphorus (BP). While the quasi-1D exciton in the interior of monolayer BP exhibits a single Lorentzian-like photoluminescence (~40 meV linewidth) at low temperatures (~5K), we observe additional red-shifted spectrally narrow (~1-5 meV) emission lines at the edges of monolayer BP flakes. We interpret the origin of such localized features to be due to a confining potential located at the physical edges of BP – supported by first principles GW-BSE calculations of BP nanoribbons. We observe the photoluminescence to be highly linearly polarized, with significant temperature and pump fluence dependence. Furthermore, we find that the emission is highly tunable with electrostatic doping and can be turned on and off, on demand – due to an interplay of doping and a linear perturbative Stark-effect. Our results help facilitate the understanding of fundamental optical excitations in monolayer BP under local structural modification and may enable further engineering of photoluminescence in BP nanostructures such as quantum dots or nanowires for bright, polarized, and reconfigurable light emitters.

Nanoscale Optical Characterizations of 2D Semiconductors via Near-field Photo-Induced Force Microscopy Jin Myung Kim[1,2], Peiwen J. Ma[1] and SungWoo Nam[1,2]; [1]University of California, Irvine, United States; [2]University of Illinois at Urbana-Champaign, United States

Atomically-thin van der Waals (vdW) semiconductors, such as transition metal dichalcogenides (TMDs), have garnered significant attentions as a platform for next-generation nano-optics and quantum optoelectronic devices. Strong light-matter interaction and reduced dielectric screening in low dimensionality allow excitons to govern optical responses of two-dimensional (2D) semiconductors. In particular, manipulating nanoscale energy landscape of 2D excitons plays a pivotal role in exciton funneling and confinement at localized energy trap. However, *in situ* and non-destructive characterizations of nanoscale optical properties persist as a challenge, particularly where optical responses are highly localized at nanoscale regions narrower than optical diffraction-limit. Here, we report nanoscale optical absorption properties of 2D TMDs via photo-induced force microscopy (PiFM). PiFM technique allows us to measure near-field tip-sample dipole interaction induced by coherent laser excitation. First, we employed polarization-controlled visible wavelength laser source to investigate the in-plane excitonic response of 2D vdW semiconductors. Aligning in-plane dipole moment of 2D TMDs with dipole in the metallic tip was achieved by controlling the polarization of incident illumination, which was critical for measuring light-induced dipole interactions. Second, we carried out PiFM mapping and spectroscopy of various monolayer TMDs. Strong resonance absorption peaks of A and B excitons were observed in fixed wavelength PiFM map as well as PiFM spectra with continuous wavelength sweep. Lastly, we analyzed nanoscale strain modulation in wrinkled and buckle delaminated 2D semiconductors. Strain-induced energy shift of A exciton was observed in PiFM hyperspectral line scanning across sub-micron buckle structure, while conventional photoluminescence (PL) scanning was not able to resolve energy shift due to limited spatial resolution. Spatial resolution of the PiFM hyperspectral mapping was revealed to be < 17 nm, indicating its capability of nanoscale optical characterization. These results suggest new opportunities for advanced nano-characterization for nanoscale optical properties of 2D semiconductors beyond optical diffraction limit.

Proximity-Induced Moiré Exciton in a Transition Metal Dichalcogenide Monolayer Sudipta Kundu and Felipe H. da Jornada; Stanford University, United States

Moiré patterns in two-dimensional materials, formed due to a lattice mismatch or a relative rotation between the layers, have gained research interest as a platform to study exotic electronic and excitonic phases. The moiré potential responsible for the emergent phenomena is induced by the atomic reconstructions and the variation of interlayer interaction upon creating a moiré pattern. Using first-principles calculations, we explore a noninvasive way to induce a spatially varying moiré potential in the target monolayer transition metal dichalcogenide (TMD) by placing it on another multilayer material with domains of alternative electric polarization, for example, a parallel-stacked bilayer hexagonal boron nitride with a small interlayer twist. Our first-principles calculations reveal novel excitons with spatial localization and excited-state series that differ from those possible in regular stackings of twisted bilayer TMDs and suggest an experimental route for the engineering of tunable moiré potential post material synthesis.

3:30 PM EL09.09.06
Direct Probing of Excitons in Layered Moiré Superlattices Medha Dandu[1], Jordan A. Hachtel[2], Mit H. Naik[3,1], Patrick Hays[4], Sriram Sankar[4], Elyse Barré[1], Takashi Taniguchi[5], Kenji Watanabe[5], Steven Louie[3,1], Felipe H. da Jornada[6,7], Sefaattin (. Tongay[4], Peter Ercius[1], Archana Raja[1] and Sandhya Susarla[4]; [1]Lawrence Berkeley National Laboratory, United States; [2]Oak Ridge National Laboratory, United States; [3]University of California, Berkeley, United States; [4]Arizona State University, United States; [5]National Institute for Materials Science, Japan; [6]Stanford University, United States; [7]SLAC National Accelerator Laboratory, United States

Artificial superlattices [1] enable self-organized arrays of interacting quasiparticles on a long-range, offering routes for dynamic simulation of many-body physics and engineering quantum optoelectronic devices. Stacking of individual layered materials offers an unprecedented bottom-up approach to design artificial superlattices with tunable light-matter interactions. Such a stacking can yield nanoscale moiré superlattices [2] modulated by interlayer hybridization and atomic reconstruction, depending on the lattice mismatch and the twist angle across the constituent materials. So far, conventional optical spectroscopy techniques have revealed the moiré superlattice effects [2] only in an indirect manner due to their diffraction limits. Localized spectroscopy analysis is an absolute necessity to directly probe the nanoscale electronic and optical modulations across moiré superlattices in layered heterostructures. Monochromated-electron energy loss spectroscopy (EELS) in a scanning transmission electron microscope (STEM) is a versatile technique that can probe spectral information with sub-nanometer spatial resolution. In the context of atomically thin layered superlattices, EELS measurements can be directly correlated with the dielectric losses and attributed to excitonic resonances deduced from the optical absorption. In a recent work [3], in-plane structural reconstruction and the corresponding exciton localization were probed using the spatial and spectral resolution in cryogenic STEM-EELS, demonstrating the possibility of direct experimental correlation between the sub-nanometer moiré superlattice and the emergent excitonic transitions. However, the distinct spectral signatures of moiré excitons could not be directly probed due to limited energy resolution. In this work, we demonstrate both spatially and spectrally resolved features of individual intralayer moiré excitons from R-stacked WS_2/WSe_2. Using hyperspectral EELS from multiple regions across the sample, we deconvolute the contribution of oscillator strength of moiré excitons from different lattice sites. The unique advantages of high spatial and spectral resolution from the STEM-EELS technique could be extended to understand other layered superlattices where electrically tunable layer hybridization and moiré superlattice effects can be harnessed for tunable quantum emitters.

SESSION EL09.10: Poster Session
Session Chair: Sonia Conesa-Boj

5:00 PM EL09.10.01
Enhancement Visible Light Sensitivity of the PbS Quantum-Dot/Graphene Hybrid Photodetector Using Ag Meta-Pattern Substrate Yamujin Jang[1], Namyun Kim[1], Yao Zhang[1], Dongmok Whang[2] and Yi Jae Lee[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Graphene is known to have excellent various characteristics such as electrical, mechanical, and optical properties. In particular, in terms of optical characteristics, graphene is transparent, has the advantage of light absorption in a wide range up to ultra-violet (UV) - infrared (IR), and has a constant light absorption rate of 2.3% at an electric wavelength. The reason why it could not be used as an optical application despite its wonderful optical characteristics is that the life-time of the optical carrier is very short at several ps, so it has a limitation in its use as an optical application. Accordingly, in order to overcome the optical limitations of graphene, hybrid structure with quantum-dot (QD) was produced to increase sensitivity and detection. This method dramatically increased the performance of the graphene-based photodetector (PD), but there are several problems. First, because organic QD is utilized, the effect of toxicity according to the components of QD cannot be avoided, and the absolute range is fixed. In addition, the second is the problem of the substrate. When light is irradiated, absorption and reflection occur simultaneously on the substrate, and the sensing characteristics of the photodetector are not maintained constant due to absorption into the substrates. Therefore, in this study, we utilized an Ag meta-surface (AMS), which can lead to maintaining the sensing characteristics of the QD-graphene-based photodetector and improving the sensing property. AMS produced a replica through nanoimprint lithography, used a method of depositing and detaching Ag on the replica, and could be ripped without damaging the AMS. After that, in order to manufacture a QD-graphene device, a flat layer is manufactured through spin coating of PVA (polyvinyl alcohol) on AMS. After that, patterned graphene is transferred on PVA/AMS, and electrodes are deposited using a shadow mask to manufacture devices. In addition, the PbS QD used in this study used commercially available PbS QD, and coating was coated using a widely known method. Before checking the characteristics of the manufactured PD, the effect of the PVA layer on the graphene layer was confirmed, and it was confirmed that the n-doping effect of PVA layer under the graphene through the Dirac point negative shift. In addition, when observing the change in the optical characteristics of graphene according to the presence or absence of AMS, it was observed that the current changes depending on the on/off of light, although the reactivity to light was not shown on the SiO2 substrate. Since it was confirmed that AMS can positively affect the optical characteristics of graphene, PbS QD was coated to improve the optical sensing characteristics of graphene-based PD. And a QD/graphene device was manufactured with SiO2 and AMS substrates to compare characteristics. Comparing the characteristics of PDs manufactured using the two substrates, it was confirmed that the current that changes in response to light at the IV curve was up to 3 times, and the current that changes at laser on/off was also 3 times higher than SiO2. In addition, it was confirmed that PD on the AMS substrate still showed similar current levels over time, but PD on SiO2 showed a characteristic that the current level gradually decreased. Therefore, we were able to present in this study that the use of AMS in PD or optical applications can improve optical properties. And the laser used in this study was a 532 nm wavelength laser. In conclusion, meta-surface and QD have the disadvantage that wavelength absorbed or reflected is fixed depending on the structure, size, and components, but on the contrary, it can be used in specific fields by increasing sensitivity to specific wavelengths, and it is expected that high-performance and high-sensitivity photodetector can be produced by combining them with graphene.

5:00 PM EL09.10.02
Monolayer TMDC Nanoribbon Exfoliation for Optical, Electronic, and Magnetic Characterization Ashley P. Saunders and Fang Liu; Stanford University, United States

Successful preparation of low dimensional materials is a prerequisite for exploring their physical properties experimentally and incorporating them in electronic and quantum devices. As a quasi-one-dimensional structure, monolayer nanoribbons have emerged as new candidates for

exotic quantum phenomena beyond those achieved in their bulk and monolayer counterparts. Atomically thin nanoribbons are expected to exhibit tunability in electronic, optoelectronic, and magnetic properties, depending on their width and edge structures. For example, nanoribbons of transition metal dichalcogenide (TMDC) will have potential properties including magnetism, topological phase transitions, and strong light matter interactions. Further discovery of new breakthrough properties for this intriguing material class depends on new sample preparation techniques with sufficient morphology control. We developed a top-down, scalable, and controllable exfoliation process to fabricate highly-aligned single-crystal two-dimensional nanoribbons directly from bulk crystals, with precise control of edge morphology and designed artificial structures. This strategy will enable a broad selection of single crystal TMDC monolayer nanoribbons, including MoS2, MoSe2, WS2, and WSe2 nanoribbons of various widths. This technique has allowed for experimental exploration of the optical, electrical, and magnetic properties of TMDC nanoribbons via photoluminescence spectroscopy, electrical transport measurements, and Magnetic Force Microscopy. 2D nanoribbons with artificially defined edge morphologies and widths will open up possibilities to realize novel quantum properties and to explore novel platforms for next-generation information processing, light processing, and quantum processing in the future.

5:00 PM EL09.10.03
A Molecuar Dynamics Investigation of Coherent Phonons in Layered Transition Metal Dichalcogenides Jesus A. Avendano Bolivar, Chaman M. Islam and Kevin Brenner; Southern Methodist University, United States

Coherent phonons (CPs) are the collective excitation of specific phonon modes in phase, which ultimately equilibrate into a distribution of thermal phonons (TPs). They are excited with laser absorption on timescales shorter than the phonon period (femtoseconds), and can be described as Raman-like scattering [1]. The device that is often formed around CPs is a resonator. When exciting CPs in a thin film, the interfaces can function as phononic mirrors, creating resonators that are central to many facets of optomechanics [2]. Furthermore, the frequency and quality factor (a measure of coherence) of these resonators determine the temperature at which their quantum ground state may be observed [3]. Layered materials, like transition metal dichalcogenides (TMDs), provide unprecedented control over the interfaces and heterogeneities (layer steps or rotations) that may be applied to tune the resonator's performance. As such, it is important to establish the fundamental relationships between the atomic structure and the decohering or deenergizing of the resonator.

In this work, we present a molecular dynamics (MD) investigation of CPs in multilayer TMDs. MD allows us to capture a wide range of atomistic disorder, and overcome limitations that other (quantum mechanical) methods may have with interfaces or nonbonded interactions. We detail new findings related to three areas of CP resonators in multilayer MoS_2. First, we present details on the manipulation of resonators via the inclusion of layer steps, layer rotations, and dissimilar layers (heterostructures). We provide some of first atomistic details on layer steps within the same resonator producing two physical-coupled yet frequency-decoupled resonances [2]. Second, we present details on the role of substrates in decohering and deenergizing the resonator. This includes how the thermal boundary resistance limits temperature rise (and anharmonic scattering) as CPs decohere into TPs. Third, we present details on ultrafast acoustic effects (Lamb wave generations) that not only leak energy from the resonator, but may also provide a foundation generating coherent in-plane and on-chip quantum signals. This work was partially supported by the Office of Naval Research's Summer Faculty Program, and we gratefully acknowledge discussions with the Naval Research Laboratory [2].

5:00 PM EL09.10.04
Biaxial Strain Engineering of Transition Metal Dichalcogenide Heterostructures Jennifer Toy[1], Healin Im[1,2], Mihir Marathe[1], Chen Chen[3], Sefaattin (. Tongay[4] and Zakaria Al Balushi[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]The Pennsylvania State University, United States; [4]Arizona State University, United States

Van der Waals (vdW) heterostructure stacking of TMD monolayers with other TMD monolayers or organic molecules such as Tetracene have type-II band alignment which encourages the formation of strongly bound interlayer excitons due to the reduction in dielectric screening and increase in coulombic interaction strength. Interlayer excitons have been shown to have increased lifetimes, large binding energies, and permanent dipole moments as opposed to intralayer excitons. These heterostructures are atomically thin in nature which suggests they may be sensitive to mechanical strain which may alter material qualities such as bandgap. While such heterostructures have undergone intense studies to better understand interlayer excitons, the effects of biaxial strain on these interlayer excitons are still unknown. Heterostructures of organic and inorganic materials are particularly interesting because they open a new class of scalable heterostructures which also have interfacial tunability for device applications. Here we have designed and built a versatile biaxial straining platform for in situ Raman and Photoluminescence measurements of strained films. A thin polymer substrate (PET) is indented symmetrically by the platform to induce biaxial tensile strain via the change in the curvature of the substrate. The system is calibrated by mapping the location of features on the PET substrate as a function of indenter displacement. In this work, we will investigate strain induced optoelectronic response through Raman and PL on biaxially strained organic-inorganic heterostructures made from CVD grown material and evaporated organic powders. From these observations, we may better understand the tunability of the interlayer exciton as a function of mechanical strain which may be useful for applications in enhancing properties like band gap and optical density in flexible optoelectronic devices such as light emitters, photodetectors and photovoltaic cells, enabling excitonic devices.

5:00 PM EL09.10.05
Correlation between Defect States and Electrical Properties of InSnZnO/InGaZnO Multi-layered Channel Thin-film Transistor Dong-Joon Yi, Hyunmin Hong, Min Jung Kim, Dong Yeob Shin, Kwangsik Jeong and Kwun-bum Chung; Dongguk University, Seoul, Korea, Korea (the Republic of)

Amorphous oxide semiconductors (AOSs) are promising materials that can replace some usage of conventional silicon-based semiconductors on account of their high optical transmittance, high electron mobility, high uniformity over large areas, and fabrication process under low temperatures. AOSs have been mainly used for display backplane thin-film transistors (TFTs) in the past, but recently their applications using optoelectronic properties are being actively studied. Since the optoelectronic properties of AOSs can be controlled by their chemical composition, AOS can be used for next-generation devices, such as photonic memory devices, solar devices and synaptic devices. AOS-based devices are mainly fabricated with amorphous indium-gallium-zinc-oxide(a-IGZO) because of its high stability and solid electron mobility. But with the advances in electronic device technology, materials with better electric performances, for example, high-mobility amorphous indium-tin-zinc-oxide (a-ITZO), are in demand. However, it is difficult to make versatile devices with a single material, for reasons such as the commonly known mobility-stability trade-off in AOSs. A well-designed multi-layered device is one of the alternatives to solve the problem. It can have several advantages derived from each single material without disadvantages.
By the way, AOSs have intrinsic defect states inside the energy band gap which can affect device properties of AOS TFTs such as mobility, threshold voltage, and stability. Defect states have been usually analyzed with conventional methods like spectroscopic ellipsometry (SE) and X-ray photoelectron spectroscopy (XPS). Because these are qualitative analyses, it is difficult to correlate the defects and electrical properties by conventional methods and alternatives are required. With photovoltaic current and non-linear (NL) optical properties of AOSs, we developed methods that can detect the defects precisely.

Here, we report multi-channel-layered AOS TFT which has multi advantages derived from each channel layer. The channel layer is structured with a high-stability a-IGZO and a high-mobility a-ITZO. Device performance has improved compared to each single-layered TFT. Defect states of the multi-layered semiconductor are analyzed quantitatively by NL optical response and photo-induced current transient spectroscopy (PICTS). By analyzing NL optical signals time-dependently, which came from non-symmetric junctions at the interfaces of the device, we can get information about interfacial defects. And we got precise energy levels and density of the defect states in multi-layered bulk AOSs using PICTS. Then building an electronic-structure model of semiconductors, we could reveal the relations between the defects and electron transport mechanism in semiconductors and also the reason why performances of multi-layered TFT were improved. Based on these results, we propose precise methods to analyze the defects in semiconductors, and also the structure-optimized multi-layered device with outstandingly high mobility and stability.

5:00 PM EL09.10.06
Fully Vacuum-Free and Solution-Processed Phosphorescence OLEDs Based by Using Lamination Process Yejin Kim, Hyuckjin Nam, Yu Seong Lee, Inwoo Lee, Sejung Park and Changhun Yun; Chonnam National University, Korea (the Republic of)

OLEDs already occupy a significant portion of the smartphone and TV markets. Furthermore, OLED is a potential solid-state lighting technology that may be used in complicated lighting designs like smart packaging because it can produce light with the uniform brightness across a wide area. However, the cost of OLED products is still a challenge for those low-cost applications. Around the world, research and development efforts have been made to develop OLED manufacturing processes using solution process and printing process to avoid the pricey high vacuum deposition process. However, although organic semiconductor thin films can be prepared at ambient pressure, the expensive vacuum deposition approach is still required to form a top electrode of an OLED.
In order to dramatically reduce the cost of OLEDs, this study created a manufacturing technique that allows for the formation of a top electrode using a vacuum-free lamination process. A hybrid electrode consisting of the stack of a conductive polymer and a silver nanowire was developed to increase conductivity and transparency. And Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) with a high work function was used as a hole injection layer. For application to highly efficient OLED lighting and displays, it was essential to use phosphorescent dopant as an emissive layer with more than 50 cd/A of luminous efficiency. Therefore, the host material for phosphorescent OLEDs was prepared by combining the polymer host material (Poly(9-vinylcarbazole), PVK) and small molecular hole-/electron- transporting materials, to ensure that the charge balance was properly matched in the light emitting layer. In particular, a study was conducted to optimize the vacuum-free thermal lamination process to enhance the electrical and physical bonding characteristics between the hybrid top electrode and the underlying emissive layer. The glass transition temperature (Tg) of the polymer host material was the key factor in the hot-pressing process. In consideration of the process temperature of the laminator and the Tg of PVK, the rubbery characteristics could be approached by pre-heating the organic layer, which helps the electrical contact between the hybrid electrode and the organic light emitting layer. Through the careful optimization of the process conditions in vacuum-free lamination, a high-efficiency phosphorescent OLED devices with comparable performance with that from the vacuum deposition were developed.

5:00 PM EL09.10.07
Enabling Interface-Dependent Energy Transfer in PbI_2/SnS mixed-dimensional van der Waals Heterostructures Through Contact Geometry Sumin Ji and Neachul Shin; Inha University, Korea (the Republic of)

Heterostructures composed of van der Waals (vdW) layered semiconductor materials have attracted attention due to their anisotropic optoelectronic properties. By leveraging the structural anisotropy of 2D lattice, a new heterostructure configuration in which the vdW layer edges faced with the surface of other layers could provide additional control of exciton/charge transfer at the heterojunction, unlike conventional vertically-stacked or laterally-connected vdW heterostructure geometries. In this sense, the ability to integrate multi-dimensional vdW layered structures with various stacking orientations is of critical importance.
In this study, we report mixed-dimensional heterostructures based on the vdW multilayer semiconductor materials – 1D lead iodide (PbI_2) nanowires and 2D tin sulfide (SnS) flakes and demonstrate that the exciton energy transfer at the heterointerface is dependent on the contact geometry. By employing vapor-liquid-solid (VLS) growth using Pb catalysts, two different types of PbI_2 nanowires oriented in [001] and [010] directions were obtained, where their sidewall facets ({100} and {001} planes, respectively) form distinct contact interfaces with the {001} plane of SnS flakes after dry transfer. Structural characterizations in conjunction with optical analyses, including photo- and cathodoluminescence, revealed that the excitonic excitation in PbI_2 nanowire could be transferred to SnS through its sidewall edges at the heterointerface, which induces luminescence from SnS of which the bandgap is indirect. The vdW contact geometry-dependent energy transfer resulted in a substantial increase in excitonic emission of SnS domains from the heterointerfaces of PbI_2{100}/SnS{001} relative to those of PbI_2{001}/SnS{001}. Furthermore, we confirm that the transferred energy travels along the SnS domain edges efficiently via guided mode. Our results demonstrate a new toolbox for controlling the excitonic emission in vdW layered heterostructures for optoelectronic and nanophotonic applications.

5:00 PM EL09.10.08
Large-Area, High-Specific-Power Photovoltaics from CVD-Grown Monolayer MoS_2 Timothy Ismael[1], Muhammad Aamir Abbas[1], Kazi M. Islam[1], George B. Ingrish[1], Carlos M. Gutierrez[2], Meghan E. Bush[3], Jeremiah S. McNatt[3], Anthony J. Hoffman[3] and Matthew D. Escarra[1]; [1]Tulane University, United States; [2]University of Notre Dame, United States; [3]NASA Glenn Research Center, United States

The future of thin film photovoltaics (PV) requires the continued development of ultrathin materials, including two-dimensional (2D) semiconducting materials like transition metal dichalcogenides (TMDCs). 2D TMDC's exhibit high absorption at sub-nanometer thickness due to their unique properties, which makes them ideal for ultralight, flexible optoelectronics. Their light harvesting capabilities are especially suitable for applications where high-specific-power ultralight components are needed, e.g., in space. In this work, we present an interdigitated asymmetric contact Schottky PV device of 25 mm^2 monolayer MoS_2 suitable for space deployment.
To fabricate the 2D PV device, large-area monolayer MoS_2 film with area > 1 cm^2 is grown using a low cost and scalable chemical vapor deposition (CVD) process, with MoO_3 and sulfur as the precursors. Film uniformity is achieved through quasi-epitaxial growth on an atomically smooth C-plane sapphire substrate. MoS_2 of 1.88 eV bandgap is confirmed using photoluminescence spectroscopy, AFM scans show 0.65 nm film thickness, and Raman spectroscopy spatial mapping confirms 85% monolayer coverage. High quality MoS_2 is confirmed by an external quantum efficiency (EQE) of 25% at 620 nm laser illumination and a carrier mobility of 3.3 cm^2/V.s. Lateral transport, Schottky-junction PV with asymmetric workfunction interdigitated Ti and Pt contacts and monolayer MoS_2 are fabricated, exhibiting 2.2 kW/kg specific power under the standard one-sun AM1.5D spectrum. Hole collector work function (Φ_h) reduction due to Fermi level pinning and sub-nanometer absorber thickness partly account for low power conversion efficiency of 0.0005% in these devices.
This Schottky junction 2D PV device is modeled with COMSOL Multiphysics using measured MoS_2 optoelectronic properties to guide metal contact selection and device design. Improved V_{OC} is obtained by increasing Φ_h, while the J_{SC} is improved by increasing the mobility of the MoS_2 active layer. Model projections show that for a device with Φ_e as 4.33 eV and Φ_h as 5.65 eV, a carrier mobility of 10 $cm^2V^{-1}s^{-1}$ and 1 µs carrier lifetime, 69.9 kW/kg at only 0.02% efficiency is attainable with a 0.65 nm thick MoS_2 monolayer. Ongoing efforts to increase cell performance through enhanced electronic transport and stacking monolayers will lead to higher efficiency ultralight cell arrays, ideal for spacecraft such as a 6U CubeSat.

2D material properties and device performance is significantly affected by defects, such as grain boundaries, due to their atomically thin nature. These defects in CVD synthesized MoS_2 can lead to mid-gap states that lead to undesirable carrier recombination. Large-area mapping of the structural, optical, and electronic properties of the films can lead to the improvement of device design and performance. On-going efforts to understand and improve device performance is being carried out through correlative spatial mapping using imaging, Raman spectroscopy, transmittance, photoluminescence (PL), and photocurrent (PC) spectroscopy. Each mapping technique individually yields insight on the growth uniformity and morphology and their correlations show their influence on the PV device performance.
Further efforts are underway to fabricate these devices on flexible, few-micron thick polyimide substrates. This work includes radiation exposure and testing to confirm survivability of these devices in space. These devices may be packaged into ultralight foldable PV modules for stowed launch and in-space deployment. These ongoing efforts to demonstrate flexible ultra-light 2D PV modules for space missions will be discussed.

5:00 PM EL09.10.09
Growth of Ordered Hexagonal and Monoclinic Thin Layers of $MoTe_2$ on Sapphire and Their Characterisation Lenka Pribusová-Slušná[1], Tatiana Vojteková[1], Jana Hrdá[1], Karol Végso[2], Edmund Dobročka[1], Marian Precner[1], Michaela Sojková[1] and Martin Hulman[1]; [1]Institute of Electrical Engineering SAS, Slovakia; [2]Institute of Physics SAS, Slovakia

Molybdenum ditelluride (MoTe2) is a member of a family of transition metal dichalcogenide compounds. It might be attractive to some applications, including optoelectronics. It adopts three crystallographic structures - hexagonal, monoclinic and orthorhombic. The latter phase creates from the monoclinic one upon cooling bulk MoTe2 below 250 K. On the other hand, the transition temperature might be significantly reduced for MoTe2 layers only a few nanometres thick.
It is now clear that thin layers covering a large substrate area (~ cm^2) are crucial from an application point of view. Not only the size of the layer is essential, but also the crystallinity and arrangement of a thin layer on the substrate determine its (opto)electronic performance.
In our contribution, we address the growth of nanometre-thick MoTe2 layers with hexagonal and monoclinic structures. The layers were prepared by tellurization of predeposited Mo and MoO_3 thin films in a CVD chamber. Mo films 10 nm thick were DC magnetron sputtered on sapphire substrates and subsequently annealed in tellurium vapours at 680°C in the H2/Ar atmosphere and ambient pressure for getting the layers with the hexagonal structure. For the monoclinic phase, an additional step of oxidising the Mo film to MoO_3 at elevated temperature must be added before the tellurisation.
The layers' chemical nature and crystallographic phase were checked by Raman spectroscopy since the two phases exhibit different Raman peaks.
We performed GIWAXS (Grazing Incidence Wide-Angle X-rays scattering) measurements to examine the layer alignment on the substrate. All the samples were grown textured with atomic planes parallel to the substrate. We also completed angular-dependent GIWAXS measurements with samples rotating around the sample normal during the experiment. Intensity variations were recorded with a step of 1° for various diffraction spots of MoTe2 hexagonal and monoclinic lattices. The recognisable maxima in the angular dependence clearly indicate that MoTe2 layers exhibit a long-range order also in the *ab* plane parallel to the substrate. The layers tend to fit into the crystallographic directions of the sapphire substrate's trigonal lattice in an epitaxial manner.
The two phases have distinctly different optical spectra when the samples are about 10 nm thick. The reflectance of the monoclinic sample is almost featureless, with a broad maximum at around 400 nm. It decreases monotonically towards mid-infrared frequencies following approximately a power-law dependence. On the other hand, the reflectance spectrum of hexagonal $MoTe_2$ features several maxima, with a prominent one at about 1200 nm corresponding to an indirect transition in the electronic structure. These findings are complemented by temperature-dependent measurements of thin layers' resistivity. The latter increases with decreasing temperature for the hexagonal phase resembling a semiconductor-like behaviour. In contrast, the monoclinic sample's resistivity steadily decreases upon cooling, showing a metallic-like behaviour.

5:00 PM EL09.10.12
Exciton-Dominant Photoluminescence of MoS_2 by Functionalized Substrate Kyungmin Yang[1], Eunji Ji[2], June-Chul Shin[1], Youngbum Kim[3], Jin-Woo Park[2], Jeongyong Kim[3] and Gwan-Hyong Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Transition metal dichalcogenides (TMDs) have been considered as promising candidates for transparent and flexible optoelectronic devices owing to their large exciton binding energy and strong light-matter interaction. However, monolayer (1L) TMDs exhibited different intensities and spectra of photoluminescence (PL), and the characteristics of their electronic devices also differed in each study. This has been explained in terms of various defects in TMDs, such as vacancies and grain boundaries, and surroundings, such as dielectric screening and charged impurities, which lead to non-radiative recombination of trions, low quantum yield (QY), and unexpected doping. However, it should be noted that the surface condition of the substrate is also a critical factor in determining the properties of TMDs sitting on the substrate. Here, we demonstrate that the optical and electrical properties of 1L MoS_2 are strongly influenced by the functionalized substrate. The PL of 1L MoS_2 placed on the oxygen plasma-treated SiO_2 substrate was highly p-doped owing to the functional groups of –OH on the SiO_2, resulting in a strong enhancement of PL by approximately 20 times. The PL QY of 1L MoS_2 on plasma-treated SiO_2 increased by one order of magnitude. Surprisingly, observed PL spectra shows the suppression of non-radiative recombination by trions, thus the exciton-dominant PL led to the prolong of lifetime in MoS_2 on plasma-treated substrate. The MoS_2 field-effect transistors fabricated on plasma-treated SiO_2 also exhibited a large hysteresis in the transfer curve owing to charge trapping of the functional groups. Our study demonstrates that the functional groups on the substrate strongly affect the characteristics of 1L MoS_2, which provides clues as to why MoS_2 exfoliated on various substrates always exhibited different properties in previous studies.

5:00 PM EL09.10.14
New Functionalized Mixed Si/Ge Nanosheets Amelie M. Mühlbach[1], Bernhard Rieger[1] and Jonathan Veinot[2]; [1]Technical University of Munich, Germany; [2]University of Alberta Edmonton, Canada

Nanosheets based on silicon or germanium exhibit special structural, electronic, and optical properties and are thus considered as promising materials for e.g. field-effect transistors[1], photovoltaic solar cells[2], photodetectors[3], or anode materials in lithium-ion batteries[4]. So-called germanane and silicane are hydrogenated analogues of graphene and are already well explored materials having direct band gaps. Surface functionalization of these nanosheets is known to influence their (opto)electronic properties, prevent the stacking of the nanosheets and in case of silicane avoid the oxidation of the material.[5]
As silicane and germanane are already well known materials, it is of interest to investigate mixed nanosheets consisting of germanium and silicon at the same time. Experimental studies showed that mixed Ge/Si nanosheets can be prepared like germanane and silicane by treatment of the Zintl phase $CaGe_xSi_{2-x}$ ($0 \le x \le 1$) with hydrochloric acid at low temperatures.[6] To the best of our knowledge, functionalization of mixed Ge/Si nanosheets with organic groups is not literature-known yet. We use hydrometalation reactions to functionalize mixed Ge/Si nanosheets with dodecyl groups. Alkylation has been accomplished. Detailed characterization, e.g. *via* FTIR, Raman, PL, DRA and TGA, and comparison of dodecyl-functionalized Si, Ge and Ge/Si nanosheets will show the influence of the functionalization as well as the Ge/Si ratio on the optical and electronic properties of the materials.

Control Se Vacancy of 2D MoSe$_2$ Thin Films Deposited by Plasma Enhanced Atomic Layer Deposition Ji-Min Lee, Jeong-Hun Choi, Dong Geun Kim and Ji-Hoon Ahn; Hanyang University, Korea (the Republic of)

Two-dimensional (2D) transitional metal dichalcogenides (TMDs) have attracted intense interest because of their fascinating electrical, optical and mechanical properties such as high on/off ratio and high carrier mobility. Moreover, the bandgap of TMDs was tunable through control thickness of TMDs. Molybdenum diselenide (MoSe$_2$), one of the TMDs, has a unique property that the carrier type of MoSe$_2$ can be controlled through various post-treatments. N-type characteristics of the MoSe$_2$ field effect transistor (FET) were enhanced after oxygen plasma treatment. Whereas, when Se vacancies increase, MoSe$_2$ FET showed p-type characteristics. Based on these characteristics, there were studies that homo-junction PN diodes and homo-stack channel FET fabricated MoSe$_2$. Meanwhile, in most studies synthesis method of MoSe$_2$ was chemical vapor deposition (CVD) or mechanical exfoliation (ME). There are relatively few studies of MoSe$_2$ deposited atomic layer deposition (ALD). ALD based on the surface limited reaction which allows precise thickness control is a very useful deposition method for TMDs because of the layer-dependent optical properties of TMDs. Therefore, there is an increasing demand for control of carrier type and depositing TMDs with ALD.
In this study, we investigated Se vacancies control of MoSe$_2$ films deposited by plasma enhanced atomic layer deposition (PEALD) according to post-treatment and properties of MoSe$_2$ depending on Se vacancies in films. Pristine MoSe$_2$ film had many Se vacancies because of the low process temperature of ALD. To fill Se vacancies in MoSe$_2$ films, we performed selenization as a post-treatment. After selenization, some of the Se vacancies in MoSe$_2$ films were filled and it was confirmed by Raman spectroscopy. Compared to pristine MoSe$_2$ FET, MoSe$_2$ FET with selenization showed enhanced p-type characteristics and increased on/off ratio. The optical properties and chemical binding states of MoSe$_2$ films were analyzed using by Raman spectroscopy and X-ray photoelectron spectroscopy (XPS).

5:00 PM EL09.10.17
Active Control of Plasmonic-Enhanced Interlayer Exciton Emission with Electrical Modulation Jiasen Zhu[1], Fuhuan Shen[1], Zefeng Chen[2] and Jianbin Xu[1]; [1]Chinese University of Hong Kong, Hong Kong; [2]Soochow University, China

Transition metal dichalcogenides (TMDs) are considered as one of the most promising materials due to their low-dimensionality and novel physical properties. More interestingly, Van der Waals (vdW) heterostructures formed by vertically stacking different materials offer even more optoelectrical properties, associated with the interlayer excitons (IEs) formed in different layers. Due to an offset in alignment of the monolayer band structures (type II heterostructures), the IEs in the heterostructure lie energetically below the excitons confined in each constituent monolayer, and typically exhibit longer carrier lifetime. Understanding and manipulation of the IEs in TMD vdW heterostructures hold great promise for the development of novel optoelectronic devices.
Due to the spatial separation of electrons and holes in different layers, the IEs carry an out-of-plane electric dipole moment, resulting in a significant decrease in the photoluminescence quantum efficiency, which hinders the further applications such as electroluminescence, nano lasers and exciton router, etc. Here, we realize the electrical control of plasmonic enhanced IEs emission in WS$_2$/InSe heterostructure. Around 6-time photoluminescence enhancement from IEs is achieved by sandwiching WS$_2$/InSe heterostructure into a gold mirror and plasmonic disk arrays. Moreover, the vertical electrical field is applied across the heterostructure to realize the active control of the resonance frequency of IEs, where more than 100 meV shift is observed for the IEs resonance. Stronger coupling can be achieved with plasmonic lattice by tuning the resonance frequency of the excitons with electrical modulation. We provide a novel method to control the excitonic processes in TMD heterostructures to build high performance optoelectronics devices.

Integration of Logic and Memory Functionalities Enabled by Asymmetric Dual-Gate Structure Yue Pang, Jianbin Xu and Yaoqiang Zhou; Chinese University of Hong Kong, Hong Kong

Conventional van Neumann computing architecture suffers from the massive time and energy waste due to theseparation of memory and processing units. Logic-in-memory architecture has emerged as an aggressive approach toimprove the computing efficiency, which demands for the higher integration of circuits. However, silicon-based system is facing the challenge of short channel effect, approaching to the limitation of Moore's law. Thus, two-dimensionallayered semiconductors are emerged as candidates for realizing down-scale semiconducting devices. Thanks to theiratom-scale thickness, the absence of dangling bonds and enhanced external field control, dual-gated FET is a practical configuration for more complicated applications. The top gate can be in sole control of the channel or utilized in reconfigurable modulation with a back gate. The top gate can also enhance the crucial parameters of transistors such as carrier mobility, on/off ratio and subthreshold swing value due to the capacitance coupling. Both independent and dependent gate control give rise to the probability in extending logic and memory functionalities of a single device unit.
In this work, we fabricate a two-dimensional field-effect transistor (FET) with an asymmetric dual-gated structure, where the top gate comprises the channel, which fulfils the logic and memory operations, typically in opposition to the common approach. The dual-gated FET(DGFET) is based on vertically stacked MoS$_2$−hBN−In$_2$Se$_3$ van der Waalsheterostructure. First, the DGFET can be functioned as a logic gate. The channel material MoS$_2$ with atomically thin body is sensitive to the electrostatic field, thus dual-surfaced channel and drain/source barriers are modulated by the top and back gates, respectively. The current level in the output presents a logic AND gate performance, giving rise toincrease the circuit density. Second, the DGFET can be operated as a non-volatile memory device. Our as-fabricateddevice exhibits a large memory window (up to 50 V), a high on/off ratio (≈ 10^5) and a long data retention (>80% data storage after 10 years). Also, the DGFET demonstrates the multibit storage state controlled by varying gate voltagepulses. The mechanism of the carrier trapping in the top gate is reported, the asymmetric gate design causes the capacitance coupling between top gate and bottom gate. The writing and erasing processes are original from the combination of capacitance coupling and charge tunneling. Besides, with photogate assisted, logic OR gate can be achieved in the DGFET due to the photo switchable property. The high value of photocurrent provides the feasibility to implement multilevel photo-erasing, and device shows 10 distinct states under different illumination powers and durations.

Revisiting the Burstein-Moss Shift, Bandgap Narrowing and Electron-Hole Effective Masses of Sputtered AZO and ITO Thin Films Erik A. Perez, Kevin Lizarraga, Luis A. Morán, Fabiola Bravo, Jorge Trevejo, Paul Llontop, Miguel Piñeiro and Andres Guerra; Pontificia Universidad Católica del Perú,

Peru

Transparent conductive oxides such as aluminum doped zinc oxide (AZO) and tin doped indium oxide (ITO) have been extensively studied for their use in new generation solar cells [1], gas sensors [2,3], luminescent materials [4], new electroluminescence device concepts [5,6], among others. The degenerated character, wide-bandgap, and the large charge carrier density in the conduction band induces the so-called Burstein-Moss shift, shifting the optical bandgap further into the ultraviolet [7,8]. In this context, recent advances in modeling the direct optical absorption edge considering Urbach tails and excitonic absorption bands, motivates a restudy and contrast of electron and hole effective masses determined by a combination of electrical and optical measurements.

In this work, we study sputtered AZO and ITO thin films with different charge carrier densities without compromising the material stoichiometry. For this, the layers are annealed after deposition at various temperatures in an argon atmosphere. We systematically investigated the variation of the optical bandgap as a function of the charge carrier density and estimate the electron and hole effective masses, as well as the intrinsic bandgap of these materials. The real and complex part of the dielectric function is obtained by ellipsometry measurements and analysis. We proceed to determine the plasma frequency and electron effective mass after each annealing step by means of the Drude and Sernelius [9] models for the free carrier contribution to the dielectric function, reflected in the infrared optical absorption. An increasing electron mass is observed for increasing charge carrier densities. This effect can be associated to a non-parabolic conduction band, which becomes evident due to the degenerated character of these materials. An analytical model that describes this nonparabolicity of the conduction band was used to determine the zero-density effective electron mass [10]. The optical bandgap of each sample is determined from fits of the dielectric function using new available models that consider the contribution of excitonic transitions by means of a band-fluctuations approach.

We perform a comprehensive review and test the available theoretical models that describe the Bandgap Renormalization effect as well as the Burstein-Moss Shift both impacting on the observed optical bandgap. The former is a result of many body interactions between electrons and impurities typically found in degenerated semiconductors leading to a bandgap narrowing, whereas the latter is a consequence of the conduction band occupation as the charge carrier density increases due to the population of low energy levels near the conduction band minimum, thus leading to a widening of the optical bandgap [7,8,11]. Finally, we estimate the hole effective mass and intrinsic bandgap of the studied materials by a simple fit of the optical bandgap as a function of the charge carrier density.

Effect of O_2 Plasma Treatment on the Thickness Uniformity of Chemical Vapor Deposited MoS_2 Thin Films on SiO_2 Substrates Irang Lim and Woong Choi; School of Materials Science & Engineering, Kookmin University, Korea (the Republic of)

Molybdenum disulfide (MoS_2) is extensively investigated as a key element of next-generation thin-film transistors with high carrier mobility and low power consumption. However, for practical application, uniform growth of MoS_2 must be developed on large-area substrates, especially on SiO_2 substrates. Therefore, we investigated the effect of O_2 plasma treatment of SiO_2/p^{++}-Si substrates to enhance the thickness uniformity of chemical-vapor-deposited (CVD) MoS_2 thin films. Raman and atomic force microscopy measurements showed that O_2 plasma treatment of SiO_2 substrates improved the thickness uniformity of CVD MoS_2 thin films. Based on the higher surface reactivity after O_2 plasma treatment suggested by contact angle measurement and X-ray photoelectron spectroscopy analysis, we attribute the enhanced thickness uniformity to the uniform nucleation of CVD MoS_2 thin films. These results demonstrate the effectiveness of using O_2 plasma treatment in improving the thickness uniformity of CVD MoS_2 thin films on SiO_2 substrates, with potentially important implications of growing other two-dimensional semiconductor thin films.

5:00 PM EL09.10.21
Large-Area Spin Coating of 2D Layered Molybdenum Disulfide Ayush S. Gupta[1,1], Healin Im[1,2], Walker E. Browning[1,1], Sela K. Murphy[3], David J. Lewis[4] and Zakaria Al Balushi[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Pasadena City College, United States; [4]The University of Manchester, United Kingdom

Molybdenum disulfide, MoS_2, is a two-dimensional semiconductor with a direct band gap in the monolayer limit, and improved carrier mobility over silicon at nanometer-scale thicknesses. These properties make thin-film MoS_2 especially interesting for potential applications in optoelectronic devices, transistors, and flexible electronics, in addition to catalysis and energy storage. However, integrating MoS_2 into complementary-metal-oxide-semiconductor (CMOS) processes requires the development of a scalable deposition process occurring at temperatures no higher than 450°C. Two methods of producing MoS_2 are chemical vapor deposition (CVD) and mechanical exfoliation, but CVD generally requires a large thermal budget, while mechanical exfoliation is not a commercially scalable process. Instead, spin coating is a deposition technique than can rapidly produce consistent wafer-scale thin films. Here, we demonstrate the spin coating synthesis of uniform MoS_2 films of nanometer-scale thickness on silicon dioxide and sapphire substrates at CMOS-compatible temperatures. The rapid synthesis of large-area MoS_2 films via spin coating has not been demonstrated previously. We use a 0.25 M solution of a xanthate precursor chemical containing both molybdenum and sulfur in dimethylformamide (DMF), showing the feasibility of using a single-source precursor for producing a thin-film compound semiconductor. The spin coating procedure consists of an initial rotation step to form the film, followed by a low-temperature anneal via an integrated heater. We are able to anneal the entire substrate to produce a film of MoS_2, or use a laser to create specific patterns of MoS_2 on the substrate. We also verify that additional techniques such as solution ultrasonication and substrate pretreatment using ozone cause increased wetting of the precursor solution on the substrate surface, leading to improved film coverage and uniformity. Film characterization via Raman spectroscopy has verified the composition and crystallinity of the synthesized thin films. This work represents an important step towards the rapid, scalable synthesis of wafer-scale semiconductor thin films.

5:00 PM EL09.10.22
h-BN Gating Bipolar Junction Phototransistor Based on TMDs Material Doping Concentration Tunable by Gate Effect Sang-Hyeon Lee and Jong-Soo Lee; DGIST, Korea (the Republic of)

Bipolar transistors, also called bipolar junction transistors (BJTs), are one of the most important semiconductor devices. Widely used in high-speed circuits, analog circuits, and power supply applications. Semiconductor P-n junctions are used in electronic and optoelectronic devices. However, signal amplification is difficult in 2D material-based p–n structures. $MoS_2/WSe_2/MoS_2$ are cascaded to the h-BN gate (h-GBT). h-GBT can control the carrier concentration by exploiting structural specificity through selective electrostatic doping. We analyze the behavior of diodes and transistors by controlling the depletion region length as a function of gate bias. Visually identify changes in work function with KPFM and examine changes in the depletion region. The pinch-off phenomenon was observed with different effects on the gate bias depending on the contact area within the material. The diode characteristic indicates the negative gate bias, and the transistor characteristic indicates the positive gate voltage. Detectivity explores the dependence of optical properties on shot and flicker noise. The diode region decreased with increasing power from $3x10^{11}$ Jones at low optical power (0.3 $\mu W/cm^2$) to $9.7x10^{10}$ Jones at high optical power (8 $\mu W/cm^2$). On the other hand, the transistor region has constant detectivity ($9x10^{10}$ Jones) regardless of the optical power. The current gain is 4 in the diode region, and the transistor region is 20. This is because increasing the depletion length of base-WSe2 reduces the recombination rate.

5:00 PM EL09.10.25
Process Optimization to Fabricate Transparent, Highly Conductive Single-Wall Carbon Nanotube Film for Optoelectronic Applications Minji Bak and Woo-Jae Kim; Ewha Womans University, Korea (the Republic of)

For various optoelectronic applications, such as solar cells, displays and wearable sensors, carbon nanotube (CNT) film has been highlighted as an alternative to ITO due to its mechanical stability, electrical conductivity, and optical transparency. Among the many wet and dry methods for fabricating the CNT film, vacuum filtration is one of the simple techniques that doesn't need complicated equipment and can be readily scaled up. However, to obtain high-performance conductive film, the involved factors in the entire preparation and film fabrication process must be well coordinated. Numerous factors influence film performance, ranging from CNT synthesis to dispersion, purification, and filtering operation, and each factor are interrelated or dependent on the others. CNTs are one-dimensional materials, and therefore, the transport of electrons in the film is hindered or promoted depending on which CNTs are used and how the CNTs connected in the film, which ultimately affects the conductivity of the prepared CNT film. Those parameters can be subdivided; basic features of CNT walls including diameter, length and degree of damage on the wall, depending on the synthesis method; suspension pretreatment of CNTs including surfactant choice, dilution concentration, degree of dispersion and centrifugation, resulting in functionalization or additional defect of the wall; electronic configuration of CNT films including metallic, semiconducting properties of CNTs and their ratio, which can be controlled by various CNT separation methods; filtering conditions including filtering flow rate, loading volume and filter choice, resulting in CNT alignment and ordering of CNTs in film. In this study, we investigated these four major parameters: CNT synthesis method, suspension pretreatment, electronic configuration of CNT, and film filtering conditions, in the fabrication of CNT films using vacuum filtration. we revealed key factors in improving film’s conductivity: the diameter of individual CNT walls sufficient to form contact between each wall, low structural defect of CNTs and alignment of CNTs in film. Based on this, we produced highly conductive CNT film with locally aligned domains in which the structural defects of the CNTs in the loaded CNT suspension were effectively controlled, so that the electrical properties of the CNTs could be maximized.

Adsorption and Diffusion of B and N atoms on Ni (111) and O-incorporated Ni (111) Surfaces Hector Gomez, Yuan Li, Yanwei He, Tianchen Yang, Chengyun Shou, Roger Lake and Jianlin Liu; University of California, Riverside, United States

Two-dimensional (2D) hexagonal boron nitride (h-BN) has recently emerged as a superior inorganic material in nanoscale devices owing to its electrical, optoelectronic, and thermal properties. Nevertheless, the growth of high-quality films via epitaxy is challenging and, as a result, applications beyond the research lab are limited. However, altering the substrate properties can significantly influence the growth mechanisms to achieve high-quality films. Here, we investigate the influence of oxygen incorporation into Ni (111) surfaces and model the adsorption/diffusion energy barriers of B/N atoms utilizing density functional theory (DFT). Our results, in agreement with the experiment, demonstrate an increased activation energy in oxygen incorporated Ni (111) compared to the bare Ni (111) surface, which corroborates the observed inhibited growth of h-BN monolayer films.

Nonclassical Exciton Interactions in a 2D Semiconductor Xiao-Xiao Zhang; University of Florida, United States

The strong exciton binding in monolayer semiconductors of transition metal dichalcogenides gives rise to intriguing excitonic interactions that are unavailable in other semiconducting systems. The conventionally-studied bright excitons have short lifetimes below 10 ps at low temperatures, and the strong non-equilibrium limits the investigation of exciton-exciton interactions. In this talk, we will discuss the nonlinear excitonic response of long-lived dark excitons at low temperatures. With ultrafast laser excitation, exciton dynamics deviate from the classical scattering model. We will also talk about their unique magnetic field response and temperature dependence.

9:00 AM EL09.11.02
Ultrafast Carrier Dynamics and Layer-Dependent Carrier Recombination Rate in InSe Ting-Hsuan Wu[1,2], Hao-Yu Cheng[1,2,3], Wei-Chiao Lai[2], Raman Sankar[2], Chia-Seng Chang[1,2] and Kung-Hsuan Lin[2]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan; [3]Taiwan International Graduate Program, Academia Sinica, Taiwan

InSe layered semiconductors with high mobility have advantages over transition-metal dichalcogenides in certain device applications. Understanding carrier dynamics, especially around the bandgap, is important for fundamental scientific interest and for improving the performance of devices. Here, we investigated ultrafast carrier dynamics in exfoliated InSe by using time-resolved pump-probe spectroscopy. We found that a shrinkage of optical bandgap ~30 meV within 20 ps, attributed to the thermalization of hot carriers via the band-filling effect and bandgap renormalization. The understanding of hot carrier dynamics and photoinduced changes on the bandgap is important for optoelectronic devices such as hot carrier photovoltaics and photodetectors. In addition, we observed the carrier recombination rate increased when the thickness of InSe nanoflakes decreased, dominated by surface recombination. For the same flake, the recombination rate becomes larger after the freshly exfoliated InSe is oxidized in the air. Layer-dependent surface recombination velocities could be obtained by using a free carrier diffusion model. Since carrier recombination is associated with light emitting efficiency, photoconductivity, and carrier mobility of devices, our findings indicate the number of layers plays an important role in the device performance.

9:15 AM EL09.11.03
Resonance Energy Transfer from ML-WS_2 to a Near Infrared Organic Dye Sylke Blumstengel[1,2], Nicolas Zorn Morales[1,2], Nikolai Severin[1], Emil J. List-Kratochvil[1,2] and Stefan Kirstein[1]; [1]Humboldt-Universität zu Berlin, Germany; [2]IRIS Adlershof, Germany

Van der Waals hybrid structures consisting of 2D transition metal dichalcogenides (TMDC) and organic molecules hold the promise to benefit from synergy effects that can improve optoelectronic properties and provide new functions. In this contribution we discuss incoherent resonance energy transfer (RET) from monolayer (ML) WS_2 to a highly photostabile organic dye molecule that converts the TMDC luminescence to the near infrared spectral range and enhances the light output. The dye features a narrow-band absorption spectrum with negligible overlap with the ML-WS_2 absorption so that dye and TMDC can be individually optically addressed. Time correlated single photon counting reveals that about 70% of the excitons created initially in ML-WS_2 are transferred to the dye molecules. The transferred excitons produce photoluminescence (PL) of the dye molecule which is proven by PL excitation spectroscopy. Photoelectron spectroscopy shows furthermore that the hybrid interface is of type I so that quenching of the luminescence due to interfacial exciton dissociation is avoided. As a result, the total PL yield in hybrid sample is about ten times larger than that of pristine ML-WS_2 since the RET process competes favorable with non-radiative recombination in the TMDC. As a consequence, a large fraction of the excitons, which would undergo non-radiative recombination in ML-WS_2 are converted into radiative excitons of the dye molecule. Key hereby is the high PL quantum yield of the molecules. Due to the close proximity of donor and acceptor both Förster and Dexter transfer can contribute to RET so that not only bright but also dark states of the TMDC can be involved in the RET process. Due to the short interaction length (< 5 nm) and the negligible spectral overlap of the TMDC and dye absorption, the RET process can be used to read out locally the optical properties of TMDCs with an unrivaled spatial resolution. In respect to practical applications, our findings pave the way for electrically driven nanoscale light source based for example on a TMDC split gate field-effect transistor geometry with tunable light output.

Imaging the Electron Charge Density in Monolayer MoS_2 at the Ångstrom Scale Joel Martis[1], Sandhya Susarla[2], Archith Rayabharam[3], Cong Su[4], Timothy Paule[4], Philipp M. Pelz[5], Cassandra Huff[1], Xintong Xu[1], Hao-Kun Li[1], Victoria Chen[1], Marc Jaikissoon[1], Eric Pop[1], Krishna Saraswat[1], Alex Zettl[4], Narayana R. Aluru[6], Ramamoorthy Ramesh[7], Peter Ercius[8] and Arun Majumdar[1]; [1]Stanford University, United States; [2]Arizona State University, United States; [3]University of Illinois at Urbana-Champaign, United States; [4]University of California, Berkeley, United States; [5]FAU Erlangen, Germany; [6]The University of Texas at Austin, United States; [7]Rice University, United States; [8]Lawrence Berkeley National Laboratory, United States

The distribution of electrons around atoms determines the emergent properties of matter. While techniques such as x-ray scattering provide atomic scale electron charge densities averaged over many unit cells and a large area, real space charge density imaging at the atomic scale is of great importance to understand the effects of perturbations such as defects, dopants, edges and grain boundaries.

Four Dimensional Scanning Transmission Electron Microscopy (4D STEM) center of mass (CoM) imaging is a real space imaging technique that has been shown to reveal atomic electric fields and charge densities[1,2]. In 4D STEM, at each probe position on the sample, the entire electron scattering (diffraction) pattern is acquired using a high speed camera[3,4,5,6]. The CoM of the diffraction pattern is then computed at each probe position to arrive at the electric field and charge density[2]. These electric fields and charge densities, however, represent the combined effect of the nucleus,core electrons and valence electrons, and separating them is non-trivial. Here we utilize simulataneously acquired 4D STEM CoM and annular dark field (ADF) images to derive the electron charge density in monolayer MoS2.

MoS2 is a 2D semiconductor of great interest because of its potential applications in optoelectronics and catalysis[7,8]. Using the ADF image, we derive the nuclear charge in MoS2 and subtract it from the net charge (derived from CoM imaging) to obtain the electron charge density. We show via DFT and STEM simulations that the electron probe shape significantly blurs the valence electron charge density, and most of the contrast in the image comes from the core electrons. We show that probe aberrations and incoherent effects contribute to the blurring induced by the probe. Our work highlights the importance of the probe shape in interpreting 4D STEM charge density images.

Chemical and Optoelectronic Control of $Ti_3C_2T_x$ MXene via Covalently-Tethered Organic Monolayers Julia Martin[1], Erika Colin-Ulloa[1], Andrew Fitzgerald[1], Kateryna Kushnir[1], Rebecca R. Ramthun[1], Kiana Montazeri[2], Mary Hassig[2], Ken Ngo[3], Joshua R. Uzarski[3], Michel Barsoum[2], Lyubov V. Titova[1] and Ronald L. Grimm[1]; [1]Worcester Polytechnic Institute, United States; [2]Drexel University, United States; [3]U.S. Army Research Laboratory, United States

Two-dimensional MXenes have demonstrated promising results in catalysis, battery storage, electromagnetic shielding, and more, however, these materials tend to oxidize which has devastating impacts on overall performance. Passivation against oxidation as well as precise control over the chemical terminations and optoelectronic behavior is critical for scalable, widespread applications. Herein, we functionalized exfoliated MXene ($Ti_3C_2T_x$) surfaces with organosilanes to change local electron density based on the inclusion of electron-donating or electron-withdrawing groups. Ultraviolet photoelectron spectroscopy (UPS) quantified valence-band and Fermi energies for the resulting derivatized $Ti_3C_2T_x$ thin films. UPS reveals 1 eV shifts in band-edge positioning based on interfacial dipoles resulting from covalent organosilane attachment. Moreover, a combination of transient absorption (TA) and terahertz (THz) spectroscopy characterize the interplay between surface chemistry and the resulting changes in electronic structure and carrier dynamics. These results inform current research efforts which aim to exploit chemical and optoelectronic tunability via mixed organic monolayers with orthogonal reactivities at $Ti_3C_2T_x$ edges versus terraces. Candidate molecular organics to impart passivation against oxidatation, optoelectronic tunability, and chemical handles for tethering to polymers and other surfaces include silanes, catechols, and alkyl triphosphates as well as polyanionic salts. We discuss these results in the context of electromagnetic shielding, catalysis, chemical sensing, and energy applications

SESSION EL09.12: Light-Matter Interactions in Layered Optoelectronic Materials

1:30 PM *EL09.12.01
Polaritonics and Nano-Photonics with van der Waals Materials Alexander Tartakovskii; University of Sheffield, United Kingdom

We present an overview of our work on nonlinear phenomena in trion-polarion system in strongly doped monolayer $MoSe_2$ exhibiting spin-selective strong light-matter coupling, and observation of nonlinear dipolar excitons and polaritons in bilayer MoS_2. We also report on a novel approach for controlling light-matter interaction using a nanophotonic platform utilizing an emerging class of layered van der Waals (vdW) crystals.

Strong coupling between light and the fundamental excitations of a two-dimensional electron gas (2DEG) is of foundational importance both to pure physics and to the understanding and development of future photonic nanotechnologies. Here we study the relationship between spin polarization of a 2DEG in a monolayer $MoSe_2$ and light–matter interaction in an optical microcavity. We find pronounced spin-susceptibility of the 2DEG to simultaneously enhance and suppress trion-polariton formation in opposite photon helicities. This results in a giant effective valley Zeeman splitting for trion-polaritons (g-factor of >20), exceeding the purely trionic g-factor by a factor of 5. We observe effective optical nonlinearity arising from the highly nonlinear behaviour of the valley-specific strong light–matter coupling regime, and allowing all-optical tuning of the polaritonic Zeeman splitting from 4 meV to 10 meV by using low-power cw laser depolarizing the electrons via formation of the trions.

In another experiment, we consider nonlinear interactions between excitons strongly coupled to light, which are key for accessing quantum many-body phenomena in polariton systems. Here, atomically-thin two-dimensional semiconductors provide an attractive platform for strong light-matter coupling owing to many controllable excitonic degrees of freedom. Among these, the recently emerged exciton hybridization opens access to unexplored excitonic species, with a promise of enhanced interactions. We employ hybridized interlayer excitons (hIX) in bilayer MoS_2 to achieve highly nonlinear excitonic and polaritonic effects. Such interlayer excitons possess an out-of-plane electric dipole as well as an unusually large oscillator strength allowing observation of dipolar polaritons(dipolaritons) in bilayers in optical microcavities. Compared to excitons and polaritons in MoS_2 monolayers, both hIX and dipolaritons exhibit about 8 times higher nonlinearity, which is further strongly enhanced when hIX and intralayer excitons, sharing the same valence band, are excited simultaneously. This gives rise to a highly nonlinear optical regime which we describe theoretically by introducing a concept of hole crowding.

In the last part, we study multilayer van der Waals structures in order to realize novel nanophotonic structures. We extract the dielectric response of 11 mechanically exfoliated thin-film (20-200 nm) van der Waals crystals, revealing high refractive indices up to n = 5, pronounced birefringence, sharp absorption resonances, and transparency windows from ultraviolet to near-infrared. We fabricate nanoantennas on SiO_2 and gold utilizing the compatibility of vdW thin films with a variety of substrates. We observe pronounced Mie resonances allowing observation of the strong exciton-photon coupling regime as well as previously unobserved high-quality-factor, hybrid Mie-plasmon modes on gold. We demonstrate further vdW-material-specific degrees of freedom in fabrication by realizing nanoantennas from stacked twisted crystalline thin-films, enabling control of nonlinear optical properties as well as post-fabrication nanostructure pick-up and transfer on another target substrate.

Conversion of Classical Light Emission from a Nanoparticle-Strained WSe_2 Monolayer into Quantum Light Emission via Electron Beam Irradiation David Xu, Albert Vong, Dmitry Lebedev, Riddhi Ananth, Alexa Wong, Paul Brown, Mark C. Hersam, Chad Mirkin and Emily Weiss; Northwestern University, United States

Solid-state single photon emitters (SPEs) within atomically thin transition metal dichalcogenides (TMDs) have recently attracted interest as scalable quantum light sources for quantum photonic technologies. Among TMDs, WSe_2 monolayers (MLs) are promising for the deterministic fabrication and engineering of SPEs using local strain fields. The ability to reliably produce isolatable SPEs in WSe_2 is currently impeded by the presence of numerous spectrally overlapping states that occur at strained locations. Here we employ nanoparticle (NP) arrays with precisely defined positions and sizes to deterministically create strain fields in WSe_2 MLs, thus enabling the systematic investigation and control of SPE formation. Using this platform, electron beam irradiation at NP-strained locations transforms spectrally overlapped sub-bandgap emission states into isolatable, anti-bunched quantum emitters. The dependence of the emission spectra of WSe_2 MLs as a function of strain magnitude and exposure time to electron beam irradiation is quantified and provides insight into the mechanism for SPE production. Excitons selectively funnel through strongly coupled sub-bandgap states introduced by electron beam irradiation, which suppresses spectrally overlapping emission pathways and leads to measurable anti-bunched behavior. Our findings provide a strategy to generate isolatable SPEs in 2D materials with a well-defined energy range.

3:00 PM EL09.12.06
Site-Controlled Coupling Between Plasmonic Nanostructures and Strain-Localized Excitons in Nano-Indented WSe_2 Nicholas Proscia, Blake S. Simpkins, Samuel W. LaGasse, Dante J. O'Hara, Hsun Jen J. Chuang, Kathleen M. McCreary, Igor Vurgaftman, Berend Jonker and Paul D. Cunningham; U.S. Naval Research Laboratory, United States

Localized excitons can be deterministically created in 2D transition metal dichalcogenides (TMDs) via strain engineering, which modifies the local band structure. It has been shown that strain-localized excitons in TMDs give rise to site-controlled single photon emission, [1-3] which is of interest for quantum information and communications applications. This is of particular technological relevance given that TMDs are sensitive to environmental perturbations and can carry spin information through their valley occupancy. These discoveries have led to recent interest in coupling these strain localized quantum emitters to photonic structures,[4,5] to influence the emission properties and create on-chip-compatible platforms. Strong coupling to plasmonic nanostructures and cavities is a pathway to coherent control at room temperature.[6] However, all prior attempts to couple strain localized excitons in TMDs to plasmonic structures have remained in the weak coupling regime characterized by Purcell enhancement of quantum emission.[7,8]

Here we achieve site-controlled coupling between a localized surface plasmon resonance (LSPR) and the strain-localized excitons in WSe_2. We employ a nano-indentation technique using an atomic force microscope (AFM) to create on-demand spatially localized excitons that display quantum emission.[9] These nano-indentations are co-located above Au plasmonic discs that host LSPRs. The exciton-plasmon coupling is characterized by the familiar mode-splitting of the scattering spectra near the exciton wavelength, indicating fast energy exchange between the two systems. The LSPR wavelength is tuned via the plasmonic disc diameter in order to map the avoided crossing between the LSPR and localized exciton absorption resonance. The observed coupling strength approaches the strong coupling regime at room temperature. Our results establish this system as a potential platform for novel quantum light sources in which to study coherent control as well as nonlinear exciton-plasmon polariton behavior.

Strain Tunable Optoelectronic Devices Based on Crumpled Graphene/Organic Semiconductor Heterostructures Zhichao Zhang[1] and SungWoo Nam[2,1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of California, Irvine, United States

The past few years have witnessed a rapid growth of graphene and organic semiconductor heterostructure in photodetecting applications. Stacking Graphene with organic semiconductor can result in a synergetic effect integrating the advantages of both materials, including high carrier mobility of graphene, efficient light absorption of organic semiconductors and potential capabilities to engineer organic semiconductor growth or interfacial charge transfer. Despite these substantial potentials, the effects of mechanical strains on the optoelectronic properties of the heterostructure remain unexplored. In this work, we introduced crumples into a heterostructure of graphene and a thin film of organic conjugated polymer (PDPP2T-TT-OD), investigating the effects of different strains (tensile/compressive) on their energy states as well as on the photoresponse. The crumples were formed by releasing pre-strains in an elastomeric substrate with heterostructure on top, and local tensile (compressive) strains were formed at the apex (valley) of the crumples. It was observed that the strains were capable of tuning the energy band structure of organic semiconductor as well as the work function of graphene, and the modulation facilitated charge carrier injections from organic layer to graphene. The modulation of energy states also contributed to a three-fold enhancement of photoresponsivity compared with flat control samples. This work provides a new perspective on strain engineering of graphene-organic semiconductor heterostructure and suggests new strategies in improving the performance of optoelectronic devices.

Layered Hexagonal Metal Oxides Derived From the Metal-Gas Interface – Adding Oxides to 2D Toolkit Jian Zhen Ou and Bao Yue Zhang; RMIT Univ, Australia

Metal oxides – one of the most abundant substances in nature, are rarely found to be naturally layered crystal. Such intrinsic property hinders their potential to form into two-dimension (2D), since the cleavage of the weak, interlayer van der Waals bonds in layered bulk crystal serves as the benchmark to obtain the atomically thin high-quality 2D layers such as ZnO. 2D-like non-layered metal oxides are usually created *via* a space-confined-growth or soft-chemically exfoliation of unilamellar bulk crystal, in which external ionic groups are necessary for crystal stabilization. Here we present our recent discovery of a series of the layered metal oxides with a unique planar hexagonal phase which can be formed across a wide variety metallic element, including transition metals, post-transition metals, lanthanides and metalloids. These oxides can naturally grow on the metallic surfaces under a controlled oxidation environment without involving sophisticated equipment or other chemicals. Subsequently, the hexagonal 2D metal oxide monolayers can be exfoliated on a substrate in a mechanical manner with ease, similar to the way of obtaining graphene and other layered metal chalcogenides. We have showcased the hexagonal TiO_2 as a representative to reveal the distinct properties of such hexagon coordinated oxides apart from their bulk counterparts. The monolayered and few-layered hexagonal TiO_2 shows p-typed semiconductor behavior with the hole mobility up to 950 $cm^2V^{-1}s^{-1}$ at room temperature. This research findings can possibly expand the exploration of metal oxides in the 2D quantum regime and initiate numerous applications in the future.

Interface Engineering with 2D Perovskites and 2D Carbon Based Systems—The Effects on the Device Efficiency and Stability Giulia Grancini; University of Pavia, Italy

Three-dimensional (3D)/low-dimensional (LD) perovskite solar cells (PSCs) offer an effective strategy to overcome the trade-off between perovskite solar cells device performance and stability. Improving the device longevity, while concomitantly simultaneously enhancing increasing the solar cell open circuit voltage and fill factor of the solar cell is the current challenge. Despite being one of the most popular and effective way processing techniques, whether the presence of this surface LDP layer would be - or not-represents the winning crucial path for the future of this technology remains elusive. In particular, atomic layer combined surface and bulk passivation using surface modifiers such as organic dopants, casts the doubts on the effective need for of having an homogeneous LDP cover capping layer. In this talk, I will discuss the interfacial passivation with different cations such as M-PEAI, M-PEABr, and M-PEACl, showing the role of the passivation and how different halides affect the device performance of the devices. In addition, I will discuss the use of low-dimensional carbon based systems - such as graphene monolayers- as additional interfacial modifiers on top of the 2D perovskites.. I will providing a comprehensive perspective on the benefits from of the passivation strategies, showing the effects on the interface processes such as charge transport[1,2].

Acknowledgements I acknowledge the “HY-NANO” project that has received funding from the European Research Council (ERC) Starting Grant 2018 under the European Union’s Horizon 2020 research and innovation programme (Grant agreement No. 802862).

Electron-Phonon Coupling and Coherent Phonon in Thin Film $LaCoO_3$ on $SrTiO_3$ Wenjie Hao[1,2], Minghui Gu[1,3], Zhenyun Tian[1], Shaohua Fu[1], Meng Meng[1,3], Hong Zhang[2], Jiandong Guo[1,3] and Jimin Zhao[1,3,4]; [1]Institute of Physics, Chinese Academy of Sciences, China; [2]Sichuan University, China; [3]School of Physical Sciences, University of Chinese Academy of Sciences, China; [4]Songshan Lake Materials Laboratory, China

We employ ultrafast pump-probe spectroscopy to investigate the excited state photo-carrier dynamics in a tensile-strained thin film of $LaCoO_3$ on $SrTiO_3$ substrate. Through varying-fluence ultrafast relaxation dynamics, we obtain $\lambda\langle\Omega^3\rangle / \langle\Omega\rangle$ of $LaCoO_3/SrTiO_3$ to be $294.9 \pm 15.2\ ps^{-2}$ corresponding to a nominal electron phonon coupling constant value of $\lambda_{Eg} = 0.97 \pm 0.05$. Furthermore, a fluence-dependent coherent acoustic phonon with a central frequency of 45.21 GHz is ultrafastly generated and detected. We attribute its origin to the ultrafast light pulse induced transient thermal strain.

9:15 AM EL09.13.05
Optoelectronic Signatures of Positive and Negative Polarons in Two-Dimensional Lead Chloride Perovskites David R. Graupner and Dmitri Kilin; North Dakota State University, United States

Lead halide perovskites are of interest for light-emitting applications due to the tunability of their bandgap across the visible and near-infrared spectrum (IR) coupled with efficient photoluminescence quantum yields (PLQY). It is widely speculated that photoexcited electrons and holes spatially separate into large negative (electron) and positive (hole) polarons. Polarons are expected to be optically active, with the observed optoelectronic signatures expecting to show potential excited states within the polaronic potential well. From the polaron excited-state we predict that large polarons should be capable of spontaneous emission, photoluminescence, in the mid-IR to far-IR regime based on the concept of inverse occupations within the polaron potential well. Here we use density functional theory (DFT) based calculations using a two-dimensional Dion-Jacobson lead chloride perovskite atomistic model as a host material for either negative or positive polarons to examine the polaronic effects. Nonadiabatic couplings are computed to allow for dynamically coupling electronic and nuclear degrees of freedom allowing us to explore nonradiative relaxation of excited polaronic states. Radiative relaxation of excited polaronic states is found from Einstein coefficients for spontaneous emission. PLQY is used to determine the efficiency of polaron emission using rates of nonradiative recombination (k_{nr}) and radiative recombination (k_r) as $k_r/(k_r+ k_{nr})$.

9:20 AM EL09.13.06
Establishing Charge-Transfer Excitons in 2D Perovskite Heterostructures Jia Zhang; Linköping University, Sweden

Charge-transfer excitons (CTEs) immensely enrich the property-tuning capabilities of semiconducting materials. However, such concept has been remaining an unexplored topic within halide perovskite structures. Here, we report that CTEs can be effectively formed in heterostructured 2D perovskites prepared by mixing PEA_2PbI_4:PEA_2SnI_4, functioning as host and guest components. Remarkably, a broad emission can be demonstrated with quick formation of 3 ps but prolonged lifetime of about 5 µs. This broad PL presents the hypothesis of CTEs, verified by the exclusion of lattice distortion and doping effects through demonstrating double-layered PEA_2PbI_4/PEA_2SnI_4 heterostructure when shearing-away PEA_2SnI_4 film onto the surface of PEA_2PbI_4 film by using hand-finger pressing method. The below-bandgap photocurrent indicates that CTEs are vital states formed at PEA_2PbI_4:PEA_2SnI_4 interfaces in 2D perovskite heterostructures. Electroluminescence shows that CTEs can be directly formed with electrically injected carriers in perovskite LEDs. Clearly, the CTEs presents a new mechanism to advance the multifunctionalities in 2D perovskites.

Low-Temperature Synthesis of MoS2 by Plasma-Assisted CVD for Transparent Transistors Arindam Bala, Anamika Sen, Yongin Cho and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

MoS_2-based transparent electronics can transform state-of-the-art display technology. The low-temperature synthesis of MoS_2 below the softening temperature of low-cost glasses is a crucial requirement. In this study, plasma-enhanced chemical vapor deposition is employed to synthesize large-area bilayer MoS_2 on an inexpensive microscopic glass (area $\approx 27\ cm^2$). A 7 × 7 array of top-gated thin film transistors (TFTs) with Al_2O_3 dielectric are fabricated. Additionally, the performance of TFTs is assessed under irradiation of visible light and estimated performance parameters, such as photoresponsivity, which is found to be $27\ A\ W^{-1}$ (at λ= 405 nm and an incident power density of $0.42\ mW\ cm^{-2}$). The stable and uniform photo-responsive behavior of transparent MoS_2 TFTs can facilitate the fabrication of transparent image sensors in the field of optoelectronics

8:00 AM EL09.14.01
Electrically Gate-tunable Two-dimensional Schottky Diode Enabled by Asymmetric Semimetal Contacts Yaoqiang Zhou, Lei Tong, Yue Pang and Jianbin Xu; The Chinese University of Hong Kong, Hong Kong

Two-dimensional (2D) materials are envisaged to extend Moore's Law and ultimate the down-scaling transistor due to their ultra-thin bodies and dangling-bong-free surfaces. Compared to conventional silicon device, the 2D transistor also show a unique doping-free polarity control (p-type or n-type) which is achieved by contact engineering. These 2D transistors are regarded as the Schottky-barrier-field-effect transistor (SBFET) in which the selective carrier injection of holes or electrons is determined by the Schottky barrier formed at the metal/semiconductor (MS) interfaces. However, the SBFETs usually show intrinsic ambipolar behaviors which limit their applications in low-power consumption electronics due to the relatively low on/off ratio and high leakage current in the off state.
The optimization of contact materials of 2D SBFETs is the efficient approach to achieving the ambipolar to unipolar polarity conversion and suppressing off-state leakage current, but it is hindered by the Fermi level pinning (FLP) effect. Emerging 2D layered semimetals such as graphene and WTe_2 provide a state-of-the-art approach to building the van der Waals MS interface and optimizing the performance of 2D SBFET due to the immunity to FLP effect. Here, we report on a unipolarity-tunable WSe_2 SBFET with asymmetric semimetal WTe_2 and graphene contacts, in which the WTe_2 was synthesized by the one-step $MoTe_2$ epitaxial growth. By using the graphene/WTe_2 asymmetric contacts, the WSe_2 SBFET shows the arbitrary carrier polarity determined by the drain bias. The leakage currents of SBFET were effectively suppressed to below 10^{-13} A and showed the controllable I_{ds} on/off ratios with a maximum of 10^6. Benefiting from the immunity to the FLP effect, the n-type and p-type contact formed through applying positive and negative source-drain voltage V_{ds}: An electron Schottky barrier height $\Phi_{B\text{-}n}$= 90 meV and a hole Schottky barrier height $\Phi_{B\text{-}p}$= 140 meV was achieved when V_{ds} = 1V and V_{ds} = -1V, respectively. The SBFET can work as the gate-modulated Schottky rectifier showing the near-unity ideality factors of ~1.0, an ultralow reverse tunneling current of 10^{-15} A, and a high rectifying ratio of 3×10^6. Furthermore, with electrically gate-tuned band engineering, the asymmetric SBFET showed a reconfigurable photovoltaic performance in which the sign of the responsivity and external quantum efficiency be substantially tuned. This WTe_2/graphene contact strategy is generally applicable to other 2D materials such as WTe_2/MoS_2 gate-tunable n-type Schottky diode. This general modulating approach of carrier injection in 2D materials provides an alternative method to reduce the logic-circuit complexity and enhance the performance of the reconfigurable photodetector.

The work is in part supported by Research Grants Council of Hong Kong, particularly, via Grant Nos. AoE/P-701/20, 14206721, N_CUHK438/18, RGC Postdoctoral Fellowship, and CUHK Group Research Scheme.

SESSION EL10.01: Neuromorphic Molecular Devices
Session Chairs: Christian Nijhuis and Yoeri van de Burgt
Wednesday Afternoon, April 12, 2023
Moscone West, Level 3, Room 3014

1:30 PM *EL10.01.01
Organic Neuromorphic Electronics for Sensory Coding and Biohybrid Systems Yoeri van de Burgt; Eindhoven University of Technology, Netherlands

Neuromorphic engineering is inspired by the efficiency of the brain and focusses on how to emulate and utilise its functionality in hardware. Organic electronic materials have the potential to operate at the interface with biology and offer promising solutions for the manipulation and the processing of biological signals with potential applications ranging from efficient artificial intelligence systems and bioinformatics to brain-computer-interfaces and smart robotics.

This talk describes state-of-the-art organic neuromorphic devices and provides an overview of the current challenges in the field and attempts to address them. I demonstrate two device concepts based on novel organic mixed-ionic electronic materials and show how we can use these devices in trainable biosensors and smart autonomous robotics.

Next to that, organic electronic materials have the potential to operate at the interface with biology. This can pave the way for novel architectures with bio-inspired features, offering promising solutions for the manipulation and the processing of biological signals and potential applications ranging from brain-computer-interfaces to bioinformatics and neurotransmitter-mediated adaptive sensing. I will highlight our recent efforts for such hybrid biological memory devices.

2:00 PM *EL10.01.02
Stable Universal Logic Gates Using a Single-Molecule Ran Liu[1,2], Enrique del Barco[1] and Christian A. Nijhuis[3]; [1]University of Central Florida, United States; [2]University of Georgia, United States; [3]University of Twente, Netherlands

Since the discrete orbitals of molecules can provide multiple distinguishable electrical states, controllable single-molecule devices stand as ideal candidates for ultra-simple circuit elements to perform high-density computations. However, the expansion of the energy levels of molecular orbitals (MOs) by the electrodes and the effect of the external potential on the absolute value of the energy levels make it difficult to build stable multifunctional devices based on the precise manipulation of MOs. Our recent study found that gated Au/S-$(CH_2)_3$-Fc-$(CH_2)_9$-S/Au (Fc=ferrocene) single-electron transistors (~2 nm) not only hold the advantage of controlling MOs via orthogonal bias (Vb) and gate (Vg) voltages, but also exhibit a unique electronic structure with two stable adjacent conductive MOs. With the $(CH_2)_n$ ($n >= 3$) chain effectively isolating the Fc from the gold electrodes, the MOs of the Fc moiety display narrow energy levels, allowing a clear current change as the energy level enters and leaves the bias window. Built upon the diamond-shaped Coulomb blockade response, a prototype single-electron logic calculator was proposed, implementing all universal 1- and 2-input logic gates within a single-molecule device. In addition, the asymmetry of the molecule leads translates into an asymmetric Coulomb blockade response, enabling switching the logic gate function by changing the bias direction.

2:30 PM *EL10.01.03
Mechanically Controlled Molecular Photoswitching Realized by Aggregation-Induced Emission Yuan Li; Tsinghua University, China

Molecular switches, which the electrical signal of conductance or voltage can be manipulated by external stimuli, have drawn great attentions recently, with photoswitches the most widely studied due to their theoretically ultrafast switching speed. While light provides a natural, addressable and tunable driving force, molecular photoswitches still suffer poor performance with low on/off ratio of electric current, poor reproducibility, or stochastic switching. One of the reasons is that all the photoswitches with on/off ratio more than 100 are based on the mechanism of molecular photoisomerization, which of the energy barrier is high and not able to provide reproducible fast switch theoretically. In this presentation, I will introduce our recent achievement of a fully reversible photoswitching in large-area self-assembled monolayers by aggregation-induced emission from bending flexible supporting electrodes to crowd the functional tetraphenylethylene molecules generating stable (>1000 reversible on/off cycles) switching with large ($3.8 \pm 0.1 \times 10^3$) on/off ratios with fast (140 ± 10 ms) switching time. The output electrical signal can be controlled by the wavelength of light, or the curvature of electrodes, or a combination of the two stimuli together. Structural characterization supported by spectroscopy and modelling shows mechanically controlled photoswitching relying on aggregation-induced emission with UV light enhancing the Coulomb interaction between the electrons and holes to decrease the energy gap between ground and excited states increasing the conductance through the junctions. Our work shows the possibility of precisely controlling the function of aggregation-induced emission to realize high-performance electronics with molecular level control via simple external mechanical force, which may also be interested by other fields where multi stimuli-responses (light/electric/mechanic) applied/required at micro/nano-region.

3:00 PM BREAK

SESSION EL10.02: Biomolecular Electronics I
Session Chairs: C. Frisbie, Christian Nijhuis, Damien Thompson and Herre van der Zant
Wednesday Afternoon, April 12, 2023

3:30 PM EL10.02.01
Ferritin-Based Single-Electron Bio-Nano Devices Jacqueline A. Labra Muñoz[1,2], Arie de Reuver[1], Friso Koeleman[1], Martina Huber[2] and Herre S. van der Zant[1]; [1]Delft University of Technology, Netherlands; [2]Leiden University, Netherlands

In this work, we study, for the first time, the electrical response of single-ferritin particles at low temperatures. Our approach, based on wide (10 um) and small (8-25 nm) self-aligned-nano-gaps devices, facilitates the trapping of single ferritin particles. Below 100 K, the devices are stable enough to allow the acquisition of reproducible currents vs. voltage characteristics. A striking feature of single ferritin particles is that the data is in excellent agreement with the Coulomb blockade model, revealing single-electron tunneling as the main transport mechanism through them.
A ferritin single-electron device is, on one hand, a system for studying the electron transport phenomena in ferritin, and therefore it broadens the scarce present knowledge on single ferritin particles: as such single-electron devices could reveal information about ferritin that may be of importance in understanding its role in neurodegenerative diseases. On the other hand, it is a basic tool for future bio-based electronics, in particular, for the fabrication of protein-based single-electron transistors, due to the exceptional stability of the devices and reproducibility of the current vs. voltage characteristics.

Electrifying the Encapsulin—Charge Transport Studies across Protein Nanocages Saurabh Soni, Riccardo Zinelli, Jeroen J. Cornelissen, Sandra Michel-Souzy and Christian A. Nijhuis; University of Twente, Netherlands

Charge transport across biomolecules, such as proteins, DNA, and peptides, has been demonstrated to be efficient over long distances. This is called long-range tunnelling which is ubiquitous in nature in several biological systems. This phenomenon is very interesting for development of next generation bio-molecular electronic devices. However, it is unknown that under which conditions the long-range tunnelling regime can be accessed in the solid-state. Further, Encapsulin protein nanocages represent self-assembled compartments with adjustable number of monomers, and subsequently, the nanocompartment size. These nanocompartments can be used to load different types and amounts of cargoes with different properties. Recently, these nanocages have been shown as useful candidates for bioengineering in targeted drug delivery. However, the effect of these electronic properties has only been investigated for encapsulins in solution. Due to such tunable properties of Encapsulin nanocages, they present an interesting platform for biomolecular electronics.

In this project, we demonstrate a first investigation of self-assembled Encapsulin protein nanocages in the solid-state, either empty or containing different cargoes. We show that these encapsulin protein nanocages can be made stable in solution and on surface without any aggregation using dynamic light scattering, transmission electron microscopy, and atomic force microscopy. We investigated the electronic properties by measuring the current density over different voltage ranges using a conical top electrode of eutectic Gallium-Indium alloy. We determined that the encapsulated cargo has a significant effect on the electronic properties. Higher current densities and rectification ratios were measured in case of a redox active protein as a cargo, such as the ferritin-like protein, compared to a redox-neutral self-folding green fluorescent protein or without any cargo. This project presents a new platform for development of biomolecular electronic devices where the properties can be controlled via an active guest inside the protein host.

KPFM Visualization of the Schottky Barrier at the Interface Between Gold Nanoparticles and Silicon—Application to Biomolecular Electronics
Luis Lechaptois[1,2], Yoann Prado[1], Sierin Lim[2] and Olivier Pluchery[1]; [1]Sorbonne Université, France; [2]Nanyang TecUniversityhnological, Singapore

Schottky barrier appears when a metal and a semi-conductor (SC), with different work function, (metal one being larger) are in contact[1]. Determination of this Schottky barrier height (SBH) is well known for an ideal plan-plan interface[2]. However, when dealing with nanostructures, such as metallic nanoparticles in contact with a semiconducting surface, this barrier is hardly predictable because the nanoparticles are already significantly charged when their size is small, which profoundly modifies their apparent work function[3,4]. Moreover their work function also depends on their diameters[4,5]. Yet predicting the presence of a Schottky barrier and the Schottky barrier height (SBH) in case of nanoparticle has become an important topic (e.g. for hot electron in photocatalysis)[6-8]. Here, gold nanoparticles (AuNPs) of 50 nm are deposited on an APTES functionalized n-doped silicon substrate. The sample surface is probed by Kelvin Probe Force Microscopy (KPFM) which allows measuring the local work function through the contact potential difference (CPD) simultaneously with the topography. This technic allows to investigate the charge transfer effects at the nanoscale. SEM and Dark-Field Microscopy characterization are also performed. KPFM measurements reveals a surprising ring-shaped pattern around the nanoparticles. We discuss how this pattern correspond to a potential barrier of 30 mV with a SBH calculated at 300 mV. The value of the SBH is strongly reduced compared to an ideal plan-plan metal/SC junction (SBH = 930 mV). The reasons of this reduction are discussed and a qualitative model is proposed. Gold nanoparticles are objects studied since a long time and widely used in nanoelectronics devices. Our study using the KPFM can act as case study for other unknow metal nanoparticles once deposited on doped silicon. We use this approach for our study on ferritin. Ferritin is a biomaterial (protein) that is formed by the self-assembly of 24 monomers (amino-acid chains) in a 12 nm nanocage that contains an iron core (with up to 4800Fe). Ferritin nanocages have already been used in different electronics devices[9]. Here, ferritins are deposited on doped silicon and characterized by KPFM. Results show also ring-shaped potential around the nanocages.

Metal-Protein-Metal Junctions—Electron Transport and Mechanical Deformation Carlos Romero-Muñiz[1], Maria Ortega[2], José Guulherme Vilhena[2], Ismael D Diez Perez[3], Ruben Perez[2], Juan Carlos Cuevas[2] and Linda Angela Zotti[2]; [1]Universidad de Sevilla, Spain; [2]Universidad Autónoma de Madrid, Spain; [3]King\'s College London, United Kingdom

Proteins have proven to be promising candidates for molecular electronics, showing in some cases much higher conductance than one would naively expect from their size. In particular, the blue-copper azurin extracted from Pseudomonas aeruginosa has been the subject of many experimental studies. The exact nature of the transport mechanism, however, is still under debate. Here I will present our efforts towards gaining an insight into this issue from a theoretical perspective, analyzing both the electronic structure and the geometrical arrangement [1-6].

Electroluminescence from Tunnel Junctions Latha Venkataraman; Columbia University, United States

Light emission from tunnel junctions is a potential photon source for nanophotonic applications. Such tunnel junctions which function as nanoscale plasmonic structures have been primarily characterized through scattering studies, but electroluminescence offers an exciting alternative from a technological standpoint by removing the need for optical excitation. In this talk, I will present results from our recent work probing the nature of electroluminescence in tunnel junctions. I will show that the photons emitted from tunnel junctions can have energies exceeding the energy supplied to the electrons by the bias.[1] I will argue that multielectron processes provide the best framework for understanding overbias light emission in tunnel junctions. I will then present results from our simultaneous measurements of electroluminescence and conductance of Au tunnel junctions.[2] I will show that the plasmonic enhancement increases as the gap size is reduced showing that the efficiency of light emission is not quenched due to electronic tunneling across the junction.

High-Yield Large-Area Photoswitching Molecular Junctions Takhee Lee; Seoul National University, Korea (the Republic of)

To achieve the ultimate miniaturization of electronic devices, a wide range of studies in the field of molecular electronics has been carried out over the last decades. Important developments include utilization of functional molecules for realizing molecular wires, rectifiers, switches, transistors, and thermoelectric devices. Among such developments, the molecular switch is a promising building block because of its potential as a memory device. In particular, light is useful for switching devices because of its addressability and compatibility with solid-state device structures. Diarylethenes (DAEs) form a class of photochromes with two different conductance states, that is, a high conductance and a low-conductance state. DAEs can be converted between these two states by illumination with UV or visible light. This property makes them good candidates for photoswitching devices because of a large conductance difference between the two states and their response to light. I will present experimental results of photoswitching properties of DAE molecular junctions that were fabricated in a large-area and high-yield vertical metal-molecule-metal structure involving a conducting polymer, reduced graphene oxides, or graphene films as a top electrode [1]. And, I will also present a recent research result of photo-responsive molecular junctions activated by perovskite/graphene electrodes [2]. Specifically, in this study, an organohalide perovskite/graphene heterojunction was employed as a photoactive electrode that acted a source of photo-generated carriers collected as photocurrent in self-assembled monolayer molecular junctions.

Intermolecular Charge Transfer Enhances the Performance of Molecular Rectifiers Ryan Sullivan[1], John T. Morningstar[1], Eduardo Castellanos-Trejo[1], Robert W. Bradford III[1], Yvonne J. Hofstetter[2], Yana Vaynzof[2], Mark Welker[1] and Oana D. Jurchescu[1]; [1]Wake Forest University, United States; [2]Technische Universität Dresden, Germany

Molecular diodes composed of self-assembled monolayers (SAMs) could yield cost-effective, versatile rectifiers that can complement the conventional silicon-based technologies with smaller, less expensive, and more versatile electronics. However, insufficient electrical performance has limited the use of this emerging technology. The efficiency in rectifying current, quantified as the rectification ratio, is dependent on factors like the molecular structure of the SAM, its density and degree of order, as well as coupling to the electrodes. In this work, we focused on molecular diodes consisting of SAMs assembled directly onto silicon, which, unlike metallic electrodes, has a very low natural roughness, and thus requires no additional processing. We co-assembled SAMs with strong electron donor and acceptor termini and found that the rectification strength increased by a factor of four compared to the neat SAMs, approaching rectification ratios of 10^4. This remarkable enhancement in rectification occurred in spite of a decrease in the order of the mixed SAMs, and is the result of the formation of a charge transfer state between the two molecules. Ultraviolet photoelectron spectroscopy (UPS) measurements confirmed a shift of 0.2 eV in the work function of the SAM, consistent with n-type doping. These results provide a novel method for controlling the electrical properties of molecular electronic devices through manipulating donor/acceptor interactions. Our molecules are obtained from a simple, robust, and high-yield synthetic procedure and may yield hybrid systems when integrated with more mature silicon technologies that are currently included in consumer electronics to expand their use toward novel functionalities governed by the molecular species grafted onto its surface. One example is that of a water sensor, which transduces the ambient moisture absorbed into the device through the porous electrode to an electrical signal. By monitoring these changes, we demonstrate clear and reproducible changes in the rectification ratio that are reversible upon multiple cycles. Their operation relies on the changes occurring in the electric field experienced by the molecular layer upon absorption of the polar water molecules, resulting in modifications in the height and shape of the tunnelling barrier.
